IMPERIAL AGRICULTURAL
RESEARCH INSTITUTE, NEW DELHI.

1366/36

CONTENTS.

PAPERS READ BEFORE THE CHEMICAL SOCIETY:—

General and Physical Chemistry.

PAGE

BECQUEREL (H.). Infra-red Radiation-spectra 1
LALANDE (F. DE) and G. CHAPERON. Copper Oxide Battery . . . 1
KROUCHKOLL. Currents Produced by Immersion and Emersion, and by the Movement of a Metal in a Liquid 2
TRUCHOT (C.). Determination of the Limits of Electrolysis 2
FRIEDEL (C.) and J. CURIE. Pyro-electricity of Blende, Sodium Chlorate, and Boracite 3
MAUMENÉ (E.). Melting Points of Salts 3
DE FORCRAND. Barium Alcoholate 4
GUNTZ. Heat of Formation of Potassium Fluorides 5
JAMIN (J.). Compressibility and Liquefaction of Gases 5
WIEDEMANN (E.). Change of Volume of Metals and Alloys on Melting . 7
WEGER (F.). Specific Volume of Saturated and Unsaturated Alkyl Salts . 8
MULLER-ERZBACH (W.). Law of Smallest Volumes 12
COOKE (J. P.). Method of Correcting the Weight of a Body for the Buoyancy of the Atmosphere when the Volume is Unknown 13
HARTLEY (W. N.). Photographic Investigations of the Ultra-violet Spark Spectra emitted by Metallic Elements and their Combinations under Varying Conditions 137
KALISCHER (S.). Production of Electricity by Condensation of Aqueous Vapour 138
RIECKE (E.). Measurement of the Quantity of Electricity produced by a Zamboni's Pile 138
WAITZ (K.). Influence of Galvanic Polarisation on Friction . . . 139
WIEDEMANN (E.). Relations between Coefficients of Friction and Galvanic Conduction 139
STOUHAL (V.) and C. BAROS. Galvanic Temperature Coefficient . . . 140
KAHLBAUM (G. W. A.). Dependence of the Boiling Point on Pressure . 141
BOILLOT (A.). Heat of Combination of Carbon and Oxygen . . . 141
DE FORCRAND. Sodium Alcoholates . . 142
GROSHANS (J. A.). Aqueous Solution . . 143
BENDER (C.). Specific Gravity of Normal . 144
ROHRBACH (C.). A New Liquid of High S a- lent, &c. 145
AMAGAT (E. H.). Compressibility of Gase . 145
AMAGAT (E. H.). Compressibility of Air . 146
AMAGAT (E. H.). Compressibility of Rare io Anhydride 146
BONSEN (R.). Condensation of Carbonic Anhydride by Glass . . . 146
EBELL (P.). Similarity of Behaviour of Ultramarine in a very fine State of Division to that of Metallic Sulphides in the Colloidal State . . . 147
KOPP (H.). Specific Volumes of Liquid Substances 147
ASSCHE (F. v.). Separation of Rays of High and Low Refrangibility . . 241
ABNEY (W. W.) and R. FESTING. Atmospheric Absorption by Aqueous Vapour 241
CROOKES (W.). Radiant Matter Spectroscopy 241

ABSTRACTS OF CHEMICAL PAPERS PUBLISHED IN BRITISH AND FOREIGN JOURNALS.

General and Physical Chemistry.

Infra-red Radiation Spectra. By H. BECQUEREL (*Compt. rend.*, **97**, 71—74. Compare also Abstr., 1883, 761).—The author has examined the infra-red radiation spectra of several metals by the method previously described (*Compt. rend.*, **96**, 121).

Sodium gives two strong lines of wave-lengths 18190 and 10980, coincident with two lines in the solar spectrum. The line at 8190 can be seen with an ordinary spectroscope, and coincides with Brewster's solar line Y.

Magnesium gives three strong lines at 8755, 10300, and 11300 respectively, coincident with three lines in the solar spectrum.

Calcium in the electric arc gives a strong band of mean wave-length about 8480, coincident with a group of lines in the solar spectrum.

Potassium gives five strong lines at 7700, 10030, 10730, 11250 and 11820 respectively.

Silver gives two very strong lines at 7720 and 8290 respectively.

Thallium gives a very strong line at 11050, very near the second sodium line, but much stronger than, and quite distinct from, the latter.

The infra-red region of the spectrum down to about wave-length 8600 can be seen with an ordinary spectroscope by concentrating the light on the slit and filtering out the more luminous rays by means of a solution of iodine in carbon bisulphide. C. H. B.

Copper Oxide Battery. By F. DE LALANDE and G. CHAPERON (*Compt. rend.*, **97**, 164—166).—The elements of the battery are zinc, cupric oxide, and potassium hydroxide. The cupric oxide is in contact with a plate of iron or brass which forms the positive pole, or the outer vessel of the battery is constructed of one of these metals. The cupric oxide is the depolarising element of the battery, and is reduced to metallic copper, its conductivity increasing therefore as the battery is used. The electromotive force of this cell is about one volt, and its internal resistance is very low and does not sensibly alter while the battery is in action. Small sizes give a current of two ampères; large sizes give as much as 30 ampères. Since the potash solution has no action on the oxide of copper nor on the amalgamated zinc, there is no waste when the battery is not in action. The reduced copper can be reconverted into oxide by roasting. This battery can be used for long periods through low resistances, since depolarisation is rapid and complete. C. H. B.

Currents Produced by Immersion and Emersion, and by the Movement of a Metal in a Liquid. By KROUCHKOLL (*Compt. rend.*, **97**, 161—163).—It has been known for some time that if two electrodes of the same metal are immersed in a liquid and one of them is moved, the motion produces a current the direction of which depends on the nature of the metal and liquid. If, too, one of the electrodes is placed in the liquid and the other is immersed afterwards, a current is produced at the moment of immersion.

The author finds that a current is also produced when one of the electrodes is withdrawn from the liquid. The current at immersion is in the opposite direction to that produced by movement of the electrode in the liquid; the current of emersion is in the same direction as the current produced by movement. These immersion and emersion currents are produced when the metal is passed from an insulating to a conducting liquid, as well as when the metal passes from the air into a liquid. The electromotive force produced by motion is analogous to that produced by polarisation: it is destroyed by solutions of salts of the metal of which the electrodes are composed, so that if the saline solutions are sufficiently strong, no current is produced by moving the electrode. These phenomena can be explained by Helmholtz's hypothesis of double layers of electrical tension. C. H. B.

Determination of the Limits of Electrolysis. By C. TRUCHOT (*Compt. rend.*, **97**, 92—93).—Since the electromotive force required to decompose a given compound depends on the heat of formation of the compound, it follows that a determination of the minimum electromotive force necessary to produce decomposition, furnishes a measure of the heat of formation of the particular compound. The author employs a small Gramme dynamo, with a Jamin magnet, driven by a Smidt's water-motor fitted with a special regulating apparatus. The electromotive force is practically proportional to the velocity of the rotation of the dynamo, and this velocity can be regulated within very narrow limits. The actual electromotive force is determined by a volt-meter graduated by means of a Daniell element. Determinations of the minimum electromotive force required to electrolyse water, potassium sulphate, and other compounds, agree very closely with thermochemical determinations. C. H. B.

Pyro-electricity of Blende, Sodium Chlorate, and Boracite. By C. FRIEDEL and J. CURIE (*Compt. rend.*, **97**, 61—66).—Crystals of the cubical system which show tetrahedral hemihedrism behave like crystals of the hexagonal system. If heated or cooled regularly, *i.e.*, so that the expansion or contraction is equal along all the axes of hemimorphism, there is no development of pyroelectricity, but if the heating or cooling is irregular, so that tension is produced in different parts of the crystal, then electricity is developed. These phenomena have been observed with blende and with sodium chlorate. Mallard has shown that boracite at ordinary temperatures belongs to the rhombic system, but at about 265° its form changes to one belonging to the cubical system. The authors find that if a plate of boracite cut parallel with one of the tetrahedral faces is heated at 300—320° for some time and then allowed to cool regularly, no electricity can be detected until the temperature falls to about 265°, but at this point there is a considerable development of electricity, which gradually diminishes in intensity and eventually changes in sign. It appears therefore that when boracite cools regularly it only becomes pyroelectric at the point at which it ceases to belong to the cubical system. C. H. B.

Melting Points of Salts. By E. MAUMENÉ (*Compt. rend.*, **97**, 45—48).—Pure potassium nitrate melts at 327°; pure sodium nitrate at 298°. The following table gives the melting points of various mixtures of these and other nitrates as calculated and as observed:—

		Calculated.	Observed.	Difference.
$3KNO_3$	$+NaNO_3$	320·7	265—247°	−55·7— 73·7°
$2KNO_3$	$+NaNO_3$	318·4	265—244	−55·7— 74·4
KNO_3	$+NaNO_3$	313·8	265—219	−55·7— 94·8
KNO_3	$+2NaNO_3$	308·8	242—224	−66·8— 84·8
KNO_3	$+3NaNO_3$	306·2	267—237	−39·2— 69·2
KNO_3	$+AgNO_3$	246·8	169—121	−77·8—125·8
$1·68KNO_3$	$+AgNO_3$	262·5	191—131	−71·5—131·5
$NaNO_3$	$+AgNO_3$	231·7	251·5°	+19·8°
$2NaNO_3$	$+AgNO_3$	248·0	263·0	+15°
$AgNO_3+KNO_3$	$+NaNO_3$	258·5	190—130	− 68—128·5
$NaNO_3$	$+Ca(NO_3)_2$	374 or 399°*	235—216°	−158 or 183*

The first of the observed temperatures is the point at which crystals begin to form in the fused mixture, and the second is the point at which the whole mass becomes solid. The fall of temperature between these two points is perfectly gradual, and there is no fixed intermediate point which can be regarded as the true melting point of the mixture. The mixtures of sodium and silver nitrates do not show this irregularity, but have a definite melting point. Calcium nitrate, which cannot be fused alone without decomposition, melts readily when added in small quantities to fused sodium nitrate, and does not decompose. Zinc nitrate behaves in a peculiar manner. When a previously fused and resolidified mixture of sodium and calcium nitrates in equivalent proportions is added gradually to gently heated zinc nitrate, the fragments of the mixture decompose at a temperature as low as 210°, and decomposition continues so long as any of the fragments remain undissolved, but ceases when the whole mass becomes completely liquid. The same phenomenon is observed on each successive addition of the mixture. A mixture of the three nitrates in equivalent proportions solidifies at 170°, about 80·5° above the calculated melting point. C. H. B.

---

* According as the melting point of calcium nitrate is taken as 450° or 500°.

Barium Alcoholate. By DE FORCRAND (*Compt. rend.*, **97**, 170—172).—Barium alcoholate is so readily decomposed by atmospheric moisture, that it is almost impossible to obtain it free from hydroxide, and in thermochemical determinations it is necessary to make a correction for this impurity. The heat of solution of the alcoholate at 20° is + 19·76 cal., from which it follows that—

$2C_2H_6O$ liquid + BaO solid = $(C_2H_5O)_2Ba$ solid + H_2O solid develops + 14·48 cal.

$2C_2H_6O$ liquid + BaH_2O_2 solid = $(C_2H_5O)_2Ba$ solid + $2H_2O$ solid develops — 1·68 cal.

This development of heat is somewhat smaller than that produced by the hydration of barium oxide. The reverse reaction $(C_2H_5O)_2Ba$ solid + $2H_2O$ liquid = $2C_2H_6O$ liquid + BaH_2O_2 solid, develops + 4·56 cal. These results explain the known properties of the alcoholate. In presence of excess of alcohol it is necessary to take into account the heat of solution of the alcoholate in alcohol and the formation of secondary alcoholates similar to those of sodium. The heat of solution in a large excess of alcohol is + 20 cal.; if a saturated solution is formed it is + 12·50 cal. By reason of the dissociation of the secondary alcoholates, an alcoholic solution of barium alcoholate always contains $(C_2H_5O)_2Ba$. If such a solution is mixed with a small quantity of water, part of the alcoholate is converted into hydroxide, and the latter, being insoluble, is precipitated. The equilibrium of the system is thus disturbed, and the conversion of the alcoholate into hydroxide continues until all the water has been precipitated as barium hydroxide.

The following table shows the relative stability of the metallic derivatives of certain alcohols and acids with respect to water and acids. It is, however, also necessary to take into account the formation of secondary compounds (hydroxides, secondary alcoholates, basic salts, &c.), since the heat of formation of these bodies may change the direction of the reaction :—

$$\left\{\begin{array}{l} 2C_2H_6O \text{ liquid} + BaO \text{ solid} = (C_2H_5O)_2Ba \text{ solid} + H_2O \text{ solid} \\ \quad \text{develops} + 14{\cdot}48 \text{ cal.} \\ 2C_2H_6O \text{ liquid} + BaH_2O_2 \text{ solid} = (C_2H_5O)_2Ba \text{ solid} + 2H_2O \text{ solid} \\ \quad \text{develops} - 1{\cdot}68 \text{ cal.} \end{array}\right.$$

$$\left\{\begin{array}{l} 2C_2H_6O \text{ liquid} + Na_2O \text{ solid} = 2C_2H_5NaO \text{ solid} + H_2O \text{ solid} \\ \quad \text{develops} + 34{\cdot}70 \text{ cal.} \\ C_2H_6O \text{ liquid} + NaHO \text{ solid} = C_2H_5NaO \text{ solid} + H_2O \text{ solid} \\ \quad \text{develops} + 0{\cdot}25 \text{ cal.} \end{array}\right.$$

$2C_2H_3NaO_3$ solid + Na_2O solid = $2C_2H_2Na_2O_3$ solid + H_2O solid develops + 34·54 cal.
$C_2H_3NaO_3$ solid + NaHO solid = $C_2H_2Na_2O_3$ solid + H_2O solid develops + 0·12 cal.

$2C_6H_6O$ solid + K_2O solid = $2C_6H_5KO$ solid + H_2O solid develops + 76·4 cal.
C_6H_6O solid + KHO solid = C_6H_5KO solid + H_2O solid develops + 17·7 cal.

H_2SO_4 solid + Na_2O solid = Na_2SO_4 solid + H_2O solid develops + 103·6 cal.
H_2SO_4 solid + 2NaHO solid = Na_2SO_4 solid + $2H_2O$ solid develops + 69·4 cal.

C. H. B.

Heat of Formation of Potassium Fluorides. By GUNTZ (*Compt. rend.*, **97**, 256—258).—*Anhydrous Potassium Fluoride.*—The neutralisation of 1 mol. hydrofluoric acid (dilute) by potassium hydroxide (dilute) develops + 16·12 cal. The heat of solution of the anhydrous fluoride is 3·6 cal. These results agree with those of Thomsen and Favre respectively.

KHO solid + HF liquid = KF solid + H_2O solid develops + 30·98 cal.
KHO solid + HF gas = KF solid + H_2O solid develops + 38·22 cal.

Crystallised Potassium Fluoride, KF.$2H_2O$.—Heat of solution —1·03 cal.: heat of hydration, KF solid + $2H_2O$, liquid = KF,$2H_2O$ solid, develops + 4·63 cal.; with $2H_2O$ solid, + 1·8 cal.

KHO solid + HF liquid + H_2O solid = KF,$2H_2O$ solid develops + 34·17 cal.
KHO solid + HF gaseous + H_2O solid = KF,$2H_2O$ solid develops + 41·41 cal.

The action of 1 mol. hydrofluoric acid on 1 mol. potassium fluoride in dilute solution is accompanied by an absorption of heat — 0·57 cal.; a phenomenon similar to that observed in the case of hydrogen potassium sulphate. The heat of solution of potassium hydrogen fluoride, KF,HF is — 6·01 cal.

KF solid + HF gas = KF,HF solid develops + 21·04 cal.
KF solid + HF liquid = KF,HF „ „ + 13·80 „
KHO solid + 2HF gas = KF,HF solid + H_2O solid develops + 53·13 cal.
KHO solid + 2HF liquid = KF,HF solid + H_2O solid develops + 38·65 cal.

C. H. B.

Compressibility and Liquefaction of Gases. By J. JAMIN (*Compt. rend.*, **97**, 10—16; see also Abstr., 1883, 898).—The author has represented the results of Andrews' experiments by a series of curves, the ordinates of which represent the density of the gas, and the abscissæ the pressure for the several temperatures 13·1°, 21·5°, 31·1°, 32·5°, 35·5°, at which the experiments were made. Below the critical point, the curve is at first slightly convex with respect to the axis x, because the density increases more quickly than the pressure, but at a certain point, B, the curve suddenly changes in direction. At this point, the gas has attained its maximum tension, and liquefaction commences, the curve continuing in the new direction until liquefaction is complete, when it suddenly takes a direction corresponding with a slow increase in density, this part of the curve being slightly concave because the compressibility gradually decreases. That this interpretation of the curve is correct is proved by the fact that the maximum tensions of the gas at the different temperatures correspond with the points B, B′, B″, &c., at which the direction of the curve changes. Comparison of the different curves shows that the minimum density of the liquid at the moment of its formation is at first much higher than the maximum density of the gas when it begins to liquefy, but the difference between these two densities diminishes as the temperature rises, and at 35° the difference is *nil*, from which it follows that below 35° the liquid ought to form and separate from the gas by reason of its higher density, but above 35°, although the liquid is still formed, it cannot separate from the gas. The author has calculated the ratios between the density of the gas and the density of the liquid in Andrews' experiments, and also the coefficient of expansion between 31·1° and 35·5°. These coefficients are very high, and undergo remarkable changes. Between 75·6 and 76 atmos. the coefficient of expansion rises suddenly from 0·0821 to 0·2716, which can only be explained by supposing that at this pressure and at 31·1° the gas is really liquefied, although apparently gaseous, and when the temperature rises to 35·5° it again passes into the gaseous state. Again, between 82 and 83·4 atmos. the coefficient suddenly falls from 0·13114 to 0·0703, a fact which can only be explained by supposing that at this pressure and even at the higher temperature the gas is again liquefied, although apparently remaining gaseous. It would appear that the homogeneous mass in the vessel under these conditions is not really gaseous, because it has too high a density, nor yet really liquid, because it has a high coefficient of expansion and compressibility, but that it exists in an intermediate state. Detailed examination of the curves corresponding with temperatures above the critical point supports these views. The following table gives the successive increments of density due to successive equal increments of pressure:—

Atmos.	70	72	74	76	78	80	82	84	86	88	90	92	94	96	98	100
D′—D	—	10	11	12	13	31	38	72	27	15	13	9	8	7	7	5

It is evident that between 82 and 84 atmos. the gas is liquefied, and it is also evident that this change although very rapid is not abrupt. It becomes less rapid and takes place at higher pressures as the temperature rises. The results of Cailletet and Amagat's experiments with oxygen, hydrogen, and similar gases at high pressures are represented by curves similar to those representing Andrews' experiments above the critical point. In every case the curve is convex at low pressures and concave at high pressures, with an intermediate point of inflexion which, according to the author's view, is the point at which the gas liquefies. The increments of density in Amagat's experiments with oxygen at 0·3° are given in the following table:—

Atmos.	20	30	40	50	60	70	80	90	100	110	120	130
D′−D	—	76	77	77	78	78	79	79	82	83	77	78

Atmos.	140	150	160	170	180	190
D′−D	78	78	77	76	75	75

It would appear that the oxygen really liquefies between 100 and 110 atmos., although the change is not so well marked as in the case of carbonic anhydride. The following table gives the points of inflexion and maximum compressibility (H) as determined by Amagat's experiments:—

	Point of inflexion.	H.
Oxygen	102 atmos.	130 atmos.
Methane	95 „	127 „
Ethylene.......	67 „	83 „
Nitrogen........	55 „	109 „
Hydrogen	0 „	0 „

It is evident that at a higher temperature these points of inflexion and maximum compressibility will correspond with higher pressures, but at a sufficiently low temperature the point H will differ but little from the point of origin of the curve, and experiments will give only that portion of the curve beyond K, which always represents a diminishing compressibility; but this is actually observed in the case of hydrogen. It follows therefore that at the ordinary temperature, and under a pressure of 3—4 atmos., hydrogen has passed its point of inflexion, or, in other words, is really liquid. This conclusion is in accord with the law of continuity, and brings hydrogen, which has hitherto been regarded as an exception, under the general laws of the compressibility of gases.

C. H. B.

Change of Volume of Metals and Alloys at Melting. By E. WIEDEMANN (*Ann. Phys. Chem.* [2], **20**, 228—243).—The author has made a series of experiments on the expansion of volume at melting point, and the relative rates of cooling of tin and certain alloys of bismuth and lead.

The dilatometer method was employed. The substance to be examined was enclosed in a closely fitting glass cylinder, at the upper end of which was fixed a capillary tube. The most convenient liquid for filling the apparatus was found to be oil, which has the advantage of not evolving air when heated to 200°; moreover, it does not possess an appreciable vapour-tension at that temperature. When heated above that point the oil attacks the metal. The rate of cooling was determined by heating the metal to 260° in an iron vessel. A thermometer protected by a glass cap filled with oil was enclosed within the molten mass. The whole apparatus was then immersed in a double walled metallic vessel, the intermediate space between the walls being filled with water. The intervals of time required for cooling 5° were carefully measured; the reciprocal value for these times may be taken as a measure for the velocity of cooling of the metal.

In three experiments, it was found that tin on melting expanded in volume 1·76, 1·69, 2·20 per cent. These results are in direct contradiction to those of Nies and Winkelmann, who melted a large quantity of the metals and then dropped in a solid fragment of the same metal, and observed whether this fragment floated or sunk. But the author points out that in this method it would be exceedingly difficult to avoid convection currents, which would be liable to carry up the solid fragments to the surface in the centre of the vessel. Experiments also proved that soft solder expands almost 2 per cent. of its volume in melting.

Alloys of Bismuth and Lead.—Pb_2Bi of sp. gr. 11·4 begins to show an increase of expansion at about 120—136°, which reaches its maximum at 180°. When heated to 240° and allowed to cool, the temperature remained constant for long intervals of time at 180° and 125°, the two melting points of the alloy. BiPb, sp. gr. 11·03, expands abnormally between 127° and 132°, melts at 146° and 125°. $PbBi_2$, sp. gr. 10·96, expands abnormally between 126° and 132°, melts at 140° and 124°. $PbBi_4$, sp. gr. 9·73, expands most markedly between 120° and 136°, melts at 125° and 200°. $PbBi_8$, sp. gr. 8·6, melts partially between 125° and 130°, contracts between 172° and 204°; its melting points are 170° and 120°. The results of these experiments show that these alloys contain a definite compound of composition between PbBi and $PbBi_2$, whose melting point is about 125°, and in which the excess of one metal, lead or bismuth, as the case may be, dissolves. For equal increments of temperature, the proportion of the metal dissolved rapidly increases. From the changes of volume at temperatures above the first melting point one can conclude whether the metal in excess expands or contracts on melting. The experiments would seem to indicate an expansion of lead and a contraction of bismuth, a result in accordance with previous observations. For example, the alloy $PbBi_8$ consists of an alloy of low melting point, in which the excess of bismuth dissolves; if it be gradually warmed to 120°, the alloy and the excess of bismuth expand regularly. At this temperature the alloy melts with marked expansion, and contains the solid bismuth in suspension; above that point, the bismuth gradually dissolves and melts, while the rate of expansion *pari passu* decreases.

Specific Volume of Saturated and Unsaturated Alkyl Salts.

By F. Weger (*Annalen*, **221**, 61—107).—The author has made a series of determinations of saturated and unsaturated hydrocarbons and alkyl salts, in order to ascertain the differences of specific volume corresponding to known differences of molecular weight. The method adopted is that proposed by Kopp, with slight modifications; the dilatometer was not heated in a bath of liquid, but was wholly immersed in the vapour of some volatile liquid. By this means corrections for the cool part of the dilatometer projecting outside the liquid, and its unequal heating from convection currents, are avoided. The readings were made with the naked eye, and a

Homologous Compounds.—On comparing the specific volumes of homologous compounds of analogous composition, it is found that the difference of specific volume for every CH_2 is very variable. In the case of the ethereal salts of phosphoric acid, the difference is equal to Kopp's average value, 22; for the alkyl salts of the acids of the acetic and acrylic series, the difference is rather greater than 23; for those of the succinic, phenylpropionic, and acrylic acids it varies from 25—26. In the homologous alcohols, the specific volume for the CH_2 group is about 20. Although the volume for CH_2 varies with different series of compounds, yet it is practically constant for various alkyl salts of one and the same acid, although not for corresponding ethereal salts of homologous acids. Thus, for example, the volume difference between ethyl oxalate and methyl ethyl succinate is not equal to that between methyl ethyl and ethyl succinate. Facts such as these cause questions to be raised as to the precise definition of homologous compounds.

Isologous Compounds.—Similarly on comparing the results obtained for saturated and unsaturated compounds, the difference in specific volume for H_2 or nH_2 varies from 5 to 9 or some multiple of these numbers. The observations of the author in this respect are in accordance with those of Buff, Zander, and Schiff.

Thorpe assigned the number 53·48 as the molecular volume of bromine (this Journal, Trans., 1880, 384); in the author's results, differences of Br_2 in isologous compounds, as allyl and dibromopropyl alcohols, correspond with differences of specific volume varying from 49 96 to 59·14. Similar variations in the differences of specific volume corresponding with uniform differences of C_6H_4 and $C_2H_2Br_2$ in the molecule are also observable.

The specific volume values of the aromatic compounds examined by the author were found to be greater than the values calculated according to Kopp's general rules. V. H. V.

Law of Smallest Volumes. By W. MÜLLER-ERZBACH (*Annalen*, **221**, 125—132).—In this communication, the author adduces further arguments in support of his law that in any chemical reaction the elements tend to arrange themselves in those forms of combination which occupy the smallest volume, or that greater condensation is correlated with greater affinity (comp. Abstr., 1882, 137, 451, 1024).

For example, the sum of the volumes of the trichlorides of phosphorus and boron plus three atoms of bromine, or of silicon tetrachloride plus four atoms of bromine, is greater than the sum of the volumes of the tribromides of phosphorus and boron plus three atoms of chlorine, or of silicon tetrabromide plus four atoms of chlorine.

Again, the experiments of Kämmerer (*Ann. Phys. Chem.*, **138**, 290) have proved that hydrated chloric acid, $HClO_3,7H_2O$, occupies a molecular volume of 164·4, and hydrated iodic acid, $H_2O_3,9H_2O$, of 158·9; if to the molecular volume of chloric acid the number 36, or the molecular volume of two molecules of water be added, the volumes of chloric and iodic acid will be in the ratio of 200 to 159. According to the author's law, iodic should be more stable than chloric acid, and the experiments of Serullas have shown that an aqueous solution of the former decomposes at 40°, whilst those of Gay-Lussac prove that only a partial decomposition of an aqueous solution of the latter commences at 200°. Kremers has demonstrated that there is an increase of volume when potash and soda are neutralised with nitric, hydrochloric, and sulphuric acids. The author has pointed out that this apparent discrepancy from his law may be explained by the greater affinity of the molecules of water for the acid and the alkali on the one hand than for the resultant salt on the other. Thus an expansion instead of a contraction is the final result. In this connection, the author cites the experiments of Ostwald, who proved that the volume occupied by a given weight of water containing in solution an equivalent of potash is less than that occupied by the same weight of water plus one equivalent of potash taken separately. The same result holds good in the case of sulphuric acid and water. Hence it may be stated that the result of the neutralisation of potash and soda with nitric, hydrochloric, and sulphuric acids is a contraction of volume, but that this contraction is so masked by the presence of large quantities of water that an expansion is the final result.

V. H. V.

Method of Correcting the Weight of a Body for the Buoyancy of the Atmosphere when the Volume is Unknown. By J. P. Cooke (*Chem. News*, 48, 39—41).—It is well known that corrections for the buoyancy of the atmosphere are seldom made because of the great trouble attached to obtaining the required data, and from them the necessary correction. The author proposes to obviate these difficulties in the following manner:—Assuming that the atmosphere within the balance-case is dry, easily effected by open vessels of strong sulphuric acid, the only corrections required are for temperature and pressure. To effect this the author fixes on two standards, viz., 30 inches for the barometric pressure, and 27° C. (= 300° on the so-called "absolute scale") for temperature: hence a variation of $\frac{1}{10}$th of an inch from this standard will cause a change of $\frac{1}{300}$ in the resultant effect of the buoyancy of the air on the load and its counterpoise, and according to the law of Charles, the variation of 1° from 27° C. produces a similar change.

With these standards, corrections for temperature are made by reducing the barometric pressure to 27° C., and then by taking weighings of the object for which the correction is required under varying conditions of temperature and pressure: the difference in weight corresponding to $\frac{1}{10}$th of an inch variation in the barometer is easily found, and a constant for the object weighed is obtained by which the weights can be readily reduced to the standard 30-inch barometric pressure, after having reduced them to the standard temperature, 27° C. It is simply necessary to multiply the difference between 300 and the reduced barometric pressure, and add or subtract the product, as the case may be, from the observed weights. An example, chosen from an observation made by the author, will illustrate the mode of working. In the first column of the subjoined table the weights of the same object are given under the varying conditions registered in the subsequent columns, and in the last column the results of the application of the constant are given (there are 15 observations in the original):—

Weight of object.	Temperature of balance	Height of bar. in $\frac{1}{10}$ ins.	Height reduced.	Result.
87·3447	23·5° C.	297·6	301·1	87·3451
87·3419	22·6	305·2	309·6	87·3451
87·3464	29·4	297·9	295·5	87·3450

Greatest weight	87·3464	Barometer highest	309·6
Smallest „	87 3419	„ lowest	295·5
Differences	00·0045		14·1

∴ Constant = 4·5 mgrms. ÷ 14·1 = 0·319 mgrm.

In this way, the relative weight of even large vessels can be obtained to a $\frac{1}{10}$th milligram; of course there is a limit to the accuracy; however it is noteworthy that the accuracy of the method is proportional to the requirement, for the greater the bulk of the load, the more accurately can the "constant" be found. Great precision is required for measuring temperatures and pressures in the case of loads of large volume.

From the data obtained by these observations and from the known normal density of the air, the volume of the object can be calculated, and therefore the same constant may be made to serve roughly for any given volume; thus in the case cited above the volume of the object exceeds that of the weights by 75 c.c., and the weight varies 0·3 mgrm. for 1° C., or $\frac{1}{10}$th inch pressure. Hence with a difference of volume = 100 c.c. the weight would vary 0·4 mgrm. for 1° C., or $\frac{1}{10}$ inch pressure, and so on. It is obvious that if the volume of the load was very large, the balance might be used for measuring the variations in atmospheric pressure and temperature. D. A. L.

Inorganic Chemistry.

Density of Liquid Oxygen. By S. WROBLEWSKI (*Compt. rend.*, **97**, 166—168).—A known volume of oxygen was liquefied at −130° in a calibrated tube, and the volume of the liquid was compared with the volume of a known amount of carbonic anhydride liquefied in the same tube at 0°. The sp. gr. of the liquid oxygen was found to be 0·89 and 0·90; mean, 0·895. C. H. B.

Active Oxygen. By E. BAUMANN (*Ber.*, **16**, 2146—2152).—It has long been observed that substances which under ordinary conditions are not affected by oxygen, are yet oxidised in presence of other substances, which combine directly with the oxygen of the air. Besides examples of these changes which have been brought forward by Hoppe-Seyler, the author, and also Leeds, have observed that carbonic oxide when passed over damp phosphorus is oxidised by the ozone formed into carbonic anhydride. Remsen and Keiser (*Chem. Soc. J.*, 1883, 454) have repeated these experiments, but with negative results, and they attribute the formation of carbonic anhydride to the oxidation by the ozone of the carbon of the corks used in the apparatus. The author has accordingly repeated his experiments with an apparatus made entirely of glass, and has confirmed his former results. In one case 36·6 mgrm. of carbonic anhydride were formed by the passage of 700 c.c. of carbonic oxide over phosphorus; this represents an oxidation of 2·6 per cent. of the carbonic oxide.

In connection with the explanation of the phenomena of oxidation put forward on the one hand by Hoppe-Seyler and Leeds, and on the other by Traube, the author considers that the former is more satisfactory: for firstly it is simpler; secondly, it explains the greater number of phenomena; and thirdly, Traube's hypothesis gives no account of the formation of ozone, hydrogen peroxide, and active oxygen by the slow oxidation of damp phosphorus in the air.

V. H. V.

Conversion of Carbonic Oxide into Carbonic Anhydride by Nascent Oxygen. By A. R. Leeds (*Chem. News*, **48**, 25—29).—The author refers to works which have been published in support of and against the theory that carbonic oxide is converted into carbonic anhydride during the oxidation of phosphorus in moist air; he then proceeds to describe the latest repetition of his original investigation in support of the theory. Sticks of phosphorus were put into a large flat-bottomed bottle, fitted with a well ground stopper, filled with water free from air and carbonic anhydride, and inverted in a pneumatic trough. Well washed carbonic oxide and air, in equal volumes, were now introduced, sufficient water being left in the bottle so as to partially cover the phosphorus. The stopper was put in while the neck of the bottle was still under water; the bottle was then reversed, and kept at a temperature of 24°. After six days the gaseous mixture was withdrawn from the bottle; and, the glass stopper being replaced by a cork saturated with paraffin, and fitted with the necessary tubes, the bottle was immediately inverted in a mercury trough, and a little mercury allowed to enter in order to cover the cork. The tubes were respectively connected with an aspirator and an air-supply free from carbonic anhydride; and the issuing gas was passed through baryta-water and potassium iodide solution. The baryta-water soon became turbid, and was subsequently tested in a carbonic anhydride apparatus, when the potash bulbs in connection therewith had increased 0·0155 gram after the decomposition. The tube passing into the barium hydrate became incrusted; the incrustation when treated with acid evolved carbonic anhydride. There was no iodine set free in the potassium iodide solution, and therefore no ozone could have been present. The author considers, therefore, that the above statement is now established by a rigid quantitative and qualitative analysis.

D. A. L.

Liquid Nitrous Anhydride. By R. H. Gaines (*Chem. News*, **48**, 97).—The author observes that this gas condenses at + 14·4° under a pressure of 755 mm., and when the liquid is heated, ebullition begins at the same temperature. The pure liquid is dark green, but changes to blue on the addition of a very little water; the blue and green liquids are not readily miscible. D. A. L.

Preparation of Caustic Potash and Soda. By Löwig (*Dingl. polyt. J.*, **248**, 260).—According to Löwig, an intimate mixture of sodium or potassium carbonate and ferric oxide is exposed to a bright red heat until the whole of the carbonic anhydride has been expelled. The resulting melt of sodium or potassium ferride is treated with water at 80—90°, the ferride being decomposed into caustic soda or potash and ferric oxide. The latter on drying is used for a further operation. D. B.

History of the Preparation of Artificial Sodium Carbonate from Common Salt. By DUMAS (*Compt. rend.*, **97**, 209—214).—A historical summary, eulogistic of Leblanc. C. H. B.

Dimorphism of Silver Iodide. By MALLARD and LE CHATELIER (*Compt. rend.*, **97**, 102—105).—It has been shown (*Bull. Soc. Min.*, **5**, 214) that boracite belongs to the rhombic system at the ordinary temperature, but changes to the cubic system at about 265° with absorption of heat of 4·77 cal. for 1 gram, and retains this form up to the melting point. Potassium sulphate behaves in a similar manner, passing from the rhombic to the hexagonal system, and ammonium nitrate, which belongs to the rhombic system at the ordinary temperature, suddenly changes to the cubic system at about 127°. Silver iodide is dull red at a sufficiently high temperature, but is light yellow at the ordinary temperature, and Wernicke has shown that at 138—138·5° the colour *suddenly* changes from deep yellow to yellowish-white, or *vice versâ*, according as the temperature is rising or falling. By examination with polarised light, the authors find that when the silver iodide is heated it suddenly passes from the hexagonal to the cubic system, the change taking place at about 146°, a temperature not very far removed from that determined by Wernicke. Measurements of the mean specific heat of the iodide between different limits of temperature, show that the passage from the hexagonal to the cubic system is accompanied by an absorption of heat of 6·8 cal. for 1 gram. According to Zepharovitch the ratio of the axes in the hexagonal form, $h : a = 1·2294 : 1$. In the cubic form, the ratio of the tertiary to the secondary axis will be $h : a = 1·2247 : 1$, from which it appears that the hexagonal form closely approaches the cubic form, and that at the point of change from one form to the other there must be contraction along the vertical axis, or expansion along the horizontal axes, or both. This contraction and expansion has been actually observed by Fizeau, and may be regarded as preparatory to the change of crystalline form. It follows from these facts that the cubical expansion of silver iodide ought to be normal above 146°, and Rodwell has observed that the iodide experiences a sudden and considerable contraction between 142° and 145·5°, but afterwards expands regularly up to the melting point. C. H. B.

Chlorides of Lime and Lithia. By K. KRAUT (*Annalen*, **221**, 108—124).—This communication contains no new experiments; the author merely controverts Lunge's experiments and deductions therefrom as to the constitution of bleaching powder and the so-called "chloride of lithia." V. H. V.

Separation of Gallium. By L. DE BOISBAUDRAN (*Compt. rend.*, **97**, 66—67, 142—144).—*From Tellurium.*—The tellurium, which must be in the state of tellurous acid, is precipitated by hydrogen sulphide in the cold, in presence of a considerable quantity of free hydrochloric acid. The filtrate is concentrated if necessary, heated to boiling, and treated with a current of hydrogen sulphide, the precipitate of tellurium sulphide being filtered off.

From Silicon.—The solution is made strongly acid with hydrochloric acid (any free sulphuric acid having been previously neutralised), evaporated to dryness, and heated for some time at 120—125°. The residue is moistened with strong hydrochloric acid, and the evaporation and ignition repeated. The gallium is then dissolved out by boiling dilute hydrochloric acid, the solution filtered, and the silica washed, first with dilute hydrochloric acid, and finally with water; the last traces of gallium are removed from the silica by dissolving it in potassium hydroxide, acidifying with hydrochloric acid, and repeating the above treatment.

From Molybdenum.—(1.) The molybdenum is precipitated in the cold by hydrogen sulphide in presence of a considerable quantity of hydrochloric acid, the precipitate being washed with dilute hydrochloric acid saturated with hydrogen sulphide. The filtrate is heated for some time at about 70°, then boiled, and any precipitate which forms is filtered off. The second filtrate is concentrated, and again treated in the same way. (2.) The solution is supersaturated with ammonia, mixed with ammonium sulphide in excess, gently heated, and then acidified with hydrochloric acid, heated to expel hydrogen sulphide, and filtered. The filtrate is concentrated, the ammonium salts destroyed by heating with aqua regia, and the solution again treated with ammonium sulphide. The molybdenum sulphide is dissolved in aqua regia, and the precipitation repeated in order to remove the last traces of gallium. Before applying methods (1) and (2) chlorides and lower oxides of molybdenum must be oxidised by means of nitric acid, excess of the latter being expelled by boiling with hydrochloric acid. (3.) The solution is acidified with sulphuric acid, mixed with a slight excess of ammonium sulphate, and the gallium alum precipitated by concentrating the liquid and adding three or four times its volume of alcohol of 85°. The alum is purified by recrystallisation. In accurate analyses, the greater part of the molybdenum should be precipitated as sulphide by (1) or (2), then the greater part of the gallium removed as alum, the last traces being separated from the concentrated mother-liquor by (1) or (2).

C. H. B.

Salts of Aurous Oxide: Colorimetric Estimation of Gold. By A. CARNOT (*Compt. rend.*, **97**, 169—170).—When an aqueous solution of hydrogen phosphide is added gradually to a very dilute solution of gold chloride, either alone or mixed with phosphoric or arsenic acid, a rose coloration is produced. It would appear that this rose coloration (this vol., p. 115) is not due simply to a complex compound of aurous oxide and ferric oxide, but is produced also by simple salts of aurous oxide, such as the phosphate or arsenate. The presence of ferric oxide apparently increases the stability of these salts, for if any foreign salt is added to a solution of the rose-coloured compound free from iron, the rose-coloured compound becomes blue and yields a slight bluish precipitate, whereas in presence of iron a purple precipitate is formed, which can be dried at 100° without alteration.

This reaction furnishes a colorimetric method for the rapid approximate estimation of gold. The intensity of the tint given by the solution under examination is compared with that of solutions of gold containing different amounts of gold in a constant volume (100 c.c.) of liquid. To obtain comparable solutions, the neutral solution of gold chloride is mixed with a drop of hydrochloric acid, one or two drops of ferric chloride, and a few drops of arsenic acid, and then diluted to 100 c.c. A small quantity of zinc powder is added, the liquid agitated, allowed to clarify by standing, and the clear liquid decanted off. The mineral to be examined is finely powdered, dissolved in aqua regia, the solution diluted, filtered, evaporated twice to dryness after addition of a little nitric acid, and heated to dull redness. The residue is treated with chlorine-water, which leaves the ferric oxide undissolved, the solution is filtered, the chlorine expelled by boiling, and the solution treated as above. C. H. B.

Action of Hydrochloric Acid on Stannous Sulphide. By A. Ditte (*Compt. rend.*, **97**, 42—45).—Dry hydrochloric acid gas has no action on crystallised stannous sulphide at the ordinary temperature, but on gently heating it, decomposition commences, and stannous chloride and hydrogen sulphide are formed.

Aqueous hydrochloric acid, even in dilute solutions, attacks crystallised stannous sulphide at the ordinary temperature, but the degree of concentration of the acid has great influence on the decomposition, the phenomena being similar to those observed by Berthelot in the case of galena (*Mécan. Chim.*, 2, 562). Decomposition takes place with a solution containing 8·3 per cent. of acid; stannous chloride and hydrogen sulphide are formed, and after some time equilibrium is established under somewhat complex conditions.

When hydrogen sulphide is passed into a solution of stannous chloride, deep brown stannous sulphide may be produced, but in many cases the precipitate consists of brilliant reddish-brown micaceous plates of a stannous chlorosulphide, which is decomposed by hydrogen sulphide and by water. The heat of formation of this compound is probably intermediate between that of stannous chloride and that of stannous sulphide, and its more or less complete decomposition by water plays a part in the establishment of equilibrium. When hydrochloric acid is brought in contact with an excess of stannous sulphide, or when hydrogen sulphide is passed into a solution of stannous chloride, equilibrium is eventually established between the hydrogen sulphide and the hydrochloric acid, the relative proportions of the two bodies depending on the temperature. The conditions of equilibrium are complicated by the fact that the solubility of hydrogen sulphide in solutions of stannous chloride decreases as the concentration of the latter increases. If, therefore, a dilute solution of hydrochloric acid acts on stannous sulphide, a small quantity of hydrogen sulphide is liberated, and dissolves in the liquid without saturating it, whilst at the same time a correspondingly small quantity of stannous chloride is formed. If, on the other hand, a current of hydrogen sulphide is passed into a strong solution of stannous chloride, in which the gas is almost insoluble, a small quantity of stannous sulphide is formed. and the hydrochloric acid which is liberated is sufficient to establish equilibrium with the small quantity of hydrogen sulphide by which the liquid is saturated. The greater part of the stannous chloride therefore remains unchanged. If, however, the experiment is arranged so that the proportion of free hydrogen sulphide is the same in both solutions, the proportion of hydrochloric acid will also be the same in both, and equilibrium will be established, although the two solutions contain very different amounts of stannous chloride. It would appear, therefore, that the stannous chloride plays a considerable, although mainly a mechanical, part in the establishment of equilibrium, by virtue of the fact that its presence diminishes the solubility of hydrogen sulphide.

No hydrochloride of stannous chloride appears to exist. When hydrochloric acid gas is passed over hydrated stannous chloride, $SnCl_2,2H_2O$, the latter melts and yields an acid solution of stannous chloride, and a new hydrate, $SnCl_2,H_2O$. The same hydrate is formed by the action of concentrated aqueous hydrochloric acid on the hydrate, $SnCl_2,2H_2O$. The decomposition of stannous sulphide by hydrochloric acid is also materially affected by the temperature which not only accelerates the action of the acid, but at the same time diminishes the solubility of the hydrogen sulphide.

Hydrated stannous sulphide is attacked by hydrochloric acid at the ordinary temperature, decomposition taking place in more dilute solutions and with greater rapidity, than in the case of the anhydrous sulphide, although the products of the reaction and the conditions of equilibrium are the same in both cases.

Similar phenomena are observed with stannous selenide. Stannous telluride is decomposed when heated in a current of dry hydrochloric acid gas, but is not attacked by the aqueous acid in concentrated solutions. C. H. B.

Antimony Pentiodide. By J. H. Pendleton (*Chem. News*, **48**, 97).—Evidence of the existence of pentiodides of phosphorus and arsenic have been obtained (Abstr., 1881, 507; and *Chem. News*, **44**, 194), and the author has now investigated a pentiodide of antimony.

Pure antimony is fused with excess of iodine in an atmosphere of an inert gas in a sealed tube, and the mixture is kept well fused for an hour or two; the tube is then heated at 130° in a sulphuric acid-bath, one end which is cooled with water serving to collect the surplus iodine which distils off. The residue is a dark-brown crystalline mass, decomposible by water or long exposure to moist air. It melts at 78—79°, but is very unstable, readily undergoing decomposition when exposed to even a moderate increase of temperature. Analytical results correspond "pretty closely to the formula SbI_5."

Several experiments were tried in which the temperature of the acid-bath and time of exposure were varied. D. A. L.

Chromic Acid and Hydrogen Peroxide. By H. Moissan (*Compt. rend.*, **97**, 96—99). The dark-blue compound formed by the action of hydrogen peroxide on chromic acid is rapidly decomposed by water, but is much more stable in ethereal solution, the stability being, however, much diminished by the presence of a small quantity of alcohol. By using carefully purified ether and a solution of 50 grams of potassium dichromate per litre, it is possible to obtain at 0° an ethereal solution of the dark-blue compound containing 0 5 per cent. of chromium. This solution may be digested over calcium chloride, and can be kept for six or eight hours at 0° without undergoing sensible decomposition, but in time it decomposes, chromic acid being deposited on the sides of the tube. Dilute solutions are more stable than concentrated solutions. The ethereal solution when evaporated at $-20°$ in a vacuum leaves a deep indigo-blue oily liquid, which readily redissolves in ether. In contact with sodium, it evolves hydrogen, and when only very gently heated it rapidly decomposes into oxygen and chromic acid. The volumes of oxygen and hydrogen given off correspond with the formula CrO_3,H_2O_2; it would therefore appear that the blue substance is a compound of chromic acid and hydrogen peroxide. The ethereal solution, in contact with phosphoric anhydride or other dehydrating agents, is rapidly decomposed with evolution of oxygen. It is also decomposed by acids, bases, lead dioxide, carbon, manganese dioxide, red lead, mercuric oxide, and sodium: in the last case with evolution of a mixture of hydrogen and oxygen. The ethereal solution also bleaches the skin like hydrogen peroxide.

The blue compound cannot be obtained by the action of ozone on chromic acid, and it is only formed by electrolysis when hydrogen peroxide is also produced. C. H. B.

Reduction of Iron Oxide with Carbonic Oxide. By R. Akermann and Särnstrom (*Dingl. polyt. J.*, **248**, 291—239).—Experiments on the reduction of ferric oxide prove that it is readily converted into ferrosoferric oxide, and that magnetite parts with its oxygen to form ferrous oxide more easily than does ferrous oxide to yield metallic iron. One volume of carbonic oxide diluted with 20 volumes of carbonic anhydride reduces ferric oxide to ferrosoferric oxide at 450°. One part of carbonic oxide with 2·1 parts carbonic anhydride effects a similar reduction at 300—350°. By raising the temperature to 850—900° 1 volume of carbonic oxide to 2 6 volumes carbonic anhydride still reduces magnetite, but with the proportions of one to three this is no longer the case even at a temperature of 800°. Ferric oxide is easily reduced to magnetite in layers 2 mm. thick without any further reduction taking place so long as the gaseous mixture contains at least three volumes carbonic anhydride to one volume of carbonic oxide. Ferrous oxide is easily reduced to the metallic state at 850° when the ratio of carbonic oxide to anhydride is 1 to 0·4. Experiments were made to oxidise iron by heating it in mixtures of carbonic oxide and carbonic anhydride, the results were unsuccessful, however, as regards the production of ferrous oxide. The reducing power of an equivalent of carbonic oxide on ferrous oxide does not equal the oxidising power of an equivalent of carbonic anhydride on iron. In both cases, however, an increase of temperature gives rise to increased action. To reduce magnetite at a temperature of 350° to ferrous oxide, the quantity of carbonic anhydride must not exceed two volumes to one of carbonic oxide. The authors find that for the production of 100 kilos. iron at least 64·3 kilos. of carbon in the form of carbonic oxide are required. Much less than this, however, is repeatedly employed in blast furnaces; it follows therefore that a reduction has taken place by the carbon as such, a reaction requiring a higher initial temperature than the reduction with carbonic oxide. In regard to the consumption of fuel, therefore, very little saving is to be anticipated. D. B.

Mineralogical Chemistry.

Minerals of the Cryolite Group recently found in Colorado. By W. Cross and W. F. Hillebrand (*Amer. J. Sci.* [3], **26**, 271—294).—Cryolite and several allied fluorides have been recently discovered in the Pike's Peak region, Colorado. The country rock of the whole district is a coarse reddish biotite granite of the Archæan formation.

The minerals described occur in two veins of massive white quartz, about one-third of a mile apart. In the vein designated A, cryolite, pachnolite, thomsenolite, gearksutite, prosopite, and, probably ralstonite appear. In vein B, prosopite, fluorite, and mixed fluorides appear intimately associated with zircon, kaolinite, and mica.

The *cryolite* from vein A is of a faint pink colour, and contains as a visible impurity the Fe_2O_3 represented in the analysis—

Fe_2O_3.	Al.	Ca.	Na.	H_2O.	F.	Total.	Sp. gr.
0·40	12·90	0·28	32·40	0·30	53·55	99·83	2·972

Previous to the analysis by J. Brandl (Abstr., 1882, 1176) of *pachnolite*, carefully selected by Groth, pachnolite and thomsenolite were considered to possess the same chemical composition. The results of all earlier analyses agree very well with the formula

$$NaF,CaF_2,AlF_3,H_2O,$$

so that Brandl's analysis agreeing with the formula NaF,CaF_2,AlF_3 caused great surprise. Groth explained the supposed anhydrous nature of pachnolite by assuming that the mineral analysed was largely contaminated with thomsenolite, but as the percentage of water never falls below 7 per cent. in any of the analyses published, this assumption necessitates a most improbable admixture of thomsenolite. All the analyses made by the authors correspond with the formula NaF,CaF_2,AlF_3,H_2O. The results of an analysis made upon crystals carefully identified as pachnolite by the rhombic section, were as follows:—

Al.	Ca.	Na.	H_2O.	F.	Total.
12·36	18·04	10·25	8·05	(51·30)	100·00

Hence it appears that the pachnolite from Pike's Peak and thomsenolite are identical in chemical composition, unless the fact of all analyses of thomsenolite showing slightly more water than that required for the formula NaF,CaF_2,AlF_3,H_2O, may indicate a partial replacement of fluorine by hydroxyl.

In small cavities in the massive pachnolite, a mineral was found, occurring sparingly in a few specimens, which seemed to be different from any known species. The analysis gave—

Al.	Ca.	Mg.	K.	Na.	F.	Total.
11·40	0·72	0·22	28·94	9·90	46·98	98·16

from which may be deduced a formula analogous to that of cryolite, in which about two-thirds of the Na is replaced by K. The authors are of opinion that this mineral and *ralstonite* are not identical, but further investigations will be made as soon as better material can be obtained for examination.

Gearksutite is abundant among the minerals from this locality. It is made up of exceedingly minute colourless needles, and resembles kaolin in a remarkable degree. The analytical results obtained were as follows:—

Al.	Ca.	Na.	K.	H_2O.	F.	Loss as oxygen.	Total.
15·31	22·30	0·10	0·04	15·46	42·07	4·72	100·00

In this Journal (Trans., 1883, 140) Flight described a mineral obtained from the cryolite bed of Greenland, which he considered new, and named *evigtokite*; but from the agreement of his analyses with those previously published, the similarity in occurrence and physical characteristics, there can hardly exist a doubt that Flight analysed gearksutite. The name evigtokite should therefore be dropped.

The rare mineral *prosopite* is more frequent in vein B than in vein A. The analytical results obtained were as follows:—

Al.	Ca.	Mg.	Na.	H_2O.	F	Loss as oxygen.	Total.
22·17	17·28	0·17	0·48	13·46	33·18	13·26	100·00

B. H. B.

Stibnite from Japan. By E. S. DANA (*Amer. J. Sci.* [3], **26**, 214—221).—In the size and beauty of the crystals, and in the great complexity of their form, the Japanese stibnite far exceeds specimens from other localities. The finest specimens known to the author are those recently acquired by the Yale Museum. They were obtained from Mount Kosang, near Seijo, in South Japan. They are of remarkable size. A simple group consists of two prismatic crystals, with vertical axes nearly parallel; the longer of the two measures 22 inches, and the other 15 inches in length, the thickness varies from 1½ to 2 inches. The lustre is very brilliant, and can be compared only with that of highly polished steel. The complexity of form observed among Japanese stibnites is their most remarkable character. Previous to 1864 but 16 planes had been identified. Krenner (*Ber. Wien. Akad.*, 1864, 436) added 28 new planes, and Seligmann (*Jahrb. f. Min.*, 1880, 1, 135) added one more. Of these 45 planes, 30 have been observed on the Japanese crystals, and, in addition to these, 40 new planes have been determined, thus increasing the list to 85. This list could be considerably enlarged if the planes admitting of only doubtful determination were to be added.* B. H. B.

Gibbsite from Brazil. By W. C. Eustis (*Chem. News*, **48**, 98). —The specimen examined had a dark-coloured incrustation containing iron, a little manganese, and traces of nickel and cobalt. The mineral was greyish-white to nearly colourless, the surface was mammillary, and the structure radiate or fibrous. Lustre, sub-vitreous or slightly silky in some parts; hardness, 3; sp. gr., 2·4. Before the blowpipe it whitens, and loses water, but does not fuse. Analysis yielded the following results:—

Al_2O_3.	H_2O.	Fe_2O_3.	CaO.	MgO.	SiO_2.		Total.
63·81	35·85	0·49	0·30	0·03	0·20	=	100·68

No aluminium phosphate could be detected. D. A. L.

Corundum Gems in India. By C. U. Shepard (*Amer. J. Sci.* [3], **26**, 339—340).—A remarkable deposit of sapphire and ruby has been discovered at Sungchang in the Himalaya Mountains. The matrix is a schistose or slaty rock, and the vein consists of quartz, amethyst, and several varieties of corundum, all beautifully crystallised. In addition to these, massive corundum, chlorite, and a little magnetite also occur. There is a great analogy in the mode of occurrence and other particulars between the crystals found in India and those produced at several of the American localities, notably at the Laurens district, S. Carolina; Pelham, Mass., and Burke Co., N. Carolina. The resemblances are, in fact, sufficiently important to lead to the belief that valuable corundum gems may yet be found in the United States. B. H. B.

Cassiterite, Spodumene, and Beryl from Dakota. By W. P. Blake (*Amer. J. Sci.* [3], **26**, 235).—Cassiterite has been discovered in the central region of the Black Hills, Dakota, in a mass of coarsely crystalline granite. The felspar, quartz, and mica are in unusually large crystals; and, in addition to these minerals, there is an abundance of spodumene in gigantic crystals ranging from 2 to 6 feet in length, and 8 to 20 inches in diameter. In the midst of the spodumene and felspar crystals, the first masses of tin-ore were found. The chief associate of the tin-ore is a dense aggregation of small mica crystals. At another locality, where muscovite mica has been mined, the author found large crystals of beryl embedded in quartz.

---

* Since the above memoir was published, a much finer group of Japanese stibnite crystals has been purchased from Mr. Henson for the British Museum. The group consists of 120 crystals from 0·5 to 2·5 inches wide and 13 inches long; weight, 150 lbs.—B. H. B.

B. H. B.

Descloizite from Mexico. By S. L. PENFIELD (*Amer. J. Sci.* [3], **26**, 361—365).—The mineral analysed was said to be from Zacatecas, Mexico. In all physical properties it seems to be identical with *tritochlorite* recently described by A. Frenzel (Abstr., 1882, 473). The analytical results obtained are given under I. Frenzel's analysis of tritochlorite is also given (II) for comparison:—

	V_2O_5.	As_2O_5.	P_2O_5.	PbO.	CuO.	ZnO.
I.	18·95	3·82	0·18	54·93	6·74	12·24
II.	24·41	3·76	—	53·90	7·04	11·06

	FeO.	H_2O.	SiO_2.	Total.	Sp. gr.
I.	0·06	2·70	0·12	99·74	6·20
II.	—	—	—	100·17	6·25

The minerals have the same density, and are alike in many particulars, but it seems hardly probable that Frenzel could have overlooked 2·70 per cent. of water. The difference in the percentage of vanadic acid is also considerable.

B. H. B.

Manganese Ores. By M. LILL and L. SCHNEIDER (*Dingl. polyt. J.*, **248**, 471).—The authors have analysed the following samples of manganese ores from Bukowina:—I. From Upper Arschitza; II. Lower Arschitza, and III and IV, from the mines Theresia and Schara. The following results were obtained:—

D. B.

Native Ferrous and Aluminium Sulphate from Mexico. By T. P. LIPPITT (*Chem. News*, **48**, 98).—The specimen was a compact mass of flexible fibres resembling asbestos. It was of a pale greenish-white colour, and had a silky shining lustre. Hardness, 2; sp. gr. 1·89. When heated in a glass tube, it gave off acid water. A small quantity of gypsum was intermixed with the mineral, which was otherwise quite homogeneous. The mineral is soluble in water, and yielded on analysis the following numbers:—

Fe (ferrous).	Al.	Ca.	SO_4.	H_2O.		Total.
7·81	4·92	0·52	41·59	43·60	=	98·44

The iron is all ferrous. Subtracting the constituents of gypsum from the results the formula $Fe_3''Al_4(SO_4)_9(H_2O)_5$ is obtained, which would be equal to a mixture of 2 mols. of halotrichite + 1 mol. melantrite.

$$2\{Fe''Al_2(SO_4)_4.(H_2O)_{22}\} + Fe''SO_4(H_2O)_7.$$

D. A. L.

Occurrence, Association, and Probable Mode of Formation of Barytes, Celestine, and Anhydrite. By Dieulafait (*Compt. rend.*, **97**, 51—53).

Barytes is generally found associated with metallic ores containing sulphur, the metals present in these ores being antimony, arsenic, lead, silver, mercury, copper, cadmium, bismuth, zinc, and manganese. With the exception of the last two these metals have a strong attraction for sulphur; they are precipitated by hydrogen sulphide from acid solutions, and they are generally found in nature in the form of sulphides, which appear to be their most stable compounds. Zinc is frequently found as sulphide, but its most stable form is the oxide, although the tendency of the natural sulphide to pass into the state of oxide does not appear to be very great. The most stable form of manganese is the dioxide. Some of the sulphides with which barytes is associated are very volatile, others are decomposed when heated in presence of air (which generally has access to metallic veins), and all are decomposed when fused with alkaline chlorides. These and other facts show that the barytes and the minerals with which it is associated have never been subjected to the action of even a moderately high temperature, and have certainly not been formed in contact with the fused alkaline chlorides.

Celestine, unlike barytes, is generally found in saliferous deposits, in which it is associated with gypsum and rock-salt, and it exists in small quantities in the gypsum of such deposits. If the gypsums are rich in organic matter, as is the case in all those in which free sulphur is found, polysulphides of calcium and strontium are formed in the interior of the rock. These polysulphides are dissolved and washed out by percolating water, and when brought in contact with the air they are decomposed, with formation of calcium sulphate, calcium carbonate, strontium sulphate, and free sulphur, and the frequent occurrence of crystals of celestine on the surface of crystals of sulphur shows that the former must have been deposited at a temperature below the melting point of the latter.

Anhydrite frequently alternates with gypsum, which agrees with Gorgeu's hypothesis, but, on the other hand, it is quite as common in gypsum, especially in the triassic deposits in the south-east of France, where the anhydrite often passes insensibly into gypsum. It cannot be supposed that the anhydrite alternating with gypsum has been deposited from fused sodium chloride, since the gypsum begins to lose its water even below 100°. It would appear, therefore, that Gorgeu's hypothesis cannot be accepted as an explanation of the mode of formation of barytes, celestine, and anhydrite existing in veins and in saliferous deposits, although it may be of value in considering the chemical changes which accompany volcanic action.

C. H. B.

New Locality of Chalchuite. By W. P. Blake (*Amer. J. Sci.* [3], **25**, 197—200).—The occurrence in New Mexico of a green turquoise, chalchuite, has already been described by the author (*Amer. J. Sci.*, 1858, **25**, 227). Chalchuite also occurs in Cochise County, Arizona, in an outlying ridge of the Dragoon Mountains, now known as "Turquoise Mountain." The mineral is identical in appearance with the New Mexican variety. It is of a light green colour, with a sp. gr. of 2·71—2·82. It is peculiarly interesting archæologically. It was in general use among the Aztecs before the arrival of the Spaniards, and the author proves its identity with the *callais* or *callaina* of Pliny.

B. H. B.

Scovillite, a new Phosphate of Didymium, Yttrium, and other rare Earths from Salisbury, Conn. By G. J. Brush and S. L. Penfield (*Amer. J. Sci.* [3], **25**, 459—463).—This mineral was discovered by J. S. Adam, occurring sparingly as an incrustation on some of the iron and manganese ores from the Scoville ore bed. The incrustation is one-sixteenth of an inch in thickness, and is frequently botyroidal or stalactitic. It is of a pink to yellowish-white colour, and presents a radiated fibrous structure. H. = 3·5. Sp. gr. 3·94—4·01. The results obtained on analysis were as follows:—

P_2O_5.	$Y_2O_3 + Er_2O_3$.	$La_2O_3 + Di_2O_3$.	Fe_2O_3.	Combined H_2O.
24·94	8·51	55·17	0·25	5·88

H_2O lost at 100°.	CO_2.	Total.
1·49	3·59	99·83

The presence of the carbonate is regarded as due to an admixture of lanthanite, $(La,Di)_2(CO_2)_3,9H_2O$. The mineral as analysed is calculated to be a mixture of 17·04 per cent. of lanthanite, and 82·79 per cent. of the new phosphate, $R_2(PO_4)_2,H_2O$. Calculating the 82·79 per cent. of Scovillite up to 100 per cent., we obtain—

P_2O_5.	$(YEr)_2O_3$.	$(LaDi)_2O_3$.	Fe_2O_3.	H_2O.	Total.
30·12	10·28	55·73	0·30	3·57	100·00

B. H. B.

Analyses of Lithiophillite. By S. L. Penfield (*Amer. J. Sci.* [3], **25**, 176).—The author has already published analyses of triphyllite and lithiophillite from the various known localities (Abstr., 1879, 695). He now adds to these two analyses, one of lithiophillite from

Norway, Me (I), the other (II) of a variety from Branchville, Conn. The results obtained were:—

	Sp. gr.	P_2O_5.	FeO.	MnO.	CaO.	Li_2O.
I....	3·398	44·40	8·60	35·98	0·78	8·50
II....	3·504	44·93	16 36	28·58	0·05	8·59

	Na_2O.	H_2O.	Gangue.	Total.
I.....	0·14	1·19	0·12	99·71
II.....	0·21	0·54	0·13	99·39

These analyses fully substantiate the formula $Li(MnFe)PO_4$, already made out for the species. B. H. B.

Determination of Alkalis in Lepidote from India. By M. PAGE (*Chem. News*, **48**, 109—110).—The mineral examined, of a lead grey colour, was found in granite associated with a violet-red lepidote, quartz. and occasionally tinstone. The total alkalis and sodium and potassium were determined in the usual way; lithium was determined as phosphate; rubidium by fractional precipitation with platinic chloride and numerous washings with boiling water. The results per cent. are:—

K_2O.	Li_2O.	Na_2O.	Rb_2O.
8·595	1·754	0·609	0·070

D. A. L.

Topaz from Maine, U.S. By C. M. BRADBURY (*Chem. News*, **48**, 109).—The sample examined consisted of large colourless translucent topaz crystals; sp. gr. 3·54. An analysis yielded the following figures:—Al 27·14; Si 14·64; F 29·21; O 28·56; total, 99·55. This is very anomalous, as three-quarters and not half the oxygen, corresponding with silicon, is replaced by fluorine in ordinary topaz. Berzelius's analytical method was employed. D. A. L.

Analyses of Franklinite Ores from New Jersey. By P. RICKETTS (*Dingl. polyt. J.*, **248**, 523).

D. B.

Chrysocolla from Arizona. By W. C. Eustis (*Chem. News*, **48**, 109).—The specimen for analysis was associated with a bluish-green variety of chrysocolla, and with much carbonate. The sample analysed was emerald-green, transparent, and pseudomorphous, with vitreous lustre. Sp. gr. 2·3; hardness, 3·5. Analysis yielded CuO, 32·22; SiO_3, 34·08; H_2O, 31·65; total, 98·95. These figures approximate to the formula $3CuO,4SiO_2,13H_2O$, which corresponds with some specimens of chrysocolla of the constitution $CuSiO_3,3H_2O$. in which one quarter of the copper is replaced by hydrogen; the mineral analysed may be looked upon as a copper hydrogen silicate. D. A. L.

Rocks of the Yellowstone Park. By W. Beam (*Amer. J. Sci.* [3], **25**, 106).

1. *Porphyritic Obsidian.*—Colour greenish-black, semi-transparent. H. = 6. Sp. gr. = 2·4. The analysis gave—

SiO_2.	Al_2O_3 and Fe_2O_3.	CaO.	MgO.	Na_2O.	K_2O.	H_2O.	Total.

2. *Pebble of quartz trachyte covered with a deposit from Echinus Geyser.*—The pebble analysed was about 1·5 inches in diameter, of a light fawn colour, and contained small masses of colourless silica. The analytical results were as follows:—

SiO_2.	$Al_2O_3+Fe_2O_3$.	CaO.	MgO.	K_2O.	Na_2O.	H_2O.	Total.
77·90	14·55	0·40	trace	4·63	2·10	1·00	100·58

B. H. B.

Volcanoes of Northern California, Oregon, and Washington. By A. Hague and J. P. Iddings (*Amer. J. Sci.* [3], **26**, 222—235).—During the year 1870 the geologists attached to the Geological Exploration of the Fortieth Parallel, made a preliminary survey of the extinct volcanic cones of North California, Oregon, and Washington, but a further study was never undertaken. As the rock specimens then collected may be considered as representing the principal types of the ejected lavas, a large number of thin sections have recently been made, and their microscopic examination has been followed up by chemical investigation.

The four great cones, Lassen's Peak, Mt. Shasta, Mt. Hood, and Mt. Ranier, which may be taken as typical of the chain, are all andesite volcanoes, with extrusions of basalt. Similar variations in mineral composition and minute details of structure are found at each of the volcanoes. All the rocks from these volcanoes may be classified under the heads of basalt, hypersthene-andesite, hornblende-andesite, and dacite.

Hypersthene-andesite.—These rocks are generally very porous, varying in colour from blue-black to steel-grey. They occur in all stages, from crystalline, dense forms to glassy pumice. They are generally crowded with very small porphyritic crystals, of which the felspars are the most noticeable, the iron magnesium silicates being more apparent in the light-coloured varieties. A complete chemical analysis is given (I) of a pumice from which the hypersthene was extracted. The ground-mass is an almost pure glass, and the microscope shows that the hypersthene was the first of the essential minerals to crystallise out from the original magma. The analysis of this pumice does not very materially differ from the analysis of the more compact lavas. After separating the heavier minerals from the felspar and glass, the latter were subjected to Thoulet's solution, in order to isolate the glass from the felspar. Two separations of felspar were obtained, one with sp. gr. from 2·66—2·68, and the other from 2·64—2·66. Analyses of these are given (III and IV). These probably represent the same felspar rendered impure by foreign ingredients. An analysis of the glass which forms the base of the pumice is given under V. Sp. gr. = 2·29.

	I.	II.	III.	IV.
SiO_2	62·00	50·33	56·41	56·95

Dacite.—This rock occurs near the highest point of Lassen's Peak. It is probably the most recent extrusion from the peak, and is quite unlike the rocks obtained from the other volcanoes. The specimens vary from a moderately compact rock to others of a pumice-like character. The rock is composed of quartz, mica, hornblende, and plagioclase, and is from 6—9 per cent. richer in silica than the prevailing rocks of the four main cones (Analysis VI). Analyses of the felspar (VII) and of the glass (VIII) are given. The felspar is probably a mixture of andesine and oligoclase.

	V.	VI.	VII.	VIII.
SiO_2	69·94	69·36	65·77	76·75
Al_2O_3	15·63	16·23	21·51	12·32

Total	100·16	100·04	100·09	99·68

The four types of rocks, basalt, hypersthene-andesite, hornblende-andesite, and dacite, exhibit four well characterised groups, but they are not sharply defined and distinct forms, as between any two in the series all possible intermediate varieties exist. B. H. B.

Meteoric Iron from Georgia. By C. U. SHEPARD (*Amer. J. Sci.* [3], **26**, 336—338).—The mass here described was found in 1879 about 14 miles north-east of Dalton, Whitfield Co., Georgia. It weighed 117 lbs. Its shape is somewhat that of a pear. The surface is black and very little oxidised. The sp. gr. is 7·986, which is somewhat higher than is usual in meteoric iron. The analysis gave the following results:—

Fe.	Ni.	Co.	Total.
94·66	4·80	0·34	99·80

with traces of phosphorus, chromium and manganese.

B. H. B.

Geyser Waters and Deposits. By H. LEFFMANN (*Amer. J. Sci.* [3], **25**, 104—105).—The specimens from which the following analyses were made were collected from the Yellowstone Park in 1878. Most of the geysers and hot springs are siliceous, and in most of the waters examined the silica is in the free condition. All the results are given in grains to the imperial gallon:—

1. *Pearl Geyser.*

$CaSO_4$.	Na_2SO_4.	NaCl.	SiO_2.	Total.
1·40	1·89	61·39	7·84	72·52

At the bottom of the bottle containing this water was a quantity of gelatinous matter, which was found on analysis to be composed of 79·1 per cent. SiO_2 and 4·9 H_2O, together with traces of Al_2O_3, Fe_2O_3, and CaO.

2. *Jug Spring.*

$CaCO_3$.	Na_2CO_3.	Na_2SO_4.	NaCl.	SiO_2.	Total.
0·79	49·14	2·12	31·57	14·56	98·18

3. *Opal Spring.*

NaCl.	$CaSO_4$.	$CaCl_2$.	SiO_2.	Total.
72·18	3·22	4·06	53 76	143 22

This is not a geyser but a spring having the temperature of 90° F. The water is opalescent.

4. *Deposit from Bronze Spring.*—This occurs in convoluted layers with bronze-coloured surfaces and fawn-coloured streak, H. = 5·5. The results obtained on analysis were as follows:—

SiO_2.	Fe_2O_3 and Al_2O_3.	Organic matter and water.
83·1	1·2	13·6

B. H. B.

Solid and Gaseous Constituents of Sea Water and Oceanic Deposits. By H. TONROE and L. SCHMELCK (*Bied. Centr.*, 1883, 217—231).—These investigations were made by the Norwegian North Atlantic Expedition in 1876–78, when a tract of ocean lying between 60° and 80° N. and 12°—37° E. was examined.

Solid Constituents.—There is but very little variation of the sp. gr. found; a few samples, however, were much lighter, but this was due to the neighbourhood of ice, or river mouth, as the solids still bore a constant ratio to one another. As regards the percentages of chlorine, lime, magnesia, and sulphuric acid present in water taken from various depths, they remain practically constant, neither are they affected by the latitude; in those cases in which potassium has been estimated (as chloride) no variation has been found. The authors found only 0·0025 gram per 100 c.c. of or ganicmatter, and no hydrogen sulphide. When sea water is boiled, the evaporated water being constantly replaced, all the carbonic anhydride is expelled, and a precipitate of magnesium salt free from lime is formed; but if on the contrary, the water be evaporated to say one-half, only part of the gas is driven off, and the precipitate consists of calcium carbonate and gypsum; in both cases the water becomes alkaline; further concentration causes the precipitation of gypsum and sodium chloride, the mother-liquor containing all the magnesium and potassium salts.

Air in Sea Water.—Jakobsen in 1871–72 found less oxygen at lower depths than at the surface.

Buchanan found the percentage of oxygen in surface water to vary with the latitude: so do the authors, obtaining 33·93 per cent. (mean) in the German Ocean, 34·94 per cent. in latitude 50—70° N., and 35·54 per cent. in latitude 70—80°.

As these results do not tally with those obtained by Bunsen, who states that the composition of the absorbed air is constant for all temperatures: experiments to elucidate the question were made, and the conclusion arrived at was, that seeing that the percentage of nitrogen was normal, there must be some unknown factor which causes the water to be supersaturated with oxygen.

When comparing the volumes of oxygen in the water collected from different depths, it was noticed that the reduction was at first very rapid, but soon became less so, and at 1000 m. the minimum was reached, increasing slowly afterwards, being 0·4 per cent. at 3000 m. The curves representing percentages of salt and nitrogen at different depths, show that the percentage of nitrogen is inversely proportional to that of salt.

Deposits.—Schmelck collected 300 samples of the sea bottom, and all may be classed under the name of clay, but of this clay there are five kinds—grey, transition, biloculine, rhabdamine, and volcanic.

The grey clay covers the whole surface of the bed of the sea, but is superposed at depths of more than 1000 fathoms by biloculine; in shallow seas, as along the coast of Norway and Spitzbergen, much sand, flint, and mussel shells are found, the percentage of calcium carbonate being 9 per cent. At 500 fathoms, brown clay overlies the grey; this brown clay is distinguished from the brown biloculine which only appears at 1000 fathoms by the coarse sand present, and the paucity of Foraminifera; it is this clay which has been termed "transition." Biloculine, which is distinguished from grey clay by its colour, and from transitional by its structureless fineness and uniformity of external appearance, is rich in Foraminifera, and consequently in lime: the principal Foraminifera present being *Globigerina biloculina, lituola*, and *nonionina;* the minerals are microscopic grains of quartz and flakes of mica; one difference is remarkable, that whereas these particles are sharp-edged in this clay, these are all rounded in the transition clay. The green or rhabdaminic clay is found in the shallow waters which lie between Norway, Beren's Island, and Nova Zembla, and contains a large number of Foraminifera, but little calcium carbonate, much silica. Volcanic sands and dark green sandy clay is found about Jan Mayen's Land, and contains lava, tufa, felspath, augite, hornblende, magnetit and olivin. All of these deposits vary considerably in their percentage of ferrous oxide, the lighter coloured kind containing least. E. W. P.

Organic Chemistry.

Bromine Substitution Products of Ethane and Ethylene. By R. Anschütz (*Annalen*, **221**, 133—157).—The author has carefully examined the physical properties of the bromine substitution-products of ethylene and ethane, and many of the results have already appeared in this Journal (Abstr., 1880, 98). The boiling points and specific gravities of the compounds are given in the following table:—

	b p.	Sp gr.	
		t.	d^t_4.
$CH_3.CH_2Br$	38·4°	15·0°	1·4189
$CH_3.CHBr_2$	110·5	21·5	2·0822
$CH_2Br.CH_2Br$	131·6	21·5	2·1767
$CHBr_2.CH_2Br$	187—188	21·5	2·6107
$CBr_3.CH_2Br$	103·5*	21·5	2·9216
$CHBr_2.CHBr_2$	114·0*	21·5	2·9629
$CH_2:CHBr$	16·0	11·0	1·5286
$CBr_2:CH_2$........	91·5	20·6	2·1780
$CHBr:CHBr$	110·0	17·5	2·2714
$CBr_2:CHBr$......	162·5	0·0	2·6900

From these results it appears that the addition of bromine raises the boiling point and increases the sp. gr. of the derivatives of ethane and ethylene. An unsymmetrical bromine-compound has a lower boiling point and a lower sp. gr. than its symmetrical isomeride. The boiling points of the ethane derivatives are higher than those of the corresponding ethylene compounds, but the specific gravities are lower. W. C. W.

Nitro-derivatives of Ethylene. By A. Villiers (*Compt. rend.*, **97**, 258—260).—When the compound $C_2(NO_2)_4Br_2,2KHO$ (Abstr., 1882, 815) obtained by the combination of potassium hydroxide with tetranitroethylene bromide is treated with dilute acids, it yields a yellowish oily liquid with a penetrating odour. This liquid is probably tetranitroethylene bromide. It may be heated to 100° without detonation, but is very unstable even at the ordinary temperature. The action of nitric acid on monobromethylene bromide, and on monobromethane yields the same product as the action of nitric acid on ethylene bromide. When this compound is treated with sodium amalgam, or with zinc in presence of dilute alkali, it is reduced with formation of ammonia, hydrobromic acid, and hydrocyanic acid. With ammonium sulphide several products are formed. If the potassium compound of tetranitroethylene bromide is mixed with ammonia and a quantity of water insufficient to dissolve it, and treated with hydrogen sulphide for a very short time, the precipitated sulphur is mixed with a compound which dissolves easily on gently warming, and is deposited in crystals on cooling. This compound forms pale-brown crystals of the composition $C_4K_2(NO_2)_4$. When heated gently, it decrepitates at a temperature below 100°, and is converted into a powder without change of constitution. The same molecular change takes place gradually at the ordinary temperature. At 200° the compound detonates violently, and when treated with even very dilute acids, it is completely decomposed with a violent explosion.
C. H. B.

Derivatives of Mannite Hexylene. By L. Henry (*Compt. rend.*, **97**, 260—263).—*Hexylene monochlorhydrin*, $C_6H_{12}Cl.OH$, is obtained

* Under a pressure of 14 mm.

by the action of hypochlorous acid on hexylene or by the action of hydrochloric acid on hexylene oxide. The product of the first reaction boils at about 170°, and its sp. gr. = 1·018 at 11°. As Domac has shown, it is the α-derivative, and has the constitution—

$$CHMe(OH).CHCl.CH_2.CH_2Me.$$

The product of the second reaction is probably the β-derivative, with the constitution $CHMeCl.CH(OH).CH_2.CH_2Me$. It is a slightly viscous colourless liquid with a peculiar odour, and a very sharp sweetish taste. It is insoluble in water, and boils without decomposition under a pressure of 761 mm.; its sp. gr. at 11° = 1·0143.

Hexylene monobromhydrin, $C_6H_{12}Br.OH$, obtained by the action of hydrobromic acid on hexylene oxide, is a colourless slightly viscous liquid, which becomes yellowish after some time. It has a penetrating odour, and a sharp taste, is insoluble in water, and boils at 188—190° under a pressure of 769 mm.; its sp. gr. at 11° = 1·2959. It probably has the constitution $Me.CHBr.CHPr(OH)$.

Hexylene moniodhydrin, $C_6H_{12}I.OH$, obtained by the action of hydriodic acid on hexylene oxide, is a colourless liquid which rapidly becomes brown on exposure to light. It is insoluble in water, and cannot be distilled.

Hexylene acetochlorhydrin, $C_6H_{12}Cl.\overline{Ac}O$, formed by gently heating the monochlorhydrin with acetic chloride, is a colourless liquid, insoluble in water; b. p. 188—190°; its sp. gr. at 6° = 1·04.

Hexylene chloronitrin, $C_6H_{12}NO_3Cl$, and *hexylene dinitrin*, $C_6H_{12}(NO_3)_2$, are formed when hexylene oxide or the monochlorhydrin is added to a cooled mixture of nitric and sulphuric acids. They are colourless combustible liquids, with a peculiar faint odour, insoluble in and heavier than water. They cannot be distilled.

Hexylene dichloride, obtained as a secondary product in the preparation of the monochlorhydrin or by the action of phosphorus pentachloride on hexylene oxide, is a colourless mobile liquid, which is not altered by exposure to light. It has a faint pungent odour and a sweetish bitter taste; its sp. gr. is 1·0527 at 11°. It boils at 162—165° under a pressure of 764 mm., and may be distilled over potash without undergoing alteration.

Monochlorhexylene, $C_6H_{11}Cl$, formed by the action of concentrated alcoholic potash on the dichloride, $C_6H_{12}Cl_2$, is a colourless mobile liquid insoluble in water, with a peculiar disagreeable odour, and a sharp taste. It is not altered by exposure to air, and boils at 122° under a pressure of 768 mm.; its sp. gr. at 11° = 0·9036; vapour-density 4·02.

Hexylene ketone, $C_6H_{12}O$, obtained by the action of sulphuric acid on monochlorhexylene, is a colourless mobile liquid with an agreeable pungent odour and very sharp taste. It is insoluble in water, and boils at 125° under a pressure of 753 mm.; its sp. gr. at 11° = 0·8343; vapour-density 3·45. The ketone is not decomposed by phosphorus pentachloride in the cold. Its constitution will depend on that of the monochlor-derivative, which has not yet been determined.

C. H. B.

Reduction of Potassium Ferricyanide by Potassium Cyanide. By C. L. Bloxam (*Chem. News*, **48**, 73).—The potassium cyanide employed contained but little carbonate, but on distilling it with water hydrocyanic acid and ammonia were found in the distillate, whilst the liquid in the retort contained,—besides cyanide,—potassium hydroxide, carbonate, and a little formate. When distilled with potassium ferricyanide, it yielded a distillate containing hydrocyanic acid and ammonium carbonate, the latter increasing in quantity towards the end of the reaction, whilst the residual liquid, when cool, deposited abundant crystals of potassium ferrocyanide, leaving small quantities of potassium cyanate and formate in the neutral mother-liquor. The author gives the following equation representing this reaction:—

$$K_6Fe_2C_{12}N_{12} + 2KCN + 2H_2O = 2K_4FeC_6N_6 + HCN + NH_3 + CO_2.$$

D. A. L.

A Polymeride of Trichloracetonitril. By A. Weddige (*J. pr. Chem.* [2], **28**, 188—189).—By heating ethyl paracyancarbonate (this Journal, 1874, 448) with phosphoric chloride, a thick yellowish-brown oil is obtained, which from its reactions appears to be paracyancarbonic chloride. By further heating this oil with phosphoric chloride in sealed tubes at 155—160°, a substance is obtained having the composition of trichloracetonitril, but different properties. It crystallises in large plates or prisms, melts at 91—92°, is insoluble in water, readily soluble in alcohol, ether, and benzene. By boiling with alcoholic ammonia, it is converted into a compound of the formula $C_6H_5Cl_7H_4$ or $C_6H_3Cl_7[NH_2]_2$, crystallising well and melting at 165°. A chlorinated product of feeble basic properties is obtained by heating in sealed tubes with aqueous or alcoholic ammonia.

A. J. G.

Action of Aldehyde on Propyl Glycol. By A. de Gramont (*Compt. rend.*, **97**, 173).—Equal parts of aldehyde and isopropyl glycol are heated together in sealed tubes at about 160° for two days, and the product is distilled. That portion which boils between 75° and 110° is dried over calcium chloride and fractionated. In this way a colourless, highly refractive liquid of ethereal odour is obtained. It boils at about 93°, and its sp. gr. is lower than that of water, in which it is only slightly soluble. The analysis of the liquid and the determination of its vapour-density did not give satisfactory results, but in all probability it is propyleneacetal, formed by the union of aldehyde and isopropyl glycol with elimination of water. In contact with water it yields aldehyde and isopropyl glycol.

Isopropylene oxide has no action on aldehyde in sealed tubes below 140°, but above this temperature decomposition takes place with formation of volatile and carbonaceous products. C. H. B.

Constitution of Natural Fats. By J. A. Wanklyn and W. Fox (*Chem. News*, **48**, 49).—The authors suggest that some fats, which do not yield glycerol on saponification, are in all probability ethers of isoglycerol. Isoglycerol, $CH_2Me.C(OH)_3$, exists in its ethers, cannot be isolated, and ought to be resolved into $CH_2Me.COOH + H_2O$.

D. A. L.

New Derivatives of Mannitol. By A. GEUTHER (*Annalen*, **221**, 59—60).—The author noticed that a white flocculent precipitate was gradually separated from a perfectly clear sample of butyric acid; it was filtered off, purified from the adhering acid by heating to 170°, and dissolved in water. On evaporating the aqueous solution, a gummy mass of the composition $C_{12}H_{18}O_7$ was obtained. As the process of lactic and butyric fermentation is always accompanied by a partial conversion of the sugar into mannitol, then this substance is probably an anhydride of mannitol, $C_{12}H_{18}O_7 = 2C_6H_{14}O_6 - 5OH_2$, and is thus a homologue of mannitan, $C_6H_{12}O_5$, and mannide, $C_6H_{10}O_4$.

V. H. V.

Relation between the Solubility and Rotation of Milk-sugar, and Rate of Transition of its Birotation into Normal Rotation. By F. URECH (*Ber.*, **16**, 2270—2271).—When finely divided milk-sugar is agitated with a quantity of water insufficient to dissolve it, a saturated solution is obtained, which exhibits birotation; but the solution gradually takes up more milk-sugar as the transition from birotation to normal rotation takes place, showing that the solubility is thereby increased. When two saturated solutions are prepared at temperatures differing by about 20°, and the warmer solution is allowed to cool down to the temperature of the other, it will still contain much more milk-sugar than the solution prepared at the lower temperature, the greater solubility at the higher temperature being due not only to the difference of temperature, but also to the more rapid conversion at a raised temperature of the birotatory sugar into the much more readily soluble sugar of normal rotation. The transition from birotation to normal rotation takes place slowly at atmospheric temperature, so that the rate of change can readily be measured by the polariscope and formulated in the same way as the rate of inversion of saccharose. A. K. M.

Starch and its Transformations under the Influence of Acids. By F. SALOMON (*J. pr. Chem.* [2], **28**, 82—154).—The principal conclusions drawn by the author from this lengthy investigation are as follows:—The transformation of starch by dilute sulphuric acid cannot be considered as a splitting up of the molecule into dextrin and dextrose, as assumed by Musculus. The products of the action of sulphuric acid on starch are soluble starch, dextrin, and dextrose; the course of the reaction being that the complex starch molecule is first converted into the more simple soluble starch, and next into the still more simple dextrin, the hydrolysis of the latter into dextrose commencing almost simultaneously. The rate of the conversion is proportional to the quantity of sulphuric acid present. The transformation of starch by organic acids (oxalic, tartaric, and citric acids) proceeds in the same manner as with inorganic acids, but the action is less vigorous.

Soluble starch, if pure, gives a deep blue coloration with iodine, but if it is contaminated with dextrin, a reddish-violet coloration is obtained; it does not reduce Fehling's solution, and has the specific rotary power $[\alpha]_j = 211\cdot5°$ (comp. O'Sullivan, Trans, 1879, 772). There is only evidence for the existence of a single dextrin; it gives a brownish-red coloration with iodine, does not reduce Fehling's solution, and has the specific rotary power $[\alpha]_j = 216{\cdot}5°$.

A. J. G.

Preparation of Isobutyraldehyde free from Acetone. By W. Fossek (*Monatsh. Chem.*, 4, 660—662).—The author's method is based on the property of the crystalline trimolecular modification of isobutyraldehyde to change into the ordinary liquid aldehyde, under the influence of strong sulphuric acid at the heat of the water-bath. The crude isobutyraldehyde was first partly purified by heating it, as previously described by the author (Abstr., 1882, 161), with a strong solution of sodium acetate at 150°. It was then polymerised by mixing it with strong sulphuric acid (1 g. acid to 100 g. aldehyde), or with hydrochloric acid, the formation of crystals being accelerated by cooling. These crystals were drained on a filter, washed with water, dried between filter-paper, and preserved for use. To convert them, when required, into liquid isobutyraldehyde, they are fused on the water-bath, mixed with a few drops of strong sulphuric acid, and heated on the water-bath in a reflux apparatus, whereby, after about an hour's boiling, the whole of the polymeride is converted into liquid isobutyraldehyde, boiling constantly at 63° (bar. 741 mm. at 0°) and having a density of 0·8057 at 0° and 0·7898 at 20°, referred to water at the same temperatures. Its vapour, when inhaled, produces nausea and headache.

H. W.

A Derivative of Isobutyraldehyde analogous to Hydrobenzoïn. By W. Fossek (*Monatsh. Chem.*, 4, 663—678).—The author has already shown (Abstr., 1883, 1278) that when the products of the action of aqueous potash on isobutyraldehyde are distilled with steam, a thick yellow oil remains, holding in solution two isomeric crystalline bodies, $C_8H_{18}O_2$, resembling one another in their chemical reactions (which are those of the pinacones), but differing in crystalline form, solubility, and melting point, the more abundant of the two crystallising in plates, being moderately soluble in water, and melting at 151°, whereas the other crystallises in groups of needles, dissolves but very sparingly in water, and melts at 91°. The former was extracted from the oil by agitation with hot water; the latter separated out on adding light petroleum. This higher-melting body could not at first be satisfactorily examined, on account of the very small quantity in which it was obtained; but the author has since found that it may be prepared much more readily by acting on isobutyraldehyde with alcoholic instead of aqueous potash, forming indeed the chief product of the reaction, which likewise yields isobutyric acid and a hydroxy-acid to be described further on.

The crystalline body melting at 91° is found by analysis to have the composition $C_8H_{18}O_2$, and its reactions show that it consists of di-isopropyl-glycol, $CHPr^{\beta}(OH).CHPr^{\beta}(OH)$. It dissolves readily in alcohol and ether, somewhat less readily in water, and separates on quick evaporation of its aqueous solution, as a supernatant oil, which, on contact with a solid body, suddenly solidifies to a cake. By very slow evaporation, however, at temperatures near 0°, it may be obtained in monoclinic crystals having the axial ratio $a : b : c =$

0·8223 : 1 : 1·9086, and the angle $ac = 97° 30'$. Observed faces, $\infty P\breve{\infty}$, $0P$, $+P$, $-P$. The crystals are flattened by predominance of $\infty P\breve{\infty}$. Twins occur united by this face. The vapour-density of the compound is by experiment 67·71—70·03; calc. 73·00.

By oxidation with nitric acid, the glycol yields isobutyric and oxalic acids; with potassium permanganate in neutral solution, the isobutyric acid formed in the first instance is further oxidised to acetic and carbonic acids.

Di-isopropyl glycol boiled for about two hours with a slight excess of acetic chloride, yields an oily diacetate,

$$C_{12}H_{22}O_4{}^{*} = C_8H_{16}(O\overline{Ac})_2O_2.$$

Treated with an equal weight of a mixture in equal parts of strong sulphuric acid and water, it dissolves in a few minutes, especially if the mixture be heated in a reflux apparatus, and there rises to the surface an oil having a camphorous odour; and on separating this oil after boiling with ether for half an hour, washing the etheric solution with aqueous sodium carbonate, evaporating off the ether, and drying the remaining liquid with calcium chloride, a residue is obtained which may be separated by fractional distillation into two liquids, the smaller in quantity smelling like camphor and boiling at 120—122°, whilst the other, which is viscid and nearly colourless, distils at 260—262°. Both these liquids have the composition $C_8H_{16}O$. They are not aldehydes, and therefore the oxygen contained in them is probably related to the other elements in the same manner as in oxides or in ketones.

The glycol heated for 6—8 hours in a sealed tube at 140° with ten times its weight of fuming hydriodic acid, is converted into an iodide which, when decomposed by alcoholic potash, yields an *octylene*, C_8H_{16}, in the form of a colourless mobile liquid, which has a strong odour of petroleum, distils for the most part at 116—120°, and unites readily with bromine, forming a very unstable addition-product. The mode of its formation from di-isopropyl glycol shows that it must be represented by the formula $CHPr^{\beta} : CHPr^{\beta}$.

The action of alcoholic potash on isobutyraldehyde gives rise also to isobutyric acid and a small quantity of a hydroxy-acid, $C_8H_{16}O_3$, which forms a white anhydrous crystalline powder, sparingly soluble in water and in ether, easily in alcohol; does not volatilise with steam; melts at 92°, and distils at a high temperature: its silver salt is amorphous, and melts at 120°. The constitution of this acid has not yet been made out.

The formation of di-isopropyl glycol and isobutyric acid from isobutyraldehyde is represented by the equation—

$$3Pr^{\beta}COH + KOH = CHPr^{\beta}(OH).CHPr^{\beta}(OH). + Pr^{\beta}.COOK.$$

H. W.

Action of Carbonic Oxide on Mixtures of Sodium Alcoholates and Sodium Salts of Organic Acids. By M. SCHROEDER (*Annalen*, 221, 34—55).—The researches of Geuther and Froelich, Looss and Poetsch (Abstr., 1883, 729) on the action of carbonic oxide on sodium alcoholates, have proved that a small quantity of the sodium salt of the corresponding carboxyl acid is formed. But in the presence of a considerable quantity of this latter salt, sodium formate is obtained, together with the sodium salts of homologous and isologous acids. The first phase of this reaction may be expressed as follows:—

---

* In the original paper the formula is printed $C_{16}H_{22}O_4$, which does not agree either with the rational formula or with the analysis ($C = 62·62$, $H = 9·52$).—H. W.

$$CO + C_nH_{2n+1}NaO_2 + C_mH_{2m-1}NaO_2 = HCOONa \\ + C_mH_{2m-2}(C_nH_{2n+1})NaO_2.$$

The author has studied the same reaction in the case of sodium phenates and the sodium salts of organic acids belonging to various series. When carbonic oxide is passed into a heated mixture of sodium phenylate and acetate, a hydrogen-atom of the acetic acid is not replaced by phenyl with formation of phenylacetic acid, but sodium salicylate is obtained in small quantity. This result is probably due to the presence of sodium carbonate in the alcoholate which yields the carbonic anhydride. The supposition the author confirms experimentally. Similarly in the action of carbonic oxide on sodium ethylate and benzoate, the hydrogen of the benzoic acid is not replaced by an ethyl-group. Conversely, when sodium phenylacetate is substituted for sodium benzoate, the sodium salts of phenylethylacetic, CHEtPh.COOH, and ethenylbutenylphenylacetic, $CPhC_2H_3.C_2H_2Et.COOH$, acids are formed; in this respect phenylacetic behaves precisely as acetic acid.

By the action of carbonic oxide on sodium ethylate and cinnamate, the sodium salts of diethylcinnamic acid, $C_9H_6Et_2O_2$, were formed in one set of experiments, when the mixture was more completely exposed to the action of the gas. In another set, the sodium salt of dibutyl cinnamic acid was obtained, derived doubtless from the diethylcinnamic acid by the replacement in each ethyl-group of a hydrogen-atom by another ethyl-group.

Experiments on the action of carbonic oxide on mixtures of sodium ethylate and potassium oxalate or sodium succinate led to negative results. V. H. V.

Behaviour of Chromium, Iron, and Aluminium Acetates. By B. REINITZER (*Chem. News*, **48**, 114).—When a solution of chromium sulphate or chloride is boiled with excess of sodium acetate, no precipitate is formed, but if the boiling is conducted for a short time only, the solution becomes violet on cooling. The solution thus prepared behaves in the following manner in the cold:—Caustic alkalis and barium hydroxide change the colour at first to olive-green and then to emerald-green, and in 12 hours the liquid sets to a green jelly. Ammonia produces no immediate effect, but in 48 hours a violet jelly is formed; ammonium sulphide and carbonate act in a similar manner after several days. When the violet chromium acetate solution is boiled with any of these reagents, or with an alkaline or barium carbonate, a precipitate is produced, immediately or otherwise, according to the strength and quantity of the reagent added. Sodium phosphate does not precipitate the solution. This non-precipitating property of chromium acetate extends to iron and alumina in solution, for neither by boiling nor by treatment with the above-mentioned reagents can certain quantities of ferric oxide and alumina be detected in the presence of chromium acetate. The quantity of these oxides thus retained is limited if the ferric oxide and alumina are present previous to boiling with sodium acetate; if, however, these substances are added subsequent to sodium acetate treatment, large quantities of iron and alumina can be dissolved. Ammonium sulphide makes an exception in the case of iron, for it precipitates it slowly but completely. If the chromium solution and sodium acetate are simply mixed in the cold, at first the chromium can be precipitated by the reagents referred to above; after a day, however, the solution acquires the solvent properties it would have done by boiling.

D. A. L.

Composition of Cocoa-butter. By M. C. Traub (*Arch. Pharm.* [3], 21, 19—23).—Kingzett has stated (Trans., 1878, 38) that this butter contains two new fatty acids, the one apparently an isomeride of lauric acid, the other, called theobromic acid (m. p. 72·8°), and having the formula $C_{64}H_{128}O_2$. The anomalous melting point of such an acid led the author to make an investigation of cocoa-butter. By a process of fractional precipitation with magnesium acetate after saponification, an acid was obtained from the first portion of the precipitate, which was not further resolved by precipitation, and after recrystallising from absolute alcohol was proved to be arachic acid ($C_{20}H_{40}O_2$). Fractional distillation under diminished pressure (100 mm.) confirmed the results obtained by fractional precipitation. In addition to arachic acid, oleic, lauric, palmitic, and stearic acids were found, but no acid isomeric with lauric acid. The author, therefore, cannot confirm the statement that cocoa-butter contains two new fatty acids, and maintains that its physical properties are due to the relative proportions of arachic, oleic, lauric, palmitic, and stearic acids, which are present.

W. R. D.

Carbonyl Iodide, COI_2. By S. P. Cowardins (*Chem. News*, 48, 97).—Several experiments were made with a view to prepare this substance, but without success. Proportional parts of dry carbonic oxide and iodine in a flask were exposed to direct sunlight. Carbonic oxide and iodine vapour were passed through a tube surrounded by ice and salt. Carbonic oxide was passed through heated arsenic pentiodide, and then through the cooled tube, also over red-hot lead iodide. Phosgene gas was passed over potassium iodide and into condensing tubes.

D. A. L.

Action of Phosphorus Pentachloride on Succinic Chloride. By E. Kauder (*J. pr. Chem.* [2], 28, 191—192).—By heating one part of succinic chloride with three parts phosphorus pentachloride in sealed tubes at 230°, there was obtained, not as was expected the chloride $C_2H_4(CCl_3)_2$, but a colourless liquid of sp. gr. 1·694, boiling at 199—215°, solidifying in large colourless plates at low temperatures, and having the composition C_4Cl_6O. If this is heated with sulphuric acid, it is decomposed into a substance of the formula $C_4Cl_2O_3$, possibly dichloromaleïc anhydride, $C_2Cl_2 \colon (CO)_2 \colon O$. It forms a white mass, sparingly soluble in water, melts at 119·5°, and sublimes in white plates.

A. J. G.

Tetric Acid and its Homologues. By W. PAWLOW (*Compt. rend.*, **97**, 99—102).—Ethylic methylmonobromacetoacetate is slowly decomposed at ordinary temperatures and more rapidly when heated, yielding monobromethane and the *tetric acid* described by Demarçay. This acid has the composition $C_5H_6O_3$, and not $C_{12}H_{14}O_7$ as stated by Demarçay. Ethylic isobutyl-monobromacetoacetate is decomposed in a similar manner when heated, and yields the *heptic acid* also described by Demarçay. This acid has the composition C 61·33, H 7·81, corresponding with the formula $C_8H_{12}O_3$, and not with Demarçay's formula $3(C_7H_{10}O_2),H_2O$, which requires carbon 63·63 per cent., hydrogen 8·08 per cent. The formation of these acids by simple evolution of monobromethane indicates that they are unsaturated compounds, and tetric acid is found to combine readily with two atoms of bromine. This fact, together with its mode of formation, shows that tetric acid has the formula $MeCO.C(COOH) \vdots CH_2$, and is in fact *acetoacrylic acid*, the general formula of its homologues being $MeCO.C(COOH) \vdots C_nH_{2n}$. Its formation is expressed by the equation $MeCO.CBrMe.COOEt - C_2H_5Br = MeCO.C(COOH) \vdots CH_2$. Ethyl monobromacetoacetate, $MeCO.CHBr.COOEt$, undergoes no similar decomposition. C. H. B.

Carboxytartronic Acid. The Constitution of Benzene. By A. KEKULÉ (*Annalen*, **221**, 230—260).—After referring to the researches of Gruber (*Wien. Acad. Ber.*, 1879; *Ber.*, **12**, 514), Barth (*Wien. Acad. Ber.*, 1880; *Wiener Monatshefte*, **1**, 869), and Werzig (*Wien. Acad. Ber.*, 1882; *Wiener Monatshefte*, **3**, 825), on carboxytartronic acid, and their bearing on the constitution of benzene, the author describes experiments proving that the so-called carboxytartronic acid is a dihydroxytartaric or tetrahydroxysuccinic acid. A mixture of racemic and inactive tartaric acid is formed by the action of zinc and hydrochloric acid on sodium carboxytartronate; and carboxytartronic acid is produced as an intermediate product by the spontaneous decomposition of nitrotartaric acid.

The nitrotartaric acid is prepared by adding sulphuric acid to a solution of tartaric acid in 4½ times its weight of fuming nitric acid. The crystalline mass is drained by means of a filter-pump, and brought in small quantities at a time into a mixture of ice and ether. After washing with ice-cold water, the ethereal solution is evaporated in a vacuum. A solution of nitrous acid in alcohol is added to an etherial solution of nitrotartaric acid, and after two or three days the liquid is shaken with ice-cold water. On the addition of sodium carbonate to the aqueous solution, sodium carboxytartronate is at once precipitated. The sodium salt is decomposed by water at 60°, with the formation of carbonic anhydride and sodium tartronate.

These experiments show that "sodium carboxytartronate" does not possess the constitution generally ascribed to it, and that carboxytartronic acid is closely related to tartaric acid. The exact composition of the sodium salt has not yet been ascertained, as it loses first water, and then water and carbonic acid on drying; but it is probably $C_4Na_2O_6 + 4H_2O$. Since this compound does not contain three carbon-atoms directly united to each other, its formation from pyrocatechol is no argument against the author's hypotheses on the constitution of benzene. W. C. W.

Isonitroso-acids. By A. FÜRTH (*Ber.*, 16, 2180—2182).—Of the isonitroso-derivatives of the acids of the acetic series, only three are at present known, viz., isonitroso-propionic, -butyric, and γ-valeric acids. The author, following the process proposed by Wleügel, has obtained, by the action of nitrous acid on ethylpropylacetoacetate, *α-isonitroso-valeric acid*, $CH_2Me.CH_2.C(N.OH).COOH$. This acid crystallises in needles which melt at 143° with complete decomposition; it is soluble in alcohol and benzene, sparingly soluble in water; its silver salt forms a white precipitate. By the action of hydroxylamine hydrochloride on ortho- and para-aldehydo-salicylic acid, the author has obtained the ortho- and para-aldoximesalicylic acids, $COOH.C_6H_3(OH).CH(NOH)$. Both acids crystallise in small golden needles. The former melts at 193°, the latter at 179°, and is more sparingly soluble than its isomeride. V. H. V.

Action of Nitrous Acid on Ethyl-glycocine Hydrochloride. By T. CURTIUS (*Ber.*, 16, 2230—2231).—When a concentrated aqueous solution of the hydrochloride of the ethylic ether of glycocine is treated with sodium nitrite, a yellow oil is precipitated and can be extracted with ether. To purify it, it is treated with baryta-water, steam-distilled, dried over calcium chloride, and heated at 95° on a water-bath. It is a neutral liquid of golden-yellow colour and of powerful characteristic odour, miscible in all proportions with ether and alcohol, but almost insoluble in water. It volatilises on exposure to air, and when heated to about 110° is decomposed with violence and with great evolution of heat. It shows great stability in the presence of alkalis, but in contact with acids, water, or alcohol, it gives off nitrogen in nearly theoretical amount. With cold concentrated hydrochloric acid, the decomposition takes place with explosive violence, ethyl chloracetate being formed. On boiling it with water, the products are ethylic glycollate, glycollic acid, alcohol, and nitrogen, whilst with alcohol, ethylic ethylglycollate is produced. These reactions would indicate the body to be ethylic diazoacetate, $CH_2(N_2OH).COOEt$, but analysis shows that its formula is—

$$CHN_2COOEt,$$

that is, ethylic diazoacetate minus the elements of a molecule of water. The author is continuing his experiments in the hopes of obtaining diazo- and diazo-amido-derivatives of the fatty acids. A. K. M.

Chemistry of Asparagine. By B. SCHULZE (*Landw. Versuchs.-Stat.*, 29, 233—240).—Having occasion to obtain rather large quantities of aspartic acid from asparagine, the author made several experiments to ascertain which was the cheapest and best decomposing agent to use. Schlösing's apparatus was used for determining the amount of asparagine converted into ammonium aspartate, and it was found that milk of lime had no action in the cold on asparagine until after 24 hours' standing.

Heated with water alone, at the ordinary pressure, asparagine is but very slowly decomposed; after 12 hours' boiling only 2 per cent. of the nitrogen was converted into ammonium salt. Under higher pressure the amount decomposed is much greater, and increases slowly with increase of pressure.

The effect of boiling with lime-water or baryta was much more rapid; when a large excess of baryta was used, one hour was sufficient for the complete conversion into aspartic acid; but if the boiling be continued some hours longer, a further separation of ammonia takes place, malic acid being formed.

Boiling with dilute sulphuric acid in slight excess also effects the complete conversion of asparagine into ammonium aspartate.

J. K. C.

Metaisopropylmethylbenzene. By H. E. ARMSTRONG and A. K. MILLER (*Ber.* **16**, 2748—2750).—According to Kelbe (*Annalen*, **210**, 30) metaisocymene yields at least two monosulphonic acids, the second of which, the β-acid, he did not thoroughly investigate, but he described the barium salt as being very readily soluble in water, and as crystallising from a concentrated syrupy solution in small lustrous scales of the composition $(C_{10}H_{13}SO_3)_2Ba + H_2O$. The authors, who give a full description of the method by which they prepare pure metaisocymene, also find that this hydrocarbon yields two sulphonic acids, which they separate by means of the barium salts, but Kelbe's description is entirely inapplicable to the more soluble modification. Although very soluble, it crystallises very readily in long thin prisms of the composition $(C_{10}H_{13}SO_3)_2Ba + 9H_2O$. The calcium salt, $(C_{10}H_{13}SO_3)_2Ca + 5\frac{1}{2}H_2O$, is very similar in appearance to the barium salt. The potassium salt, $C_{10}H_{13}SO_3K + 2\frac{1}{2}H_2O$, crystallises in long well-formed prisms.

A. K. M.

Contributions to our Knowledge of Camphor. By H. E. ARMSTRONG and A. K. MILLER (*Ber.*, **16**, 2255—2261).—By the action of zinc chloride on camphor, Fittig, Köbrich, and Jilke (*Annalen*, **145**, 129) obtained a hydrocarbon, $C_{10}H_{14}$, which they regarded as most probably identical with ordinary cymene, together with much toluene, xylene, pseudocumene, and *laurene*, the last-mentioned being, according to their analysis, a hydrocarbon of the formula $C_{11}H_{18}$. By the same reaction Montgolfier (*Ann. Chim. Phys.*, 1878 [5], **14**, 87) obtained what he thought to be cymene and an isomeric hydrocarbon boiling at about 195°, from which he prepared a dibromo-derivative melting at 199°; this isomeric hydrocarbon he assumed to be Jannasch's tetramethylbenzene (1 : 2 : 3 : 5), and regarded it as identical with Fittig's laurene. From the fraction 173—176°, supposed to be cymene, Fittig, Köbrich, and Jilke prepared a sulphonic acid, the barium salt of which contained 10·13 per cent. water, whereas ordinary barium cymenesulphonate contains 8·75 per cent. It would seem that Montgolfier prepared the same salt (with 10·74 per cent. water) from the crude distillate boiling at about 195°. Fittig's fraction boiling at 188° ($C_{11}H_{16}$), was assumed to be a dimethylpropylbenzene, as it yielded a tribromo-derivative melting at

125°, and on oxidation gave monobasic lauroxylic acid, $C_9H_{10}O_2$, melting at 155°

The authors heat camphor with twice its weight of zinc chloride at a moderate temperature, until a homogeneous mixture is obtained, and then distil at as low a temperature as possible. The crude distillate is extracted with sodium hydroxide solution, then steam-distilled, and the distillate is agitated with dilute sulphuric acid (4 vols. acid to 1 vol. water) to remove the unattacked camphor, and again steam-distilled. On passing steam into the retort, a second distillate is obtained, consisting of camphorone, $C_9H_{14}O$, and camphor mixed with some hydrocarbon, which can be separated by means of sulphuric acid of the above strength, in which the camphorone is soluble; a residue of zinc chloride mixed with a black carbonaceous mass remains in the retort. The above-mentioned alkaline extract yields pure carvacrol on addition of an acid.

When the mixture of hydrocarbons remaining after treatment of the crude distillate with dilute sulphuric acid, is heated with sulphuric acid, a considerable amount of a saturated hydrocarbon, $C_{10}H_{20}$, remains undissolved, whilst the sulphuric acid solution contains principally benzene hydrocarbons of the formula $C_{10}H_{14}$, only a very small amount of lower and higher homologues being formed, together with a hydrocarbon which has not yet been isolated, and which is carbonised by the action of heat on the dilute acid solution. The chief constituents of the hydrocarbon mixture are a *methylpropylbenzene*, a *dimethylethylbenzene*, and a *tetramethylbenzene;* the presence of ordinary cymene has as yet not been detected.* The sulphonic acid of the first-mentioned hydrocarbon yields a very sparingly soluble anhydrous barium salt, a sodium salt containing 1 mol. H_2O, and an anhydrous potassium salt, the last two crystallising in large lustrous plates. The hydrocarbon boils at 176°, is oxidised by dilute nitric acid to metatoluic acid, and is identical with the metaisopropylmethylbenzene discovered by Kelbe in rosin spirit. The dimethylethylbenzene (b. p. 189°) is probably identical with Fittig's laurene; it yields paraxylic acid on oxidation, and must therefore have the constitution [Me : Me : Et = 1 : 2 : 4]. It yields two isomeric sulphonic acids. From the chief product there may be obtained a barium salt crystallising with $4H_2O$, and a magnesium salt containing about 25 per cent. water, magnesium cymenesulphonate containing 16·6 per cent. The tetramethylbenzene is identical with Jannasch's isodurene, and yields a dibromo-derivative melting at 209°, as stated by Jacobsen.

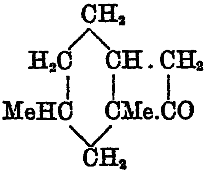
The chief products of the action of iodine on camphor are carvacrol, and the saturated hydrocarbon, $C_{10}H_{20}$. Dimethylethylbenzene and tetramethylbenzene are also formed, but no cymene or metacymene.

Ordinary cymene appears to be the only benzene hydrocarbon which is formed by the action of phosphoric anhydride on camphor, and is also the chief product of the action of phosphorous pentasulphide, but in the latter case a considerable amount of metaisopropylmethylbenzene, and a small quantity of tetramethylbenzene are also obtained together with traces of higher and lower homologues, and a small percentage of the hydrocarbon $C_{10}H_{20}$. The hydrocarbon which carbonises when its sulphuric acid solution is heated (see above) is also formed by the action of phosphorus compounds and of iodine on camphor.

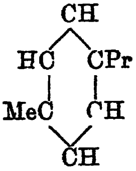
---

* Subsequent investigation has shown that no cymene is present.—H. E. A.

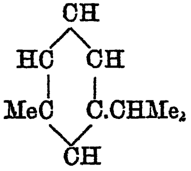
The formation of these different hydrocarbons from camphor cannot well be represented by Kekulé's formula, but can be to some extent accounted for by the assumption of the following formula, which is a slight modification of that previously suggested by Armstrong (*Ber.*, **11**, 1698; **12**, 1756).



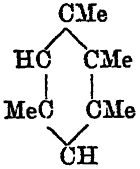
Camphor.



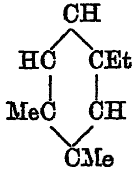
Cymene.



Metacymene.



Tetramethylbenzene.



Dimethylethylbenzene.

Artificial Formation of Thiophene. By V. MEYER and T. SANDMEYER (*Ber.*, **16**, 2176).—If ethylene or acetylene is passed through boiling sulphur large quantities of carbon, hydrogen sulphide, and carbon bisulphide are formed. The last contains a small quantity of an oil which resembles thiophene in all its properties, giving the indophenine reaction with isatin and sulphuric acid, and dye-stuffs with benzoyl cyanide and sulphuric acid, and with phenylglyoxylic and metazophenylglyoxylic acids. V. H. V.

The Thiophene Group. By V. MEYER and H. KREIS (*Ber.*, **16**, 2172—2176).—One of the authors has recently isolated and described thiophene, C_4H_4S (Abstr., 1883, p. 1091), a substance obtained from coal-tar benzene; in the present communication some of its derivatives are described.

Tetrabromothiophene, C_4Br_4S, is formed by the action of bromine in excess on the residue left in the course of the fractional distillation of dibromothiophene. This substance crystallises in white glistening needles melting at 112°, and boiling at 26°.

Thiophenesulphonic acid, $C_4H_3S.SO_3H$, is obtained as a deliquescent crystalline mass, of strongly acid reaction, and yielding thiophene on dry distillation. The corresponding *acid chloride*, $C_4H_3S.SO_2Cl$, is a heavy golden oil, converted by trituration with ammonium carbonate into *thiophenesulpamide*, $C_4H_3S.SO_2NH_2$, which forms delicate white crystals melting at 141°.

Thiophenenitril, $C_4H_3S.CN$, obtained by the distillation of potassium cyanide and thiophenesulphonates, is an oil boiling at 190°, and smelling like bitter almonds; it is readily transformed into the *carboxylic acid*, $C_4H_3S.COOH$, on boiling with alkalis. Thiophenic acid resembles benzoic acid in appearance, smell, and manner of sublimation; it is very volatile in vapour of steam, melts at 118°, and boils at 258°. Its calcium salt forms spear-shaped crystals, its silver salt a precipitate, sparingly soluble when dried.

The authors briefly note the presence of a sulphur compound boiling at 110° in the purest toluene of commerce; they are now engaged in investigating it, and the dye-stuffs derived from it, as also those from thiophene. V. H. V.

Separation of Aniline, Paratoluidine, and Orthotoluidine. By LEWY (*Dingl. polyt. J.*, **248**, 260).—By decomposing the hydrochlorides of the bases with sodium phosphate, Lewy obtains the sparingly soluble phosphates of aniline and paratoluidine besides free orthotoluidine and readily soluble basic orthotoluidine phosphate. By warming the mixture after the decomposition is completed, it is possible to dissolve the first-named salts; the resulting supernatant oily layer of orthotoluidine is then decanted, and the aniline and paratoluidine salts are allowed to crystallise out. The mother-liquor contains the basic orthotoluidine phosphate. By liberating the bases with sodium hydroxide, the sodium phosphate originally used may be recovered. D. B.

Meta-isocymidine. By W. KELBE and C. WARTH (*Annalen*, **221**, 157—178).—*Nitrometa-isocymene*, $C_{10}H_{13}NO_2$, prepared by the action of strong nitric acid on meta-isocymene (Abstr., 1880, 878) is decomposed by boiling, but may be distilled in a current of steam. By the prolonged action of dilute nitric acid (1 of acid to 4 of water), it is converted into *nitrotoluic acid*, $C_6H_3Me(NO_2).COOH(\alpha)$, which is not identical with either of the nitrotoluic acids described by Jacobsen (*Ber.*, **14**, 2347), and must consequently have the formula $C_6H_2Me(NO_2)H.COOH(\gamma)$ or $C_6HMe(NO_2)H_3.COOH(\delta)$. This acid is deposited from an alcoholic solution in glistening needles (m. p. 214°). The *barium* salt crystallises in silky needles, freely soluble in alcohol and in water.

Meta-isocymidine, $C_{10}H_{13}NH_2$, obtained by reducing nitro-isocymene with tin and hydrochloric acid, is purified by conversion into the benzoic-derivative, $NHBz.C_{10}H_{13}$. This compound crystallises in needles melting at 165°, soluble in alcohol. It is decomposed by alcoholic potash at 180°, yielding meta-isocymidine, a strongly refractive liquid boiling at 232°, freely soluble in alcohol, ether, benzene, and light petroleum. The platinochloride of meta-isocymidine is unstable. The *sulphate*, $(C_{10}H_{13}.NH_2)_2H_2SO_4$ forms thin plates, sparingly soluble in water and alcohol. The aqueous solution is decomposed by boiling. The *oxalate*, $C_{10}H_{13}.NH_2.H_2C_2O_4$, is sparingly soluble in water and alcohol.

Acetic chloride acts readily on dry cymidine, forming *acetometa-isocymidide*, $NH\overline{Ac}.C_{10}H_{13}$, which crystallises in plates melting at 115°. By the action of strong nitric acid on benzoic isocymidide, the nitro-compound $NH\overline{Bz}.C_{10}H_{12}.NO_2$ is produced. It is deposited from an alcoholic solution in yellow needles melting at 177°, which are sparingly soluble in ether. On oxidation with dilute nitric acid, benzoic isocymidide yields amidometatoluic acid, which melts below 100°.

Phthalic metaisocymidide, $C_6H_4(CO)_2N.C_{10}H_{13}$, is deposited from a hot alcoholic solution in needles, which melt at 145°. The nitro-product forms yellow needles melting at 167°, soluble in alcohol and ether.

Metaisocyminylcarbylamine, $C_{10}H_{13}NC$, prepared by the action of chloroform and alcoholic potash on cymidine, is a colourless liquid having a powerful odour. It is freely miscible with alcohol, ether, benzene, and light petroleum. It cannot be distilled without decomposition. *Metaisocyminylcarbamide*, $C_{10}H_{13}.NH.CONH_2$, is obtained by boiling an excess of potassium isocyanate with a feebly acid solution of cymidine sulphate. It forms lustrous needles melting at 176°, soluble in alcohol. By the action of carbonyl chloride on cymidine dissolved in absolute ether, dimetaisocimynylcarbamide, $(C_{10}H_{13}NH)_2CO$, is produced in colourless needles, freely soluble in alcohol, less soluble in ether.

Metaisocyminylurethane, $C_{10}H_{13}$ NH.COOEt, is a colourless crystalline compound melting at 229°, soluble in alcohol and ether. *Dicyminylthiocarbamide*, $(C_{10}H_{13}.NH)_2CS$, prepared by the action of carbon bisulphide on cymidine, crystallises in needles melting at 160°, soluble in alcohol and ether.

Neither *metaisocyminylethylthiocarbamide*, $C_{10}H_{13}.CSNH.NHEt$, nor metaisocyminylethylguanidine, $C_{10}H_{13}.C(NH)NH.NHEt$, could be obtained in a crystalline condition.

Nitrophthalylcymidide is decomposed by strong hydrochloric acid at 180°, yielding *nitroisocymidine*, $NO_2.C_{10}H_{12}.NH_2$, an oily liquid miscible with alcohol and ether.

Metaisocymidinesulphonic acid, $C_{10}H_{12}(NH_2).SO_3H$, forms thin yellow-coloured needles, very soluble in water.

The *barium salt*, $(NH_2.C_{10}H_{12}.SO_3)_2Ba$, also crystallises in needles, which are very soluble in water. W. C. W.

Action of Dichloracetic Acid on Aromatic Amines (II). By P. J. Meyer (*Ber.*, **16**, 2261—2269).—The author previously showed (*Ber.*, **16**, 926) that the reaction of dichloracetic acid with orthotoluidine is different from that between dichloracetic acid and paratoluidine, the latter yielding a substituted imesatin. To prepare *paratolylparamethylimesatin (paramethylisatin-paratolylimide)*, $C_8H_4MeNO.NC_7H_7$, dichloracetic acid (1 mol.) is heated with paratoluidine (4 mols.) at 100° until a dark-red crystalline mass is formed, which is then treated with hot water to remove the toluidine hydrochloride; or an aqueous or alcoholic solution of dichloracetic acid may be digested with paratoluidine, or finally dichloracetamide (1 mol.) heated with paratoluidine (3 mols.). It crystallises in splendid lustrous gold-coloured needles and scales. The reaction may be compared with the formation of quinoline from aniline and glycerol (*Ber.*, **13**, 2086): $2C_7H_7.NH_2 + C_2H_2Cl_2O_2 = C_{16}H_{14}N_2O + 2HCl + H_2O + H_2$. Paramethylisatin-paratolylimide melts at 259°, is insoluble in water, dissolves sparingly in cold, more readily in hot alcohol, and in ether. With concentrated soda solution, it yields a salt crystallising in red prisms, and which is decomposed by water. Cold concentrated hydrochloric acid converts it into paramethylisatin and toluidine; hot dilute acid or long-continued heating with soda solution decomposes it in the same way; it can be reproduced by heating these products with absolute alcohol. When paramethylisatin-paratolylimide is heated for 2 to 3 hours at 100° with alcoholic ammonia, *paramethylimesatin* (*paramethylisatinimide*), $C_9H_7NO.NH$, is formed, and can be freed from toluidine and colouring-matter by repeated boiling with alcohol. In its properties, it differs from Laurent's imesatin (*J. pr. Chem.* **25**, 457); it has a pale yellow colour, is insoluble in cold water and cold alcohol, and very sparingly in boiling alcohol, from which it crystallises in extremely slender silky needles; it is not converted into paramethylisatin by acids or bases, and bears a strong resemblance to Sommaruga's diimidoisatin (*Annalen*, **190**, 371; **194**, 85; *Ber.*, **12**, 979). *Paramethylisatin*, $C_8H_4MeNO_2$, obtained as above, is isomeric with the substance obtained by Baeyer and Œconomides (*Ber.*, **15**, 2093) from isatin silver and methyl iodide; it is odourless, separates from alcohol or hydrochloric acid in deep red transparent crystals resembling chromic anhydride, and from water in lustrous red scales, melting at 187°; it is sparingly soluble in cold, more readily in hot water, readily in hot hydrochloric acid and in alcohol; with alkalis, it forms a deep violet-coloured solution, yielding methylisatates when heated or on long standing. It yields the indophenin-, and with hydroxylamine the ketone-reaction, and forms condensation and substitution-derivatives similar to those of isatin. *Phenylparamethylimesatin* (*paramethylisatinphenylimide*), $C_8H_4MeNO : NPh$, is obtained on adding the equivalent quantity of aniline to a concentrated solution of paramethylisatin in absolute alcohol. It crystallises in thick, yellowish-red, transparent plates or prisms, melts at 239—240°, is sparingly soluble in water or cold alcohol, more readily in hot alcohol, and in its properties resembles paratolylimide. *Metabromoparatolylparamethylimesatin* (*paramethylisatinmetabromoparatolylimide*), $C_8H_4MeNO : NC_7H_6Br$, is prepared in the same way as the last compound; it crystallises from alcohol in transparent brick-red needles and prisms, melting at 210°. *Orthotolylparamethylimesatin* (*paramethylisatinorthotolylimide*), $C_8H_4MeNO.NC_7H_7$, isomeric with the above paratolylimide, crystallises in red transparent prisms, melting at 191°. *Paramethylnitroso-oxindole*, $C_9H_8(NO)NO$, is prepared by the action of hydroxylamine hydrochloride on paramethylisatin (*Ber.*, **16**, 518). It forms long transparent yellow prisms, is sparingly soluble in water, more readily in alcohol, dissolves in potash without decomposition, and melts at 225—226°. On adding coal-tar benzene to a solution of paramethylisatin in concentrated sulphuric acid, a deep blue coloration is produced, and on agitating with water *paramethylindophenin* separates. The numbers obtained on analysis agree only approximately with the formula $C_{13}H_9NOS$. It forms an indigo-blue powder, sparingly soluble in water, alcohol, and acetic acid, more readily in concentrated sulphuric acid and hot phenol, from which it is reprecipitated by water or alcohol. When treated with zinc and glacial acetic acid, it yields a bright green substance, which becomes blue again on exposure to the air. A. K. M.

Difference in Chemical Behaviour of Aromatic Diamines. By E. LELLMANN (*Annalen*, **221**, 1—34).—The isomeric aromatic diamines, in some cases, present characteristic differences in chemical behaviour. Thus for example, Ladenburg has observed that the hydrochlorides of the orthodiamines react with benzaldehyde according to the equation—

$$C_xH_y(NH_2)_2,2HCl + 2PhCHO = C_xH_y(NCHPh)_2,HCl + 2H_2O + HCl,$$

whereas the meta- and para-derivatives are unaltered. Similarly, Hobrecker and Hübner have shown that ortho-diamines are differentiated from the meta- and para-compounds in yielding the so-called anhydro-bases,  $C_xH_y<{NH \atop -N-}>C_tH_w$. Again the reaction of nitrous acid on the ortho- resembles that on the para-, but differs from that which it exerts on the meta-compounds.

The author has studied the reaction of potassium thiocyanate and cyanate, and of the thiocarbimides, on the aromatic diamines, with a view of tracing analogous differences in chemical behaviour.

At the outset some remarks are made on the method of preparation of ortho- and para-phenylene diamines. It is found that to obtain the former it is best to nitrate benzanilide and not acetanilide as recommended in the text-books; on the other hand, acetanilide is more suitable for the preparation of the latter.

Action of Thiocyanates on the Diamines.—The diamine thiocyanates are easily obtained from the hydrochlorides of the diamines and the thiocyanates; but the compounds produced differ in their mode of decomposition, the meta- and para-thiocyanate yielding the corresponding phenylene*di*thiocarbamides, $C_6H_4(NHCSNH_2)_2$, whilst the ortho-compounds give the corresponding thiocarbamide, $C_6H_4<{NH \atop NH}>CS$, together with thiocarbamide, $CS(NH_2)_2$.

Orthophenylenethiocarbamide, $C_6H_4<{NH \atop NH}>CS$, obtained by the evaporation of an aqueous solution of 1 mol. orthophenylenediamine hydrochloride and 2 mols. potassium thiocyanate, crystallises in large leaflets, which melt at about 290° with considerable carbonisation.

Metaparatolylenethiocarbamide, $C_6H_3Me<{NH \atop NH}>CS$, from metaparatolylenediamine and potassium thiocyanate, crystallises in silvery leaflets melting at 284°, and soluble in soda and ammonia, but reprecipitated on acidifying the solution.

Metaphenylenedithiocarbamide, $C_6H_4(NHCSNH_2)_2$, crystallises in microscopic leaflets melting at 215°; the corresponding para-compound in colourless needles melting at 218°, soluble in alkalis, sparingly soluble in alcohol.

The action of potassium cyanate on the diamines is the same for all three isomerides; a phenylenedicarbamide is formed.

Orthophenylenedithiocarbamide, $C_6H_4(NH.CSNH_2)_2$, crystallises in hard needles melting at 290°, easily soluble in alcohol, sparingly in water, chloroform, or ether. The *para*-compound crystallises in silvery leaflets and decomposes completely at a high temperature without melting; the *meta*-compound crystallises in small colourless needles melting at 280°, soluble in concentrated hydrochloric acid, but reprecipitated on the addition of alkalis.

By the *action of thiocarbamides on the diamines* complex thiocarbamides of the generic formula $C_xH_y(NH.CSNH.C_tH_u)_2$, are produced, which in the case of the ortho- and para-compounds are decomposed, when melted, according to the equation $C_xH_y(NH.CSNH.C_vH_w)_2 =$ $C_xH_y<\substack{NH\\NH}>CS$ $+ CS(NH.C_vH_v)_2$, while the meta-compound is unchanged.

Diphenylmetaparatolylenedithiocarbamide, $C_6H_3Me(NH.CSNHPh)_2$, from tolylenediamine and phenylthiocarbamide, is a crystalline substance which when heated to 140—150°, is decomposed into diphenylthiocarbamide subliming in the upper part of the vessel, and metaparatolylenethiocarbamide.

Diethylmetaparatolylenedithiocarbamide, $C_6H_3Me(NH.CSNHEt)_2$, from ethylthiocarbamide and tolylenediamine forms microscopic crystals which melt between 149° and 153°, and on more protracted heating are decomposed into metaparatolylene- and ethyl-thiocarbamides. The former is a crystalline substance melting at 284°, sparingly soluble in water, easily soluble in alcohol and hot soda. *Diallylmetaparatolylenedithiocarbamide*, $C_6H_3Me(NH.CSNH.C_3H_5)_2$, from tolylenediamine and allylthiocarbamide, crystallises in delicate silky needles, melting at 150°, sparingly soluble in water, soluble in alcohol and chloroform.

The corresponding *diallylmetaphenylenedithiocarbamide*,

$$C_6H_4(NH.CSNH.C_3H_5)_2,$$

forms an amorphous white powder, which melts at 105°, and is not decomposed when heated. *Diphenylparaphenylenedithiocarbamide*, $C_6H_4(NH.CSNHPh)_2$, is a crystalline substance, soluble in hot soda solution. When heated to 260° it is decomposed partly into paraphenylenethiocarbamide,  $C_6H_2<\substack{NH\\NH}>CS$, which crystallises in small leaflets, melting at 270°. *Diallylparaphenylylenedithiocarbamide*,

$$C_6H_4(NH.CSNH.C_3H_5),$$

is a crystalline substance, insoluble in water, sparingly soluble in alcohol. It melts at 200°, with evolution of a gas and emission of a smell resembling diallylthiocarbamide: its decomposition may probably be expressed by the equation, $C_6H_4(NH.CSNH.C_3H_5)_2 =$

$$C_6H_4<\substack{NH\\NH}>CS + CS(NH\,C_3H_5)_2.$$

The author also made some experiments on the reduction of the orthonitranilides and toluides of phenylsulphonic acid. When phenylsulphonyl chloride is added to orthonitraniline dissolved in benzene, crystals of orthonitraniline hydrochloride separate out. On filtering these and evaporating the filtrate, *phenylsulphorthonitranilide*,

$$PhSO_2.NH.C_6H_4.NO_2,$$

is obtained. This substance is crystalline, moderately soluble in petroleum, easily soluble in alcohol; it is reduced by tin and hydrochloric acid to the corresponding *amidoanilide*, $PhSO_2.NH.C_6H_4.NH_2$. This compound crystallises in long colourless needles melting at 168°, sparingly soluble in water, readily soluble in alcohol and chloroform; its hydrochloride forms large thick crystals. *Phenylsulphometanitroparatoluide*, $PhSO_2.NH.C_6H_3Me.NO_2$, obtained together with the corresponding dinitro-derivative by the action of fuming nitric acid on phenylsulphoparatoluide, crystallises in cubes, which melt at 99°. On reduction with tin and hydrochloric acid, it is converted into the corresponding amido-derivative, which crystallises in long, colourless needles, melting at 146·5°, sparingly soluble in water, soluble in alcohol.

In a summary, the author remarks that the above observations do not form sufficient material for general conclusions with regard to the reactions of the diamines. To complete the study of these compounds, it is necessary to compare the decomposition of the isomeric phenylenediamines with the diamines of the paraffin series. As a step in this direction, Hofmann has observed that ethylenediaminethiocyanate when melted yields ethylenethiocarbamide, a decomposition perfectly analogous to the decomposition of the corresponding orthodiphenylene compound. V. H. V.

Organic Hydroxylamine Derivatives. By C. SCHRAMM (*Ber.*, **16**, 2183—2188).—When a solution of bromacetophenone in aqueous alcohol is heated with an excess of hydroxylamine hydrochloride for 12 hours on a water-bath, the alcohol evaporated, and the product extracted with ether, a yellowish oil is obtained which solidifies on standing. It can be purified by precipitating its solution in soda with dilute sulphuric acid and extracting with ether; it then melts at 162—163°. Its formula is $CPh(N.OH).CH_2.NH.OH$. It dissolves readily in alcohol or ether, sparingly in hot water and benzene, and is insoluble in light petroleum and in cold water. On heating it with concentrated acids, hydroxylamine is given off. A *silver derivative*, $C_8H_9AgN_2O_2$, is obtained by precipitating a solution in concentrated ammonia with a concentrated solution of silver nitrate. *Dibenzylhydroxylamine*, $(CH_2Ph)_2N.OH$, is obtained on heating a solution of benzyl chloride (3 grams), hydroxylamine hydrochloride (3 grams), and crystallised sodium carbonate (6 grams) in aqueous alcohol for half an hour on a water-bath. On cooling, it separates in long white needles which melt at 123°, and are decomposed by distillation. It is soluble in alcohol, ether, and benzene, less soluble in light petroleum, carbon bisulphide, and glacial acetic acid, sparingly in hot water, and insoluble in ammonia, soda solution, and hydrochloric acid. A *hydrochloride*,

$(C_7H_7)_2N.OH,HCl$, can be obtained by the action of dry hydrochloric acid gas on its solution in absolute ether.

Methylpropylglyoxime, $CMe(NOH).C(NOH)Pr$, obtained by the action of hydroxylamine hydrochloride on a solution of isonitrosopropylacetone in aqueous alcohol, forms spiral-like groups of needles melting at 168°. *Phenylglyoxime*, $CPh(N.OH).CH\!:\!N.OH$ (m. p. 152°) is prepared by the action of alkaline hydroxylamine solution on dibromacetophenone, at a gentle heat, acidifying and extracting with ether. It can be purified by precipitating the ethereal solution with light petroleum and washing the precipitate with benzene, or by dissolving it in alkali, acidifying and extracting with ether. The *silver derivative*, $C_8H_7AgN_2O_2$, forms a yellowish-white curdy precipitate. On dissolving sodium in absolute alcohol and adding an ethereal solution of methylethylglyoxime, the *sodium derivative* of the latter, $C_5H_9NaN_2O_2$, is thrown down as a white curdy precipitate. The *diacetyl-derivative of methylglyoxime*, $CMe(NO\overline{Ac}).CH(NO\overline{Ac})$ is formed when a mixture of *methylglyoxime* with a slight excess of acetic anhydride is gently boiled until the mass begins to turn brown. The product is poured into shallow clock-glasses and exposed in a vacuum when needles are obtained melting at 51°. It crystallises from light petroleum in white transparent prisms; when heated, these explode with evolution of hydrocyanic acid.

The *diacetyl-derivative of methylethylglyoxime*,

$$CMe(NO\overline{Ac}).CEt(NO\overline{Ac}),$$

crystallises in flat prisms readily soluble in alcohol and in ether, sparingly in hot water. The *diacetyl-derivative of methylbenzylglyoxime* forms small white crystals melting at 80°. A. K. M.

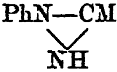
Hydrazines of Pyroracemic Acid. By E. FISCHER and F. JOURDAN (*Ber.*, **16**, 2241—2245).—Some of the compounds of the hydrazines with ketones have been described by Reisenegger (Abstr., 1883, 798). The reaction is a general one, and holds for the primary and secondary hydrazines of the fatty and aromatic series, and for all simple and most of the more complicated ketones and diketones, the ketonic acids combining with extreme readiness with the hydrazines either in neutral or in acid solutions. Pyroracemic acid and phenylhydrazine combine with great violence, so that it is advisable to dilute each substance with five volumes of ether, to cool well and to mix gradually.

The *phenylhydrazinepyroracemic acid*, $C_9H_{10}N_2O_2$, separates as a yellowish crystalline powder which after being washed with ether and crystallised from boiling alcohol, forms hard lustrous needles, melting at 169° with evolution of gas; it is readily soluble in hot alcohol, very sparingly in ether, chloroform, carbon bisulphide, and light petroleum, readily in alkalis and alkaline carbonates. The sodium salt is sparingly soluble in an excess of concentrated soda solution, with which it can be boiled without decomposition. The formation of phenylhydrazinepyroracemic acid takes place also in aqueous, acetic acid, and dilute hydrochloric acid solutions, and with such readiness that the reaction can be employed for the detection of pyroracemic acid (also of phenylglyoxylic acid and levulic acid) in very dilute solutions. Heated above its melting point, it yields carbonic anhydride and ethylidenephenylhydrazine:—$PhN_2H\colon CMe.COOH = CO_2 + PhN_2H\colon CHMe$. It can be boiled with dilute hydrochloric and sulphuric acids without decomposition, and on boiling with alcoholic sulphuric acid, the *ethyl derivative*, $PhN_2H\colon CMe.COOEt$, is obtained melting at 114—115°, and soluble in alcohol, ether, and chloroform. By the action of sodium-amalgam on a cold dilute solution of phenylhydrazinepyroracemic acid, *phenylhydrazinepropionic acid*,

$$PhN_2H_2.CMeH.COOH,$$

is produced, crystallising from boiling alcohol in white slender needles melting at 152—153° with decomposition. It is very sparingly soluble in cold alcohol, ether, and water, much more readily in hot alcohol, also readily soluble in alkalis and in concentrated hydrochloric acid. Mercuric oxide and copper salts are readily reduced by it in alkaline solution, ammoniacal copper solution reconverting it into phenylhydrazinepyroracemic acid.

In order to decide which of the formulæ $PhNH.N\colon CMe.COOH$ or PhN—CMe.COOH is correct, the action of pyroracemic acid on methylphenylhydrazine was studied. This yields an acid of the formula $PhNMe.N\colon CMe.COOH$, the behaviour of which to mineral acids is, however, quite different from that of the acid obtained from phenylhydrazine.



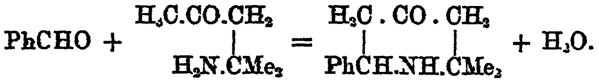
$$\underset{NH}{PhN{-}CMe}.COOH$$

Methylphenylhydrazinepyroracemic acid softens at 70°, and melts at 78°; it crystallises in yellowish needles readily soluble in alcohol and in ether, sparingly in light petroleum and in water; it is decomposed by long-continued boiling with water, but is stable in alkaline solutions. On warming it with a 10 per cent. solution of hydrochloric acid it becomes red, and then dissolves, the colour disappearing as the temperature is raised, whilst colourless slender needles separate, increasing in quantity on cooling and as the liquid is diluted with water. This new substance, apparently of the formula $C_{10}H_9NO_2$, seems to be formed by the abstraction of ammonia from the methylphenylhydrazinepyroracemic acid, a considerable quantity of ammonia being found in the acid liquid. It is readily soluble in hot alcohol, from which it crystallises in colourless needles melting at 206°. It can be distilled unchanged, dissolves readily in soda, ammonia, and sodium carbonate, and can be reprecipitated by acids. A. K. M.

Diacetonamine. By E. Fischer (*Ber.*, **16**, 2236—2238).—In preparing diacetonamine from acetone containing aldehyde, Heintz (*Annalen*, **189**, 214) obtained a base $C_8H_{15}NO$, (vinyldiacetonamine); this he afterwards obtained by the action of acetaldehyde on diacetonamine oxalate, and he thought it probable that it might be a lower homologue of triacetonamine; this is now confirmed by the author. It is converted into an alkamine by the action of sodium-amalgam, and on heating this with concentrated sulphuric acid, a readily volatile base is obtained, the properties of which show it to be a homologue of triacetonine (Abstr., 1883, 1153).

Other aldehydes, both of the fatty and aromatic series, yield bases with diacetonamine, and in this way numerous homologues of hydroxypiperidine and piperidine can be obtained. *Benzdiacetonamine*, $C_{13}H_{17}NO$, is prepared by boiling a solution of acid diacetonamine oxalate (1 part) in alcohol (3 parts) with bitter almond oil (1 part) for about ten hours; the product is filtered hot, and the oxalate formed is washed with hot alcohol. By the action of potash the free base is obtained as an oil, which solidifies on standing; it crystallises from hot light petroleum in splendid colourless plates, melts at 62—63°, dissolves very readily in alcohol and in ether, sparingly in water; the *oxalate* $(C_{13}H_{17}NO)_2C_2H_2O_4$, forms white scales, very sparingly soluble in alcohol and in water, readily in hydrochloric and oxalic acids. On adding gold chloride to the hydrochloric acid solution, the aurochloride is precipitated as a yellow oil, which solidifies to magnificent gold-coloured needles. By the action of sodium-amalgam on an acidulated solution of benzdiacetonamine, the latter is partially converted into *benzdiacetonalkamine*, $C_{13}H_{19}NO$. The hydrochloride, $C_{13}H_{19}NO,HCl$, forms small hard crystals, readily soluble in water, sparingly in alcohol. On decomposing it with an alkali, the base is precipitated as a thick colourless oil. Sulphuric acid acts on this base or the hydrochloride in the same way as on triacetonalkamine, with formation of a new base, which is volatile in steam, has an odour resembling that of piperidine, and yields a sparingly soluble hydrobromide.

From these reactions, it is assumed that benzdiacetonamine has a constitution similar to that of triacetonamine, its formation being thus expressed:—



$$PhCHO + \begin{array}{c} H_3C.CO.CH_2 \\ | \\ H_2N.CMe_3 \end{array} = \begin{array}{c} H_3C\,.\,CO\,.\,CH_2 \\ |\qquad\quad | \\ PhCH.NH.CMe_2 \end{array} + H_3O.$$

The author intends to try the reaction with other aldehydes, with ethyl acetoacetate, and with pyroracemic and other ketonic acids.

A. K. M.

Action of Phosphorus Trisulphide on Phenols. By A. GEUTHER (*Annalen*, **221**, 55—59).—Kekulé and Szuch (*Jahresber*, 1868, 628) have isolated from the products of the reaction of phosphorus pentasulphide on phenol, besides phenyl mercaptan and sulphide, a small quantity of benzene. As the formation of this hydrocarbon can only arise from the reduction of the phenol, it is probable that the samples of pentasulphide contained some trisulphide as an impurity. In order to confirm this suggestion, the author has studied the action of phosphorus trisulphide on phenol. On submitting the crude product of the reaction to fractional distillation, it was separated into two portions, the one boiling below 100°, the other above 280°. The former was principally benzene, together with traces of phenyl mercaptan and sulphide, the latter triphenylphosphate. The reactions of phosphorus trisulphide and pentasulphide on phenol may probably be expressed by the following equations:—(1) $8PhOH + P_2S_3 = 2Ph_3PO_4 + 3H_2S + 2C_6H_6$, and (2) $8PhOH + P_2S_5 = 2Ph_3PO_4 + 3H_2S + 2PhSH$.

As an analogous case, it is shown that cresol is similarly reduced to toluene by phosphorus trisulphide; the other products of the reaction, which were not minutely examined by the author, are probably tolyl mercaptan and tolylphosphate. V. H. V.

A Fourth Monobromophenol. By A. FITTICA (*J. pr. Chem.* [2], **28**, 176—188).—10 grams of phenol are dissolved in 10 grams absolute alcohol, 3 grams of amorphous phosphorus added, and 17 grams of bromine allowed to flow in through a capillary tube; the vessel is surrounded with cold water; the temperature of the mixture must not rise above 20°. The product is shaken with water, with dilute sodium carbonate, again with water, dried and distilled. The fraction 235—240° repeatedly redistilled, finally yields the new monobromophenol as a liquid boiling at 236—238°, and not solidifying at 10—12°. The pure substance cannot be distilled without decomposition. No further description of its properties is given. The boiling and melting points of ortho-, meta-, and para-bromophenol are—

	Ortho.	Meta.	Para.
Melting point	(Liquid)	32—33°	64°
Boiling point......	194—195°	236—236·5	238

By nitration in glacial acetic acid solution, a crystalline compound melting at 60—65°, and of the formula

$$C_6H_3Br(NO_2).OH,C_6H_2Br(NO_2)_2OH,$$

is obtained. This on further nitration yields a bromodinitrophenol, $C_6H_2Br(NO_2)_2.OH$, crystallising in yellow prisms, and melting at 108—110°. The same product is obtained on boiling with baryta-water, together with a substance melting at 68—70°, and crystallising in stellate groups of yellow needles, to which the author assigns the formula $2C_6H_3Br(NO_2).OH,C_6H_2Br(NO_2)_2.OH$.

A. J. G.

Action of Phenol on Ketonic Acids. By C. BÖTTINGER (*Ber.*, **16**, 2071—2075).—By the action of phenol on pyroracemic acid in presence of sulphuric acid, a condensation-product of the composition $C_{15}H_{14}O_4,H_2O$ is obtained. This substance, which the author proposes to name *diphenylpropionic acid*, forms a horny mass (m. p. 268°), soluble in acetone, insoluble in water, benzene, and chloroform. It is a monobasic acid, and a solution of its ammonium salt gives precipitates with salts of barium, calcium, lead, and silver.

Dibromophenopropionic acid is a pale golden amorphous and electric powder, insoluble in water and alcohol; on heating this with concentrated hydrochloric acid at 230° in a sealed tube, it gives off bromine and carbonic anhydride, and is converted into a black substance.

Acetyldiphenopropionic acid is an amorphous yellowish substance, soluble in acetone, insoluble in chloroform; its barium salt forms an insoluble amorphous precipitate.

Acetyldibromophenopropionic acid is coloured at first violet, and then dissolved by ammonia; it forms sparingly soluble barium salt.

V. H. V.

Derivatives of Thymol. By H. Kobek (*Ber.*, 16, 2096—2105). —*Parathymotic aldehyde*, $C_6H_2MePr^{\alpha}(OH).CHO$ (Me : OH : Pr : CHO = 1 : 3 : 4 : 6) obtained by heating thymol with chloroform and soda, crystallises in long white glistening needles melting at 133°, sparingly soluble in water, soluble in alcohol and ether. It dissolves in ammonia and sodium carbonate to form a golden-coloured solution. The author was unable to obtain a crystalline compound of the substance with sodium hydrogen sulphite; but its other general properties characterise it as an aldehyde. Its *anilide* derivative,

$$C_6H_2MePr^{\alpha}(OH).CHNPh,$$

prepared by heating parathymotic aldehyde and aniline in molecular proportions, crystallises in golden needles melting at 142°, insoluble in water, soluble in alcohol and ether; it is decomposed by boiling with water or dilute acids into the aldehyde and aniline.

Parathymotic alcohol, $C_6H_2MePr^{\alpha}(OH).CH_2.OH$, obtained by the reduction of the aldehyde with sodium-amalgam and water, forms a greyish amorphous powder, which melts gradually at 120—130°; it is insoluble in water, soluble in alcohol and ether.

Methylparathymotic aldehyde, $C_6H_2MePr^{\alpha}(OMe).CHO$, prepared from parathymotic aldehyde, methyl iodide, and alcohol, is a golden oil boiling at 270°, insoluble in water, soluble in alcohol and ether; it dissolves with difficulty in a solution of sodium hydrogen sulphite. Its *anilide* crystallises in clear transparent tablets (m. p. 80°), insoluble in water, readily soluble in other menstrua. On oxidation with potassium permanganate, it is converted into the corresponding *carboxylic acid*, $C_6H_2MePr(OMe).COOH$, which crystallises in long white silky needles melting at 137°; a solution of this acid gives no coloration with ferric chloride, and precipitates more or less sparingly soluble, with salts of calcium, silver, copper, zinc, and lead.

In order to determine the constitution of the compounds, and to compare the parathymotic acid corresponding with the above-mentioned aldehyde with the thymotic acid described by Kolbe and Lautemann (*Annalen*, 115, 205), the author prepared both acids, and studied their reactions. The former can be best obtained by heating thymol with carbon tetrachloride and soda; it crystallises in leaflets melting at 157°; the latter by the joint action of sodium and carbonic anhydride on thymol melts at 123° and gives a deep blue coloration with ferric chloride. This reaction, characteristic of those aromatic acids in which the hydroxyl is in the ortho-position to the carboxyl group, taken in connection with the method of preparation, shows that the thymotic acid of Kolbe and Lautemann is the ortho-acid, possessing the constitution

$$C_6H_2MePr^{\alpha}(OH).COOH\ [Me : COOH : OH : Pr^{\alpha} = 1 : 2 : 3 : 4].$$

On the other hand, the method of preparation of the author's acid, together with the absence of any reaction with ferric chloride, point probably to its constitution as expressible by the formula

$$C_6H_2MePr(OH).COOH\ [Me : OH : Pr : COOH = 1 : 3 : 4 : 6].$$

Thymodialdehyde, $C_6H_2MePr(OH)(CHO)_2$, obtained in the course of the preparation of parathymotic aldehyde, forms golden compact needles melting at 80°; it gives a cherry-red coloration with ferric chloride; on boiling with sodium acetate and acetic anhydride it is converted into *thymoparacrylic acid*, $C_6H_2MePr(OH).CH:CH.COOH$, which forms microscopic crystals melting at 280°. The *methyl* derivative of the latter crystallises in golden needles melting at 141°, sparingly soluble in water, soluble in alcohol and ether. Both acids give sparingly soluble calcium, barium, and copper salts; their silver salts, however, differ, that of the former crystallises from water, that of the latter dissolves in hot water, forming a resinous mass.

V. H. V.

A New Glycerol. By A. Colson (*Compt. rend.*, **97**, 177—179).—The aromatic tribromhydrin, $C_6H_3(CH_2Br)_3$, previously described (Abstr., 1883, 734), can be obtained in crystals by prolonged refrigeration, and the crystals, after recrystallisation from alcohol, melt at 94·5°. The tribromhydrin is decomposed by water, yielding *mesitylene glycerol*, $C_6H_3(CH_2.OH)_3$. To obtain this compound, the crude product of the action of bromine on mesitylene is boiled for several hours with 25—30 parts of water and an excess of lead carbonate, the liquid filtered, and concentrated by evaporation in a vacuum. The crude product is mixed with a small quantity of silver oxide, then treated with hydrogen sulphide in order to remove lead, and the solution filtered and concentrated. The viscous liquid thus obtained is purified by successive treatment with ether, alcohol, and chloroform, and is finally concentrated in a vacuum. Mesitylene glycerol is a viscous liquid with a bitter taste; it is insoluble in ether and in chloroform, but is very soluble in alcohol and in water. When treated with hydrobromic acid, it yields the original tribromhydrin. Hydrochloric acid forms a colourless oily liquid, which is in all probability the trichlorhydrin: the same compound is obtained by the action of chlorine on the vapour of mesitylene; it boils at 170—180° in a vacuum, and at 277—284° with partial decomposition, under atmospheric pressure. It is decomposed by water with formation of the glycerol. Acetic acid also combines with mesitylene glycerol, forming a compound which is only slightly soluble in water.

If the product of the saponification of the crude tribromhydrin is treated with ordinary ether after evaporation of the water, the ether dissolves a substance which separates out in crystals on evaporation. When purified by repeated crystallisation from water, this substance forms nacreous plates which melt at 126°. They are tasteless and inodorous, soluble in 55 parts of boiling water, but only slightly soluble in cold water, still less soluble in ether, but very soluble in alcohol. They have the composition, $C_9H_9(OH)_2Br$; when boiled with water and potassium carbonate, this compound is not decomposed; and when treated with hydrobromic acid it yields a tribromide which, after recrystallisation from alcohol, melts at 81—82°. The compound is therefore not a derivative of mesitylene glycerol, but is a monobromo-glycol, $C_6H_2BrMe(CH_2.OH)_2$ and its dibromohydrin,

$$C_6H_2BrMe(CH_2Br)_2,$$

(m. p. 81—82°), is isomeric with mesitylene glycerol tribromhydrin.

C. H. B.

Quinone Derivatives. By R. Nietski (*Ber.*, **16**, 2092—2096).—The author has shown that by passing nitrous acid into an ethereal solution of quinol, a dinitrohydroxyquinone, $C_6(OH)_2(NO_2)_2O_2$, or nitranilic acid, is formed; the same substance may also be obtained either by the action of fuming nitric acid on dinitroquinol, or by the nitration of diacetylquinol: all these methods of preparation, however, are very unsatisfactory. In the present communication a detailed account is given of an improved process, which consists in acting on diacetylquinol with nitrosulphuric acid in the cold, and precipitating the characteristic sparingly soluble potassium nitranilate from an ice-cold solution of the crude product. The corresponding acid, which is very unstable, may be obtained from this derivative. The potassium-derivative is converted by a strongly acid solution of stannous chloride into nitramidotetrhydroxybenzene, $C_6(OH)_4(NH_2).NO_2$, which crystallises in needles, having a violet iridescence, insoluble in alcohol, ether, and benzene. Potassium nitranilate is further converted by stannous chloride, with an excess of tin, into a substance crystallising in delicate iridescent green leaflets, resembling quinhydrol in appearance. This compound is probably a diimido-derivative of dihydroxyquinone,  $C_6(OH)_2O_2\langle\begin{smallmatrix}NH\\|\\NH\end{smallmatrix}$, and analogous to diimidonaphthol: a view which receives some support from the similarity of phenomena observable in the preparation of these two substances. V. H. V.

Action of Orthonitrobenzaldehyde on Acetaldehyde. By A. Baeyer and V. Drewsen (*Ber.*, **16**, 2205—2208).—In a previous communication (Abstr., 1883, 341) the authors mentioned the formation of a condensation-product by the action of alkalis on a solution of orthonitrobenzaldehyde in acetaldehyde. It is prepared by gradually adding a 2 per cent. solution of sodium hydroxide to a solution of orthonitrobenzaldehyde in freshly prepared aldehyde kept cool with ice, until an alkaline reaction remains for at least five minutes. The acetaldehyde is expelled by a current of air, the crystalline product dried on a porous tile and crystallised from ether. It forms moderately large colourless monoclinic prisms, readily soluble in alcohol and chloroform; it softens at 120° and melts at 125° with evolution of aldehyde vapour. Its formula, $C_9H_9NO_4,C_2H_4O$, corresponds with that of a compound of orthonitrophenyllactic aldehyde with aldehyde. On passing a current of air through its solution at 40—50°, as long as the odour of aldehyde is perceptible, a non-crystallisable product is obtained (probably *orthonitrophenyllactic aldehyde*), combining with acid sulphites and reddening rosaniline sulphite. Like the condensation-product, it yields indigo with aqueous alkalis. *Orthonitro-β-phenyllactic acid*,

$$NO_2.C_6H_4.CH(OH).CH_2.COOH,$$

(m. p. 126°) is obtained on warming a solution of the condensation-product in dilute alcohol with an excess of freshly precipitated silver oxide, until the addition of alkali no longer produces indigo; the product is boiled with hydrochloric acid, filtered, and extracted with ether, and the acid purified by means of the barium salt. It crystallises in short well-formed prisms, readily soluble in water, alcohol, and ether, and is identical with the acid obtained by Einhorn from the addition-product of orthonitrocinnamic acid with hydrobromic acid (see p. 66). *Orthonitrocinnamic aldehyde*, $NO_2.C_6H_4.CH : CH.CHO$, is obtained on boiling the condensation-product with acetic anhydride until indigo ceases to be formed by the addition of soda solution. It forms colourless needles melting at 127°, readily soluble in boiling water, very sparingly in cold water, readily in chloroform, less so in alcohol and ether. It forms a crystalline compound with hydrogen-sodium sulphite, reacts with rosaniline sulphite, reduces ammoniacal silver solution with formation of orthonitrocinnamic acid, and on reduction readily yields quinoline. From the above, it is seen that the condensation of orthonitrobenzaldehyde with aldehyde takes place in the same way as with acetone, the resulting orthonitro-β-phenyllactic aldehyde, $NO_2.C_6H_4.CH(OH).CH_2.COH$, forming, however, an unstable compound with acetaldehyde. A. K. M.

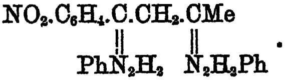
Benzoylacetone. By E. FISCHER and H. KUZEL (*Ber.*, **16**, 2239—2241).—On boiling ethyl benzoylacetoacetate with 4 parts of 25 per cent. sulphuric acid, carbonic anhydride, alcohol, acetic acid, and acetophenone are produced as stated by Bonné (*Annalen*, **187**, 1). The authors find that a small quantity of benzoic acid and about 4 per cent. of *benzoylacetone* are also produced, the formation of the latter corresponding with the production of nitrocinnamylacetone from ethyl nitrocinnamylacetoacetate (Abstr., 1883, 587). To isolate the benzoylacetone, the oil is dissolved in ether, agitated with dilute soda solution, which dissolves the benzoic acid and the benzoylacetone; the solution is then acidified, extracted with ether, and the residue from the evaporation of the latter dissolved in cold dilute soda solution, from which the benzoylacetone is precipitated by carbonic anhydride as a colourless oil, which crystallises on cooling. It may be obtained in larger quantity by boiling ethyl benzoylacetoacetate for some hours with 7—8 parts water. Benzoylacetone,

$$CH_2Bz.CO.CH_3,$$

melts at 58°, distils unchanged, is volatile in steam, and has an agreeable penetrating odour. It dissolves sparingly in cold water, more readily in hot water, very readily in alcohol and in ether. The alkalis dissolve it readily, sodic carbonate less so, whilst it is insoluble in the acid carbonates. The sodium salt of benzoylacetone is precipitated in the form of yellowish scales on adding concentrated alkali to its solution in dilute soda; the silver salt, $C_{10}H_9O_2Ag$, obtained on adding an excess of silver nitrate to an ammoniacal solution of benzoylacetone, forms a white crystalline precipitate, almost insoluble in water. Benzoylacetone gives an intense red coloration with ferric chloride. It is decomposed by boiling alkali with formation of acetophenone.

When warmed with phenylhydrazine, the two combine forming a slightly coloured oily product insoluble in alkali.

Orthonitrobenzoylacetone is obtained in the same way from ethyl orthonitrobenzoylacetoacetate, and likewise combines with phenylhydrazine, forming a compound of the formula—



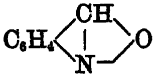
$$\mathrm{NO_2.C_6H_4.}\underset{\mathrm{PhN_2H_2}}{\underset{\|}{\mathrm{C}}}\mathrm{.CH_2.}\underset{\mathrm{N_2H_2Ph}}{\underset{\|}{\mathrm{C}}}\mathrm{Me}.$$

The behaviour of benzoylacetone with alkalis shows that the hydrogen of the methylene-group can be substituted by metals, which is not the case with the hydrazine-derivatives in which the oxygen of the CO-groups is replaced by nitrogen. A. K. M.

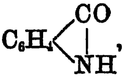
Anthroxanaldehyde and Anthroxanic Acid. By A. Schillinger and S. Wleügel (*Ber.*, **16**, 2222—2226).—When a solution of orthonitrophenylhydroxyacrylic acid in an equal weight of glacial acetic acid is heated on a water-bath as long as carbonic anhydride is evolved, and then diluted with water, neutralised with chalk, and steam-distilled, a distillate is obtained from which ether extracts *anthroxanaldehyde* mixed with anthranil; the latter is removed by boiling with light petroleum, from which solvent anthroxanaldehyde crystallises in long yellowish needles of a slightly aromatic and penetrating odour; it dissolves readily in boiling water, and volatilises easily in steam. It melts at 72·5°, and can be sublimed without decomposition. Its formula, $C_8H_5NO_2$, shows it to be isomeric with isatin. An intense reddish-violet coloration is produced on adding zinc-dust to its solution in very dilute ammonia and warming. When an aqueous solution, containing also anthranil, is boiled with ferrous sulphate, slender red silky needles separate, which, after crystallisation from chloroform, contain no iron; this substance melts above 215° with decomposition; it has basic properties. Anthroxanaldehyde dissolves readily in concentrated hydrogen-sodium sulphite, and produce a red coloration with rosaniline sulphite. When it is warmed with aniline, an oil is obtained which solidifies to large fan-shaped crystals, melting at about 40°. *Anthroxanic acid*, $C_8H_5NO_3$, is prepared by adding the calculated quantity of a 4 per cent. permanganate solution to a cold solution of the aldehyde in very dilute soda, filtering and slightly acidifying. The solution is warmed with animal charcoal, filtered, and dilute sulphuric acid added, when *anthroxanic acid* separates in delicate white needles. It is moderately soluble in hot water, almost insoluble in cold water, readily in acetone, more sparingly in glacial acetic acid, and still less readily in benzene and other solvents. It melts at 190—191° with decomposition. On warming its solution in dilute ammonia with ferrous sulphate, filtering and acidulating, isatin is obtained.

The authors assign to this acid the constitution , analogous to isatogenic acid, , which it resembles in its behaviour to feeble reducing agents. Unsuccessful attempts were made to decompose it into carbonic anhydride and *anthroxane*,  $C_6H_4\left\langle\begin{matrix}CH\\|\\N-\end{matrix}\right\rangle O$, which, if capable of existing, would be isomeric with anthranil. Possibly anthroxane becomes converted into the latter in the same way as isatogen into isatin. A. K. M.

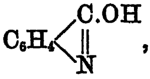
Constitution of Anthranil. By P. FRIEDLÄNDER and S. WLEÜGEL (*Ber.*, 16, 2227—2229).—From the close relationship of anthranil to anthroxanic acid (see last Abstract) an attempt was made to prepare the latter by heating anthranil with ethyl chlorocarbonate at 120—140°. Of the three possible formulæ for anthranil—



$$C_6H_4\left\langle\begin{matrix}CH\\|\\N\end{matrix}\right\rangle O,$$



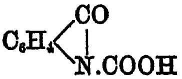
$$C_6H_4\left\langle\begin{matrix}CO\\|\\NH\end{matrix}\right.,$$



$$C_6H_4\left\langle\begin{matrix}C.OH\\\|\\N\end{matrix}\right.,$$

the first alone could yield anthroxanic acid, the second an isomeric anthranilcarboxylic acid, whilst the third could not yield a carboxylic acid.

The product of the reaction was an acid (*anthranilcarboxylic acid*) isomeric with anthroxanic acid, but possessing different properties. It dissolves sparingly in the usual solvents, most readily in acetone and in ether, and crystallises from hot water in slender needles melting at about 230° with evolution of carbonic anhydride, but anthranil is not re-formed. The presence of a carboxyl-group is proved by its solubility in dilute ammonia and in alkaline carbonates, mineral acids reprecipitating it unchanged. It dissolves in a one per cent. soda solution, showing a blue fluorescence which soon disappears, and on then acidifying with acetic acid and extracting with ether, the equivalent quantity of *anthranilic acid* is obtained. This change probably takes place thus:—



$$C_6H_4\left\langle\begin{matrix}CO\\|\\N.COOH\end{matrix}\right. + H_2O = COOH.C_6H_4.NH.COOH$$

$$= COOH.C_6H_4.NH_2 + CO_2.$$

Anthranilcarboxylic acid is decomposed by hot concentrated soda solution, with formation of anthranilic acid and of a high-melting acid, probably a derivative of diphenylcarbamide.

On gently heating a mixture of dry anthranil with benzoic chloride, an abundant evolution of hydrochloric acid takes place, whilst *benzoylanthranil*,  $C_6H_4\left\langle\begin{matrix}CO\\|\\N.COPh\end{matrix}\right.$, is formed. The product crystallises on cooling, and can be purified by recrystallisation from dry benzene with the addition of light petroleum. It forms long white needles readily soluble in the ordinary solvents, insoluble in water and light petroleum; it melts at 122—123°, and distils above 360° nearly unchanged. Like anthranil, it readily takes up the elements of water with formation of *benzoylanthranilic acid*, $COOH.C_6H_4.NH.COPh$; the change being effected by solution in hot dilute alkalis or by crystallisation from dilute alcohol, when the melting point is raised from 123° to 180—181°. The benzoylanthranilic acid obtained is identical with the acid obtained from anthranilic acid and benzoic chloride (*Annalen*, **205**, 130). It yields sparingly soluble *barium* and *calcium salts*, and a nearly insoluble stable *silver salt*, $C_{14}H_{10}NO_3Ag$.

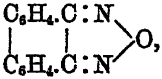
These results prove that anthranil is represented by the second of the above formulæ, and that it is the lactam of anthranilic acid.

A. K. M.

Action of Hydroxylamine on Diketones. By H. GOLDSCHMIDT (*Ber.*, **16**, 2176—2180).—The author and V. Meyer have isolated and described a diphenylglyoxime (m. p. 237°), $C_{14}H_{12}N_2O_2$, obtained by the action of hydroxylamine on benzil. Under other conditions, the author has obtained an isomeride which in contradistinction to the first named substance may be called β-diphenylglyoxime; it differs from its isomeride in its melting point (206°), its appearance, and its greater solubility in water and alcohol. The α-glyoxime may be converted into the β-isomeride by heating to 180°.

On heating phenanthraquinone with alcohol and hydroxylamine hydrochloride, a monisonitroso-derivative of phenanthraquinone, $C_{14}H_9NO_2$, is formed.

This substance crystallises in small golden needles melting at 158°, soluble in alcohol; it dissolves in soda to form a green, and in sulphuric acid to form a red solution. It is converted by hydroxylamine hydrochloride into a dioximide derivative of phenanthraquinone, of possible constitution,



$$\begin{array}{l} C_6H_4.C:N \diagdown \\ \; | \qquad \; | \qquad \;\; \rangle O \\ C_6H_4.C:N \diagup \end{array}$$

which crystallises in golden needles melting at 181°, insoluble in soda. When anthraquinone is heated with alcohol and hydroxylamine hydrochloride, in a flask fitted with an inverted condenser, no reaction takes place.

In order to obtain the monisonitroso-derivative of anthraquinone, it is necessary to heat the reacting substances in a sealed tube at 180°, when the compound separates out as a pale red powder, soluble in alcohol, to form a red solution. It sublimes at 200°, volatilising completely, without melting. Its constitution may be expressed by the formula,

$$C_6H_4{<}{\begin{array}{c}CNOH\\-\,CO\,-\end{array}}{>}C_6H_4.$$

V. H. V.

Derivatives of Benzil. By B. S. BURTON (*Ber.*, **16**, 2232—2233).—With the view to obtain diphenyltartaric acid, the author has made experiments on the saponification of Zinin's nitril of diphenyltartaric acid, $C_{14}H_{10}O_2(CHN)_2$, obtained by the action of anhydrous hydrocyanic acid on an alcoholic solution of benzil (*Annalen*, **34**, 189). The finely powdered nitrile is introduced into a large excess of glacial acetic acid saturated at 0° with hydrobromic acid, and frequently agitated. After some weeks, the unaltered substance is separated, and the clear liquid yields monoclinic crystals of a vitreous lustre. On adding ammonium carbonate to the filtrate, a white precipitate, $CONH_2.CPh(OH).CPh(OH).CONH_2$, is produced, insoluble in cold water, but which can be crystallised from dilute alcohol; it crystallises from hot water in small needles. It softens gradually on heating, begins to darken at 150°, becoming completely liquid at 230°. Its basic properties are very feeble, as it crystallises unchanged from hot concentrated hydrochloric acid, although it yields a crystalline hydrobromide. It has no acid properties, is not dissolved by sodium carbonate solution, but is soluble in soda solution with decomposition. On boiling it with hydrochloric acid, acid substances are obtained still containing nitrogen. The above mentioned monoclinic crystals consist of the hydrobromide of the amide; this melts at 185° with evolution of hydrobromic acid. Sodium carbonate converts it into the amide. A. K. M.

Benzoylacetic Acid. By A. BAEYER and W. H. PERKIN, Jun. (*Ber.*, **16**, 2128—2133).—One of the authors has recently shown that ethyl phenylpropiolate is converted by sulphuric acid into ethyl benzoylacetate, thus: $PhC \vdots C.COOEt + H_2O = COPh.CH_2.COOEt$ (see Abstr., 1882, 336). The latter is a colourless oil resembling ethyl acetoacetate in odour; when quickly heated, it distils with slight decomposition between 268—270°; it is coloured by ferric chloride. On boiling with water or acids, it is decomposed according to the equation, $CH_2\overline{Bz}.COOEt + H_2O = PhCOMe + CO_2 + EtOH$. In order to prepare benzoylacetic acid, a solution of the alkyl salt in soda is left at rest; after filtration, the solution is cooled with ice and carefully acidified, and then exhausted with ether. The acid is obtained from the ethereal extract as a hard crystalline mass, which melts at 85—90° with evolution of carbonic anhydride; it is soluble in alcohol and ether, and its solution is coloured violet by ferric chloride.

Ethylbenzoylacetic acid, $CHEt\overline{Bz}.COOH$, is obtained as an ethyl salt by the joint action of sodium and ethyl iodide on ethyl benzoylacetate; on subsequent saponification of this salt, the pure acid is obtained. This latter melts at 112—115°, and is generally contaminated by benzoic acid. On boiling the ethyl salt with alcoholic potash, like ethyl acetoacetate, it yields either a mixture of acids, or a ketone, according to the concentration of the alkali, thus:—

$$\text{(1.)}\ CHEt(COPh).COOEt + 2KOH = PhCOOK + CH_2Et.COOK + EtOH, \text{ or}$$

$$\text{(2.)}\ CHEt(COPh).COOEt + 2KOH = COPh.CH_2Et + EtOH + K_2CO_3.$$

Diethylbenzoic acid, $CEt_2\overline{Bz}.COOH$, obtained by a repetition of the process used for the acid above, forms a colourless, crystalline mass melting at 128—130°; when heated with alcoholic potash, it yields diethylacetophenone, boiling at 230°, thus:—

$$CEt_2(COPh).COOH + 2KOH = COPh.CHEt_2 + K_2CO_3.$$

Allylbenzoylacetic acid, $CH\overline{Bz}(C_3H_5).COOH$, prepared by the action of allyl iodide on the ethyl salt of sodium benzoylacetic acid, is isomeric with benzoyltetramethylenecarboxylic acid from trimethylene bromide and ethyl benzoylacetate. The former exists as a colourless crystalline mass melting at 122—125°, soluble in all menstrua except water; when its ethyl salt is heated with alcoholic potash, it yields allylacetophenone (b. p. 238°), thus:—

$$CH(COPh)(C_3H_5).COOEt + 2KOH = COPh.CH_2(C_3H_5) + K_2CO_3 + EtOH.$$

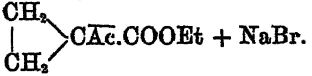
Ethylnitrosobenzoylacetate, COPh.CNOH.COOEt, formed by the action of nitrous acid on ethyl benzoylacetate, crystallises in long needles melting at 121°, which dissolve in alkalis to form a golden solution. On long standing in contact with soda, it is converted into an acid, COPh.CH(OH).COOH, crystallising in small prisms.

Dibenzoylacetic acid, $CH\overline{Bz}_2.COOH$, obtained by the action of benzoic chloride on ethyl sodium benzoylacetate, and subsequent saponification, crystallises in needles melting at 109°, sparingly soluble in alcohol. This substance on protracted heating with water is converted into *dibenzoylmethane* with evolution of carbonic anhydride, thus:—

$$CH\overline{Bz}_2.COOH = CH_2\overline{Bz}_2 + CO_2.$$

This latter compound crystallises in large tables belonging to the rhombic system, which melt at 81° and boil at 200°. By the combined action of sodium and benzoic chloride it is converted into *tribenzoyl methane*, $CH\overline{Bz}_3$, which crystallises in small needles (m. p. 224°), and sublimes without decomposition. V. H. V.

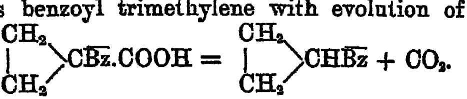
Action of Ethylene Bromide on Ethyl Aceto- and Benzoyl-Acetates. By W. H. Perkin, Jun. (*Ber.*, **16**, 2136—2140).—By the combined action of ethylene bromide and sodium on ethyl acetoacetate, the *ethyl salt of acetyl trimethylene carboxylic acid* is formed according to the equations: I. $CH\overline{Ac}Na.COOEt + CH_2Br.CH_2Br = CH\overline{Ac}(C_2H_4Br).COOEt + NaBr$; and II. $C\overline{Ac}Na(C_2H_4Br).COOEt =$



$$\left.\begin{array}{l}CH_2\\ |\\ CH_2\end{array}\right\rangle C\overline{Ac}.COOEt + NaBr.$$

This substance is a colourless oil boiling at 193—195°, and yields the corresponding acid as a thick oil on saponification and subsequently acidifying the alkali salt. The silver salt crystallises in characteristic warty masses.

Similarly, *benzoyl trimethylene carboxylic acid*,  $\left.\begin{array}{l}CH_2\\ |\\ CH_2\end{array}\right\rangle C\overline{Bz}.COOH$, may be obtained; it crystallises in the monoclinic system, and melts at 148° with evolution of carbonic anhydride. Its *silver* salt forms a white flocculent precipitate, the *ethyl* salt a colourless oil boiling at 280—283°. Benzoyl trimethylene carboxylic acid when heated to 200° yields benzoyl trimethylene with evolution of carbonic anhydride, thus



$$\left.\begin{array}{l}CH_2\\ |\\ CH_2\end{array}\right\rangle C\overline{Bz}.COOH = \left.\begin{array}{l}CH_2\\ |\\ CH_2\end{array}\right\rangle CH\overline{Bz} + CO_2.$$

The author is engaged in investigating homologues of the substances above described. V. H. V.

Phenylhydroxyacetimidoether and Amidine. By C. Beyer (*J. pr. Chem.* [2], **28**, 190—191).—Benzaldehyde cyanhydrin is dissolved in ether, 1 mol. proportion of alcohol added, and a stream of dry hydrochloric acid passed into the liquid. The resulting *hydrochloride*, CHPh(OH).C(OEt) : NH,HCl, crystallises in needles, melts at 121°, and on treatment with potash and ether, yields *phenylhydroxyimidoether*, CHPh(OH).C(OEt) : NH, crystallising in fine needles and melting at 71—72°. On strongly heating the hydrochloride, it is resolved into ethyl chloride and mandelamide; on treatment with water, it yields *ethyl mandelate*, CHPh(OH).COOEt, as a heavy colourless liquid of faint jasmine-like odour, boiling at 253—255°, and solidifying to a crystalline mass in a freezing mixture.

By the action of alcoholic ammonia on the imidoether hydrochloride, the corresponding *phenylhydroxyamidine hydrochloride*,

$$CHPh(OH).C(NH_2) : NH,HCl,$$

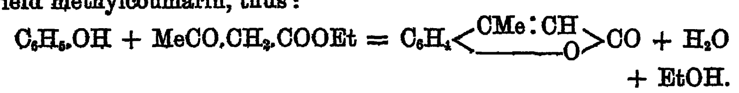
was obtained crystallised in fine prisms, melting at 213—214°. The free amidine could only be obtained in an impure state, and then formed stellate groups of needles having a strongly alkaline reaction and melting at 110°.

A. J. G.

Derivatives of Orthonitrocinnamic Acid. By A. Einhorn (*Ber.*, **16**, 2208—2216).—*Orthonitrophenyl-β-bromopropionic acid*, $NO_2.C_6H_4.CHBr.CH_2.COOH$, is prepared by heating orthonitrocinnamic acid (10 grams) with a solution of hydrobromic acid in glacial acetic acid (100 grams) saturated at 0°. The mixture is heated in a sealed tube for about half an hour on a water-bath, and frequently shaken until the nitro-acid is dissolved. The product is purified by boiling it with benzene and recrystallising from chloroform; it forms pale yellow monoclinic crystals melting at 139—140°, with decomposition. It dissolves readily in the ordinary solvents, but is only sparingly soluble in benzene. It dissolves to a small extent in warm water, decomposition however taking place with formation of indoxyl. Boiling concentrated sulphuric acid is almost without action on it, whilst alkalis very readily decompose it. On treating the powdered acid with an excess of cold sodium carbonate solution, a clear solution is obtained, which soon assumes a bright red colour, whilst a precipitate forms which the author assumes to be the *lactone* of orthonitrophenyl-β-lactic acid, $NO_2.C_6H_4.CH{<}\genfrac{}{}{0pt}{}{CH_2}{-O-}{>}CO$. The filtrate contains small quantities of orthonitrocinnamic acid, orthonitrophenyl-β-lactic acid, and orthonitrostyrene. The lactone is readily soluble in chloroform, acetone, benzene, and glacial acetic acid, sparingly in ether and in absolute alcohol, whilst alkalis convert it into the corresponding hydroxy-acid. It is converted into orthonitrostyrene and carbonic anhydride by boiling with water, some indoxyl, indigo, and probably also orthonitrophenyl-β-lactic acid being simultaneously produced. Indigo is also formed when it is boiled with glacial acetic acid or acetic anhydride. By the action of zinc-dust and hydrochloric acid on a solution of the nitro-lactone in glacial acetic acid, hydrocarbostyril is formed, and not the expected amido-lactone. When finely powdered orthonitrophenyl-β-bromopropionic acid is added to a hot solution of sodium carbonate and the product steam distilled, an oil is obtained solidifying in a freezing mixture to a white crystalline mass, which melts at about 12—13·5.° When *orthonitrostyrene*, $C_8H_7NO_2$, is heated with concentrated sulphuric acid, it assumes a blue colour. On adding a solution of bromine in chloroform to nitrostyrene also dissolved in chloroform, the liquid being kept cool with ice, *orthonitrostyrene dibromide*, $NO_2.C_6H_4.CHBr.CH_2Br$, is obtained, melting at 52° and volatile in steam. Besides nitrostyrene (10 per cent.), orthonitrocinnamic acid (16 per cent.), and orthonitrophenyl-β-lactic acid (42 per cent.), are formed in the above reaction, and the latter compound can also be obtained by warming the lactone with baryta-water. The purified acid, $NO_2.C_6H_4.CH(OH).CH_2.COOH$, is readily soluble in alcohol and in water, crystallising from the latter in six-sided monoclinic prisms, melting at 126°. When heated with dilute sulphuric acid at 190°, it yields orthonitrocinnamic acid; with concentrated sulphuric acid it yields indoïn. The *methyl derivative* melts at 51°; the *barium salt*, $(C_9H_8NO_5)_2Ba + 2H_2O$, crystallises in needles. A direct comparison of this acid, with that obtained by Baeyer and Drewson (p. 59), shows that the two are identical.

A. K. M.

Substituted Coumarins. By H. v. PECHMANN and C. DUISBERG (*Ber.*, **16**, 2119—2128).—The ethyl salts of aceto- and benzoyl-acetic acids react with the phenols in presence of a dehydrating agent to form substituted coumarins or hydroxycoumarins. Thus, for example, phenol and ethyl acetoacetate, in presence of strong sulphuric acid, yield methylcoumarin, thus:



$$C_6H_5.OH + MeCO.CH_2.COOEt = C_6H_4{<}\begin{matrix}CMe:CH\\ \overline{\qquad\quad O}\end{matrix}{>}CO + H_2O + EtOH.$$

In this communication a description is given of the preparation and properties of various substituted coumarins obtained by means of this general method.

β-Methylumbelliferone, $OH.C_6H_3{<}\begin{matrix}CMe:CH\\ \overline{\qquad\quad O}\end{matrix}{>}CO$, from resorcinol and ethyl acetoacetate, crystallises in prisms or needles melting at 185°, insoluble in water, soluble in alcohol and in ammonia and caustic alkalis. Its solutions are of a pale yellow colour, and display a characteristic blue fluorescence. When heated with potash, it yields resacetophenone and also resorcinol, and in this connection the author mentions that traces of resorcinol can be detected by the fluorescence formed on adding ethyl acetoacetate and sulphuric acid to the suspected solution. The resacetophenone, $C_6H_3(OH)_2.COMe$, is identical with the substance obtained by Nencki and Sieber from resorcinol and acetic acid. The *acetyl* and *benzoyl* derivatives of β-methylumbelliferone crystallise in needles, soluble in alcohol, sparingly soluble in water and ether; the former melts at 150°, the latter at 160.°

The *methyl-ether* of *β-methylumbelliferone* is a crystalline substance

(m. p. 159°), resembling in all its properties the corresponding hydroxyl-compound mentioned above; when heated with potash, it is converted into a *carboxyl-acid*, $C_6H_3(OMe)(OH)\,CMe : CH.COOH$, crystallising in four-sided tables, which melt at 140° with evolution of carbonic anhydride, and are insoluble in water, easily soluble in alcohol. *Dimethyl-β-resorcylic acid*, $C_6H_3(OMe)_2COOH$, obtained by further methylation and subsequent oxidation of the above-mentioned methyl-ether, crystallises in white needles (m. p. 108°).

β-Phenylumbelliferone,  $C_6H_3(OH)\left<\begin{matrix}CPh : CH \\ O\end{matrix}\right>CO$, from resorcinol and ethyl benzoylacetate, crystallises in colourless leaflets melting at 244°; *αβ-dimethylumbelliferone*,  $C_6H_3(OH)\left<\begin{matrix}CMe : CMe \\ O\end{matrix}\right>CO$, from resorcinol and ethyl dimethylacetoacetate in colourless needles melting at 256°; *β-methylcoumarin* from phenol and ethyl acetoacetate in colourless needles; *meta-toluene-β-methylcoumarin*,

$$C_6H_3Me\left<\begin{matrix}CMe : CH \\ O\end{matrix}\right>CO,$$

from paracresol and ethyl acetoacetate in large refracting needles; *dihydroxymethylcoumarin*,  $C_6H_2(OH)_2\left<\begin{matrix}CMe : CH \\ O\end{matrix}\right>CO$, in colourless needles (m. p. 235°). The solutions of all these substances, with the exception of the last named, display a well-marked blue fluorescence.

V. H. V.

Æsculetin. By W. WILL (*Ber.*, 16, 2106—2119).—The author, associated with Tiemann, has shown that dimethylæsculetin resembles in many points methylumbelliferone and coumarin (Abstr., 1882, 199). As the former has been recognised to be a monhydroxyl-derivative of coumarin, it becomes exceedingly probable that æsculetin is a dihydroxyl-derivative. In order to obtain further evidence in support of this conjecture, the author has repeated with æsculetin Perkin's researches on coumarin (this Journal, Trans., 1881, 409), and proves that the former undergoes transformation precisely similar to the latter, yielding isomeric α- and β-æsculetic acids, related to one another as the α- and β-orthomethoxyphenylacrylic acids.

Monethylæsculetin,  $\begin{matrix}OEt \\ OH\end{matrix}{>}C_6H_2\left<\begin{matrix}CH : CH \\ O\end{matrix}\right>CO$, is obtained, together with the di-derivative, by heating æsculetin with solid potash and ethyl iodide in alcoholic solution; the two products may be separated by ether which dissolves the di-derivative. Monethylæsculetin forms more or less colourless crystals (m. p. 143°), soluble in dilute alkalis; its solutions give a blue fluorescence. *Diethylæsculetin*,

$$C_6H_2(OEt)_2\left<\begin{matrix}CH : CH \\ O\end{matrix}\right>CO,$$

crystallises in glistening leaflets (m. p. 109°), sparingly soluble in water, readily soluble in ether and benzene. It dissolves in hot soda, forming a red solution, from which the sodium compound separates out on evaporation. If the residue be digested with ethyl iodide, there is formed the *ethyl salt of β-triethylæsculetic acid*,

$$C_6H_2(OEt)_2.CH:CH.COOEt.$$

This substance crystallises in glistening tablets melting at 75°, boiling at 360°, insoluble in water, readily soluble in dilute acids and alkalis; on saponification it is converted into β-triethylæsculetic acid,

$$C_6H_2(OEt)_3.CH:CH.COOH.$$

This acid forms colourless glistening prisms melting at 144°; a solution of its ammonium salt gives precipitates with salts of lead, mercury, copper, and silver. If in the preparation of the ethyl salt of β-triethylæsculetic acid an excess of ethyl iodide be avoided, and the time of heating be not more than 4—5 hours, the *ethyl salt of the isomeric α-acid* is produced. It forms thick golden prisms melting at 51°, boiling at 230°, insoluble in water, soluble in alcohol and ether; when heated to its boiling point it is transformed into the isomeric β-compound. *α-Triethylæsculetic acid* can be obtained by the saponification of the corresponding ethyl salt; it is a crystalline substance melting at 102°, and a solution of its ammonium salt gives precipitates with salts of lead, zinc, copper, and mercury. When heated to its boiling point or with hydrochloric acid, it is converted into the isomeric β-acid. On reduction with sodium-amalgam, both the α- and β-triethylæsculetic acids yield the same *triethoxyphenylpropionic acid*,

$$C_6H_2(OEt)_3.CH_2.CH_2.COOH,$$

which crystallises in leaflets melting at 77°; a solution of its ammonium salt gives precipitates with salts of lead, silver, mercury, and copper. α- and β-triethylæsculetic acids are converted by oxidation with alkaline permanganate in the cold into the same triethoxybenzaldehyde, $C_6H_2(OEt)_3.CHO$, forming colourless crystals melting at 95°, insoluble in water, soluble in alcohol and ether. It has all the characteristic properties of an aldehyde. If the oxidation of the triethylæsculetic acid be effected at 60° instead of the aldehyde, *triethoxybenzoic acid*, $C_6H_2(OEt)_3.COOH$, is obtained: this substance crystallises in delicate needles melting at 134°, and solution of its ammonium salt gives precipitates with salts of lead, mercury, and silver. On distilling the potassium salt of this acid with potash, it is converted into a substance crystallising in needles melting at 57°, which gives the characteristic phloroglucol reaction with ferric chloride. From want of material the author was unable to examine the compound more fully.

α-Dimethylumbellic acid, $C_6H_3(OMe)_2.CH:CH.COOH$, obtained by heating 1 mol. methylumbelliferone with 1 mol. of sodium dissolved in methyl alcohol, and 1 mol. methyl iodide, crystallises in colourless needles melting at 138°, soluble in alcohol, ether, and benzene. On boiling with hydrochloric acid, it is converted into the more stable isomeric compound.

Both α- and β-dimethylumbellic acids when reduced by sodium-amalgam yield the same *dimethoxypropionic acid*,

$$C_5H_3(OMe)_2.CH_2.CH_2.COOH,$$

which forms a white crystalline powder melting at 105°; its ammonium salts give precipitates with salts of silver, lead, and mercury. α-Dimethylumbellic acid is converted by oxidation into a dimethoxybenzoic acid, $C_6H_3(OMe)_2.COOH$, identical with the β-dimethylresorcylic acid, $C_6H_3(OMe)_2.COOH$ [COOH : OMe : OMe = 1 : 2 : 4], obtained by the oxidation of the corresponding aldehyde.

Bromine acts readily on diethylæsculetin dissolved in carbon bisulphide to form monobromdiethylæsculetin, $C_{13}H_{13}O_4Br$, a crystalline substance melting at 169°, and converted on boiling with concentrated alcoholic potash into diethoxycoumarilic acid, $C_{13}H_{14}O_5$, which crystallises in delicate transparent needles melting at 195°. On reduction with sodium-amalgam, it is converted into a substance probably homologous with hydrocoumarilic acid. V. H. V.

Benzylsulphonic Acid. By G. MOHR (*Annalen*, **221**, 215—229). —*Nitrobenzylsulphonic acid*, $C_6H_4(NO_2).CH_2.SO_3H$, prepared by the method described by Böhler (*Annalen*, **154**, 50; *Ber.*, **5**, 688), yields a chloride which is decomposed by heat into sulphurous oxide, and paranitrobenzyl chloride (m. p. 71·5°) mixed with a small quantity of the ortho-compound. On reducing an ammoniacal solution of the nitrobenzylsulphonic acid with sulphuretted hydrogen, *paramidobenzylsulphonic acid*, $C_6H_4(NH_2).CH_2.SO_3H$, is deposited in colourless needles. The mother-liquor contains a mixture of the para- and ortho-compounds. The para-acid is sparingly soluble in cold water; 100 grams of the solution at 11° contain 0·097 gram acid. The salts are crystalline, and freely soluble in water. The *diazo-compound*,

$C_6H_4{<}\begin{array}{c}\text{——}N\\CH_2SO_3\end{array}{>}N$, is prepared by passing nitrous acid into the amido-acid suspended in water. As soon as an evolution of nitrogen is observed, the mixture is filtered. On adding alcohol to the filtrate, the diazo-compound is obtained in colourless microscopic crystals. When boiled with water it is decomposed, yielding parahydroxybenzylsulphonic acid, $C_6H_4(OH).CH_2.SO_3H$, which crystallises in deliquescent needles, freely soluble in alcohol. The solution of the acid or of its salts gives with ferric chloride a blue coloration, which is destroyed by alcohol. The potassium and the barium salts crystallise in prisms soluble in water. The former contains 0·5, and the latter 7·5 mols. H_2O.

By the action of hydrobromic acid on the diazo-compound, *parabromobenzylsulphonic acid*, $C_6H_4Br.CH_2.SO_3H$, is obtained as a syrupy liquid. The *barium* salt, $(C_6H_4Br.CH_2.SO_3)_2Ba + 1\frac{1}{2}H_2O$, forms colourless plates, soluble in water. The *chloride* (m. p. 107°) is soluble in benzene and ether.

The diazo-compound is decomposed by absolute alcohol under pressure, yielding *paraethoxylbenzylsulphonic acid*,

$$C_6H_4(OEt).CH_2.SO_3H.$$

The barium salt of this acid crystallises with 2 mols. H_2O.

Parazobenzyldisulphonic acid, $C_6H_4(CH_2.SO_3H).N_2.C_6H_4.CH_2.SO_3H$, prepared by the oxidation of amidobenzylsulphonic acid with potassium permanganate, forms the following salts: $C_{14}H_{12}N_2S_2O_6K_2 + 1\frac{1}{2}H_2O$, orange-coloured plates, soluble in water; $C_{14}H_{12}N_2S_2O_6Ba + 1\frac{1}{2}H_2O$, yellow needles, sparingly soluble; $C_{14}H_{12}N_2S_2O_6Ag_2,H_2O$, yellow needles, soluble in hot water. The *chloride* forms crystalline leaves melting at 149°, soluble in benzene.

Nitrobenzylsulphonic acid is converted into the dinitro-acid by the action of a mixture of strong sulphuric and nitric acids. The anhydrous potassium salt, and the lead and barium salts containing 4 mols. H_2O, are soluble in water. *Amidonitrobenzylsulphonic acid* is sparingly soluble in cold water. The *potassium salt* forms purple anhydrous crystals, and the *barium salt*, $[C_6H_3(NH_2)(NO_2)CH_2SO_3]_2Ba,2H_2O$, yellow needles or plates.

Diamidobenzylsulphonic acid, $C_6H_3(NH_2)_2.CH_2.SO_3H$, crystallises in colourless needles, soluble in acids or alkalis. The ammoniacal solution gives, with silver nitrate, a white precipitate which rapidly turns black.

W. C. W.

Parabromotoluenedisulphonic Acid. By O. KORNATZKI (*Annalen*, **221**, 191—202).—*Parabromotoluenedisulphonic acid*, prepared by passing sulphuric anhydride into a solution of bromotoluene in sulphuric acid, forms a deliquescent crystalline mass.

The *potassium* salt, $C_7H_5Br(SO_3K)_2 + H_2O$, crystallises in colourless needles or rhombic prisms, which dissolve freely in cold water. The *barium* salt, $C_7H_5BrS_2O_6Ba + 5H_2O$, forms colourless prisms, needles, or plates, soluble in hot water, and the *lead* salt, $C_7H_5BrS_2O_6Pb + 2H_2O$, crystallises in colourless needles, which dissolve easily in water. The *chloride*, $C_7H_5Br(SO_2Cl)_2$, is deposited from an ethereal solution in colourless rhombic plates melting at 99°. The *amide* is sparingly soluble in water and alcohol. It melts above 260°.

Parabromotoluenedisulphonic acid is slowly attacked by strong nitric acid with the formation of sulphuric, dibromonitrotoluenesulphonic, nitrotoluenedisulphonic, and bromodisulphobenzoic acids.

Potassium parabromodisulphobenzoate, $C_6H_2Br(COOK)(SO_3K)_2 + H_2O$, forms colourless plates, soluble in water. The *barium* salt crystallises in plates containing 12 mols. H_2O. The *chloride* is deposited from an ethereal solution in rhombic plates melting at 151°. The *amide* crystallises in prisms soluble in ammonia and in warm water. It melts above 250°.

Potassium dibromonitrotoluenesulphonate, $C_7H_4Br_2.(NO)_2SO_3K + H_2O$, is soluble in alcohol and water. The *barium* salt forms thin plates, containing $3\frac{1}{2}$ mols. H_2O.

Potassium nitrotoluenedisulphonate, $C_7H_5NO_2(SO_3K)_2$, crystallises in thin needles, soluble in warm water. The *amidotoluenedisulphonic acid*, obtained by the action of ammonium sulphide on this salt, is not identical with either of the amido-acids described by Pechmann (*Annalen*, **173**, 217), or Lorenz (*ibid.*, **172**, 188). It forms yellow needles or prisms, which dissolve freely in water. The *toluenedisulphonic acid*, which is formed by the reduction of sodium parabromotoluenedisulphonate, is not identical with any of the toluenedisulphonic acids described by Blomstrand and Hakansson (*Ber.*, **5**, 1084), Claesson and Berg (*ibid.*, **13**, 1170), or Senhofer (*Annalen*, **164**, 126). It yields an anhydrous potassium salt, and a barium salt,

$$C_7H_6(SO_3)_2Ba + 4H_2O,$$

both of which are very soluble in water. The *chloride* crystallises in prisms melting at 86·5°, soluble in ether and light petroleum, and the *amide* forms colourless needles which melt above 260°.

W. C. W.

Azotoluenedisulphonic Acids. By O. KORNATZKI (*Annalen*, **221**, 179—191).—The author finds that the only satisfactory general method of preparing azotoluenesulphonic acids is by the oxidation of the potassium salt of the amido-acids.

Orthazotoluenediparasulphonic acid, and *parazotoluenediorthosulphonic acid*, which Neale (*Annalen*, **203**, 73) prepared by reducing the corresponding nitrotoluenesulphonic acids with zinc-dust and potash solution, are also formed by the action of potassium permanganate on orthamidotolueneparasulphonic acid (described by Hayduck, *Annalen*, **172**, 204), and on paramidotolueneorthosulphonic acid.

Parazotoluenedimetasulphonic acid, obtained by a similar reaction from the corresponding amido-acid (*ibid.*, **173**, 195) yields a *barium* salt, $C_{14}H_{12}BaN_2S_2O_6 + 3H_2O$, which forms small red crystals, sparingly soluble in water.

Orthazotoluenedimetasulphonic acid crystallises in plates of a red colour, which dissolve freely in alcohol or water. The *potassium* salt, $C_{14}H_{12}K_2N_2S_2O_6$, also forms beautiful red-coloured plates, soluble in warm water. The *barium* salt, $C_{14}H_{12}BaN_2S_2O_6 + H_2O$, forms sparingly soluble microscopic plates, which effloresce on exposure to the air. The *calcium* salt crystallises in microscopic needles containing 3 mols. H_2O. The *lead* salt, $C_{14}H_{12}PbN_2S_2O_6 + H_2O$, is deposited from a solution in hot nitric acid, in needles which effloresce in the air. The *chloride*, $C_{14}H_{12}N_2(SO_2Cl)_2$, crystallises in dark red needles melting at 218°, soluble in benzene. The *amide*,

$$C_{14}H_{12}N_2(SO_2NH_2)_2,$$

forms rhombic plates which melt at 250°, and are soluble in ammonia.

Dibromoparamidotolueneorthosulphonic acid, described by Jenssen (*ibid.*, **172**, 234) is slowly converted into *dibromazotoluenedisulphonic acid* by oxidation with potassium permanganate. The azo-acid crystallises in glistening red plates which dissolve freely in water. The *potassium* salt, $C_{14}H_{10}K_2Br_2N_2S_2O_6 + 4H_2O$. forms six-sided plates, soluble in hot water. The orange-coloured *barium* salt, $C_{14}H_{10}BaBr_2N_2S_2O_6 + 5H_2O$, and the red *calcium* salt,

$$C_{14}H_{10}CaBr_2N_2S_2O_6 + 4\tfrac{1}{2}H_2O,$$

forms microscopic plates, sparingly soluble in hot water. The *lead* salt is deposited from hot dilute nitric acid in beautiful rhombic prisms containing 5 mols. H_2O. The *chloride*, $C_{14}H_{10}Br_2N_2(SO_2Cl)_2$, crystallises from benzene in pale red prisms melting at 226°. The *amide* melts at 260°.

Tetrabromorthoazotoluenediparasulponic acid, prepared from Hayduck's dibromamidotoluenesulphonic acid (*ibid.*, **172**, 211), forms glistening red plates, which dissolve easily in water and alcohol. The *potassium* salt forms microscopic plates, containing 2 mols. H_2O. It is sparingly soluble. The *barium* salt, $C_{14}H_8BaBr_4N_2S_2O_6 + 9H_2O$, crystallises in six-sided plates, which are sparingly soluble in hot water. The *calcium* salt, $C_{14}H_5CaBr_4N_2S_2O_6 + 8HO$, and the *lead* salt, $C_{14}H_8PbBr_4N_2S_2O_6 + 9H_2O$, form red-coloured plates. The *chloride*, $C_{14}H_8Br_4N_2(SO_2Cl)_2$, is deposited from benzene in dark red plates, which melt at 243° with decomposition.

A hydrazo-acid is not produced by the action of stannous chloride on the potassium salt. W. C. W.

Amidobenzenemetasulphonamide. By F. Hybbeneth (*Annalen*, **221**, 204—208).—The preparation of *amidobenzenemetasulphonamide*, $C_6H_4(NH_2).SO_2NH_2$ (m. p. 142°), has been previously described (*Annalen*, **172**, 72). The oxalate, nitrate, and hydrochloride are crystalline. When nitrous acid is passed into a mixture of absolute alcohol and the sulphonamide, an orange-coloured diazo-compound is produced. If nitric acid is substituted for alcohol, either an orange-coloured powder soluble in water, or a yellow crystalline compound, will be obtained. The orange-coloured substance has the composition $C_6H_4(SO_2NH_2).N_2.NO_3$. It is decomposed by boiling with water or alcohol, yielding nitrogen and benzenesulphonamide (m. p. 156°).

The yellow crystalline compound

$$NH_2SO_2.C_6H_4.N_2.NH.C_6H_4.SO_2NH_2,$$

previously mentioned, is insoluble in water. It melts at 183° with decomposition. It is decomposed by hydrochloric acid, yielding chlorobenzenesulphonamide (m. p. 148°), which was first prepared by Kieselinsky (*Annalen*, **180**, 110).

$$2[C_6H_4(NH_2).SO_2NH_2] + HNO_3 = NH_2SO_2.C_6H_4.NH.N_2.C_6H_4.SO_2NH_2.$$

The conditions which determine the formation of either of the two compounds have not yet been ascertained. W. C. W.

Orthamidotolueneparasulphonamide. By W. Paysan (*Annalen*, **221**, 210—215).—The amide of orthamidotolueneparasulphonic acid, $NH_2.C_6H_3Me.SO_2NH_2$, prepared by the action of sulphuretted hydrogen on an ammoniacal solution of orthonitrotolueneparasulphonamide (m. p. 128°), crystallises in four-sided prisms melting at 175°, which are sparingly soluble in cold water or alcohol. It forms a series of crystalline salts.

The *diazo*-compound, $NH_2SO_2.C_6H_3Me.N_2.NHC_6H_3Me.SO_2NH_2$, is obtained as a pale-yellow powder, when nitrous acid is passed into a mixture of the sulphonamide and alcohol. It detonates feebly when heated, and is also easily decomposed by dilute acids, *e g.*, by hydrochloric acid, it is split up into nitrogen, amidotoluenesulphonamide hydrochloride and orthochlorotolueneparasulphonamide, $C_6H_3MeCl.SO_2NH_2$

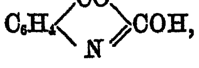
(m. p. 135°). The latter compound crystallises in white needles or plates, which are sparingly soluble in water. By the action of hydrochloric acid at 150°, it is converted into orthochlorotolueneparasulphonic acid. The acid exists as an oily liquid. Its potassium and barium salts do not contain water of crystallisation. The chloride is also an oily liquid. When nitrous acid is passed into orthamidotolueneparasulphonamide, made into a paste with nitric acid, an exceedingly unstable colourless diazo-compound is produced, which is decomposed by boiling alcohol, yielding the ethyloxidetoluenesulphonic acid described by Hayduck (*Annalen*, **172**, 215). W. C. W.

Paramidotolueneorthosulphonamide. By A. Heffter (*Annalen*, **221**, 208—210).—*Paramidotolueneorthosulphonamide*,

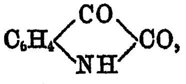
$$C_7H_6(NH_2).SO_2NH_2,$$

is obtained by the action of sulphuretted hydrogen on a warm ammoniacal solution of paranitrotoluenesulphonamide (*Annalen*, **172**, 233). It crystallises in silky needles or plates which melt at 164°, and dissolve in alcohol or warm water. It forms a crystalline nitrate, oxalate, and hydrochloride. When nitrous acid is passed into an alcoholic solution of the sulphonamide, a yellow amorphous compound is produced, which is decomposed by hot absolute alcohol, yielding the amide of tolueneorthosulphonic acid (m. p. 154°), which has been described by Claesson and Wallin (*Ber.*, **12**, 1850). A diazo-derivative of amidotoluenesulphonamide could not be isolated. *Parachlorotolueneorthosulphonamide* (m. p. 138°) is produced when nitrous acid acts on the sulphonamide in presence of hydrochloric acid. The SO_2-group in paramidotoluenesulphonamide is not eliminated by oxidation with potassium permanganate; but the amide of azotoluenedisulphonic acid (m. p. 270°), described by Neale (*Annalen*, **203**, 52), is formed. W. C. W.

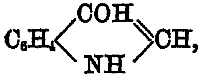
Compounds of the Indigo-group. By A. Baeyer (*Ber.*, **16**, 2188—2204).—Part IV.—The author has finally established the position of the hydrogen-atom (external to the benzene-ring) in indigo, showing that the latter is an imido-body, produced by the union of two indogen-groups. In the conversion of isatin and indoxyl into members of the true indigo-group, an isomeric change takes place, *pseudoisatin* and *pseudoindoxyl* existing however only in combination:



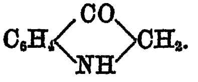
Isatin.



Pseudoisatin.



Indoxyl.



Pseudoindoxyl.

For the stability of pseudoisatin it is sufficient to replace the hydrogen of the NH-group by a monad radicle, whilst in the case of pseudoindoxyl, a dyad-group must replace both hydrogen-atoms of the group CH_2.

Action of Nitrous Acid on Indoxyl and Indoxyl-compounds.—On treating a solution of indoxyl with sodium nitrite and then acidifying, slender yellowish needles separate which, from their similarity to the nitrosamine of ethylindoxyl (obtained in the same way), and from their behaviour to hydrochloric acid, must be the *nitrosamine of indoxyl*,  $C_6H_4<\begin{smallmatrix}C(OH)\\N(ON)\end{smallmatrix}>CH$. By the action of indoxyl on diazobenzene hydrochloride in dilute aqueous solution, *phenylazoindoxyl*, $C_{14}H_{11}NO_3$, separates in very sparingly soluble red needles; it is moderately soluble in alcohol, from which it crystallises in thick orange-coloured prisms of yellowish-green metallic lustre; it melts at 236° with decomposition, and dissolves in warm soda solution, from which it is reprecipitated by carbonic anhydride. Zinc-dust decolorises the alkaline solution, and on exposure to air indigo is formed. *Isonitrosopseudoindoxyl (pseudoisatin-α-oxime)*,  $C_6H_4<\begin{smallmatrix}CO\\NH\end{smallmatrix}>CNOH$, was previously described as nitrosoindoxyl (Abstr., 1882, 1102), but an examination of its ethers shows that it is an isonitroso-derivative. The first ether, *pseudoisatin-α-ethyloxime*, is obtained on heating an alcoholic solution of pseudoisatoxime with ethyl iodide and sodium ethylate (1 mol.). It yields isatin on reduction and oxidation, showing that the ethyl-group does not replace the imido-hydrogen; neither can it be derived from a nitrosoindoxyl of the formula  $C_6H_4<\begin{smallmatrix}COH\\-NH-\end{smallmatrix}>C.NO$, for it can be boiled with concentrated hydrochloric acid without undergoing change; nor from  $C_6H_4<\begin{smallmatrix}CO\\NH\end{smallmatrix}>CHNO$, as such a compound, containing ethyl attached to the α-carbon atom, would not be so readily converted into isatin. Its formula must therefore be  $C_6H_4<\begin{smallmatrix}CO\\NH\end{smallmatrix}>CNOEt$, and that of the parent-substance the one given above. This ethyl-derivative is a weak acid, dissolves in alcoholic potash with a violet colour, and in alcoholic sodium ethylate with a blue colour. To prepare the second ether (*ethylpseudoisatin-α-ethyloxime*) an alcoholic solution of pseudoisatoxime, mixed with ethyl iodide and sodium ethylate (1 mol.), is boiled until the sodium salt first formed is completely dissolved, when a quantity (1 mol.) of sodium ethylate and ethyl iodide is added, and the boiling continued for about half an hour; the alcohol is removed by distillation, the product dissolved in ether, and washed with dilute soda solution. It is readily soluble in alcohol and in ether, sparingly in hot water, from which it crystallises in yellow needles melting at 99°; it is neither attacked by alkalis nor by boiling hydrochloric acid. Its formula is  $C_6H_4<\begin{smallmatrix}CO\\NEt\end{smallmatrix}>CNOEt$. Isatoxime and its two ethers, pseudoisatoxime and its first ether, all yield isatin on reduction and subsequent oxidation, whilst the second ether of pseudoisatoxime (containing ethyl attached to nitrogen) yields *ethylpseudoisatin*,

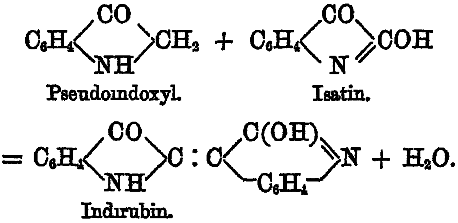
$C_6H_4<\genfrac{}{}{0pt}{}{CO}{NEt}>CO$. This crystallises in large blood-red plates melting at 95°, is readily soluble in hot water and in alcohol, less so in ether. It dissolves in alkalis with a yellow colour and formation of ethylisatates. Acetylpseudoisatin behaves in a similar manner, being at once converted into an acetylisatate. On acidulating a solution of an ethylisatate, ethylpseudoisatin is at once precipitated, whilst acetylisatic acid is perfectly stable. Barium ethylisatate—

$$(C_{10}H_{10}NO_3)_2Ba,$$

obtained by dissolving ethylpseudoisatin in warm baryta-water, crystallises in silky yellow needles; the silver salt forms flat yellow needles, moderately soluble in water. Ethylpseudoisatin yields an indophenin with coal-tar benzene and sulphuric acid, which forms a blue solution with ether (distinction from isatin). Ethylpseudoisatin, even when heated with concentrated hydrochloric acid for seven hours at 150—160°, is in great part unattacked, whilst ethylisatin is saponified by cold dilute alkalis. By the action of a solution of hydroxylamine hydrochloride and sodium carbonate in dilute alcohol, *ethylpseudoisatin-β-oxime*, $C_6H_4<\genfrac{}{}{0pt}{}{C(NOH)}{NEt}>CO$, is obtained crystallising in yellow four-sided prisms (m. p. 160—162°). On reduction and subsequent oxidation, it yields ethylpseudoisatin; it does not yield indigo with ammonium sulphide.

Action of Aldehydes and Ketonic Acids on Indoxyl.—On treating an aqueous solution of indoxyl with aldehyde, or with benzaldehyde, and then acidulating with hydrochloric acid, an extremely unstable yellow precipitate is obtained, whilst paranitrobenzaldehyde, terephthalic aldehyde, anthroxanaldehyde, and pyroracemic acid, when treated in the same way, yield very stable red precipitates. On cautiously heating a mixture of dry indoxylic acid (7 parts) and benzaldehyde (10 parts) carbonic anhydride is evolved; this ceases as soon as the temperature is raised to 120°. When the action is completed, the excess of benzaldehyde is removed by steam-distillation, and the residue crystallised first from alcohol and then from ether. The *indogenide of benzaldehyde* thus obtained crystallises in long, flat, orange-yellow needles, melting at 175—176°. It dissolves readily in alcohol and chloroform, more sparingly in ether, with which it forms a fluorescent solution; it is dissolved by concentrated sulphuric and hydrochloric acids, but is reprecipitated on adding water; it is insoluble in aqueous, but soluble in alcoholic alkalis. Its formation from indoxyl and benzaldehyde takes place thus: $C_8H_7NO + C_7H_6O = C_{15}H_{11}NO + H_2O$, similar to the action of nitrous acid on indoxyl, and from the similarity of both products and their behaviour with sodium ethylate, it is evident that they are similarly constituted, and that the formula of the indogenide of benzaldehyde is $C_6H_4<\genfrac{}{}{0pt}{}{CO}{NH}>C : CHPh$. It yields a blue solution with sodium ethylate, showing the indigo-spectrum, the blue colour disappearing on the addition of alcohol. The *indogenide of paranitrobenzaldehyde*, $C_{15}H_{10}N_2O_3$, is prepared by adding a solution of paranitrobenzaldehyde in glacial acetic acid to an aqueous solution of indoxyl acidulated with hydrochloric acid, and then treating the precipitate several times with boiling water, and recrystallising it from acetone. It forms small red needles melting at 273°. The *indogenide of pyroracemic acid*, $C_6H_4<\substack{CO\\NH}>C : CMe.COOH$, is obtained by adding concentrated hydrochloric acid to an aqueous solution of indoxyl and pyroracemic acid, and can be purified by passing a current of air through its solution in ammonia, filtering and precipitating with hydrochloric acid; it crystallises in red needles, and melts at 197°. It is readily soluble in acetone and in alcohol, is a strong acid, forms brownish-red solutions with the alkalis and alkaline carbonates, and a blue solution with sulphuric acid. It is reduced by ammonia and zinc-dust, forming a colourless solution, which becomes yellow on exposure to air, and yields a yellow flocculent precipitate on the addition of an acid.

Action of Isatin and Ethylpseudoisatin on Indoxyl.—The formation of indirubin from indoxyl and isatin may be compared to the above reactions, in which case indirubin must be regarded as the indogenide of isatin, thus:—



Pseudoindoxyl. Isatin.

Indirubin.

When a hot aqueous solution of indoxyl is poured into a hot solution of ethylisatin mixed with one-fourth its volume of concentrated hydrochloric acid, a violet-coloured liquid is obtained, which yields crystals of the *β-indogenide of ethylpseudoisatin*. It crystallises from boiling alcohol in needles of a coppery lustre, sparingly soluble in acetone, more readily in chloroform. It melts at 197—198°, and at higher temperatures volatilises in yellowish-red vapours. The powdered substance is violet, its concentrated solution in chloroform red, and its dilute solution pink, showing a broad band in the middle of the spectrum. It is reduced by zinc-dust and alkalis, yields a brown solution with concentrated sulphuric acid, which changes to violet when heated, and behaves like indigo. From the fact that in the reduction of ethylpseudoisatin, the CO-group next to the benzene nucleus is the one attacked, and also in the reaction with hydroxylamine, it may be assumed that this is also the case in the condensation-product with indoxyl. Its formula is therefore—

$$C_6H_4<\substack{CO\\NH}>C : C<\substack{-CO-\\C_6H_4}>NEt,$$

and it is possible that indirubin has a corresponding constitution.

Diethylindigo.—Assuming the probability of indigo being an indigo-body, the author attempted to convert ethyl- and benzyl-amidoacetophenone into ethyl- and benzyl-indigo, but without success. By the reduction of the second ether of pseudoisatin-α-oxime by alcoholic ammonium sulphide, *diethylindigo* can be obtained, in which ethyl is attached to the nitrogen, and which still possesses the properties of indigo. It crystallises in blue needles with coppery lustre, it is distinguished from indigo by its moderate solubility in alcohol; but is more sparingly soluble in acetone, chloroform, aniline, ether, and carbon bisulphide. Its solutions are of a pure blue colour, and give an absorption-spectrum very like that of indigo. It forms a greenish-blue solution with concentrated sulphuric acid, which changes to blue on warming (from formation of a sulphonic acid). When heated, it yields purple vapours, condensing in the form of thick blue prisms. With alkalis and zinc-dust, it yields a reduction-compound, and on oxidation, ethylpseudoisatin, proving that the ethyl in diethylindigo is united with nitrogen. In the same way that diethylindigo is obtained from ethylpseudoisatin-α-ethyloxime, indigo can be obtained from pseudoisatin-α-oxime, and also by the action of ammonium sulphide on isatin chloride and on ethylisatin, but from the formulæ of these three indigo-producing substances it will be seen that by their reduction and the splitting off of hydroxylamine, hydrochloric acid, and alcohol respectively, each is capable of yielding an indogen-group or indoxyl.

The constitution of indigo can be adduced from the following considerations:—1. Indigo contains the imido-group; 2. From its formation from diphenyldiacetylene, the carbon-atoms must be arranged thus: Ph.C.C.C.C.Ph; 3. It can only be obtained from such compounds in which the carbon-atom next to the benzene nucleus is also united to oxygen; 4. Its formation and properties show that it is closely related to indirubin and to the indogenide of ethylpseudoisatin; 5. This last substance is formed by the union of the α-carbon-atom of pseudoindoxyl with the β-carbon-atom of pseudoisatin. Indigo must therefore be the α-indogenide of pseudoisatin, although from the want of activity of the α-oxygen-atom in isatin it cannot be directly obtained from indoxyl and isatin.

$$C_6H_4<\substack{CO\\NH}>CH_2 + CO<\substack{CO\\C_6H_4}>NEt$$

Pseudoindoxyl. Ethylpseudoisatin.

$$= C_6H_4<\substack{CO\\NH}>C : C<\substack{CO\\C_6H_4}>NEt + H_2O.$$

Indogenide of ethylpseudoisatin.

$$C_6H_4<\substack{CO\\NH}>CH_2 + CO<\substack{CO\\NH}>C_6H_4$$

Pseudoindoxyl. Pseudoisatin.

$$= C_6H_4<\substack{CO\\NH}>C : C<\substack{CO\\NH}>C_6H_4 + H_2O.$$

Indigo.

The half molecule (C_8H_5NO) of indigo is called by the author *indogen*, and compounds in which this dyad-group replaces an oxygen-atom, *indogenides*. The indogenides are of a yellow to bluish-red colour, and some of them yield blue salts showing the indigo-spectrum. A. K. M.

Chemical Constitution of Acetylisatin and Acetylisatic Acid. By H. Kolbe (*J. pr. Chem.* [2], **28**, 79—82).—The author objects to the formulæ assigned by Baeyer to isatin and its derivatives; he regards isatin as having the constitution $C_6H_4N.CO.COH$ (the nitrogen-atom acting as a monovalent element, and replacing one of the hydrogen-atoms in phenyl), and represents the conversion of acetylisatin into sodium acetylisatinate by the equation—

$$C_6H_4N.CO.CO\overline{Ac} + NaOH = C_6H_4(NH\overline{Ac}).CO.COONa.$$

A. J. G.

Quinisatin. By A. Baeyer and B. Homolka (*Ber.*, **16**, 2216—2221).—Baeyer obtained isatin from oxindole by converting the latter into a nitroso-derivative, then into the amido-derivative which yields isatin on oxidation. The authors have obtained the isatin of quinoline in the same way from γ-hydroxycarbostyril (Abstr., 1883, 197). To prepare nitroso-γ-hydroxycarbostyril, $C_9H_6N_2O_3$, γ-hydroxycarbostyril is dissolved in dilute soda solution, a slight excess of sodium nitrite added, and the mixture gradually poured into cold dilute sulphuric acid. The precipitate is washed with water, dried and crystallised from alcohol, when it is obtained in small orange-coloured prisms, sparingly soluble in water, cold alcohol, ether, benzene and chloroform, readily in glacial acetic acid and in hot alcohol. It melts at 208° with decomposition. Alkaline carbonate and ammonia dissolve it, forming a green solution, whilst the fixed alkalis yield reddish-brown solutions. On boiling it with concentrated hydrochloric acid, it decomposes into isatin and hydroxylamine. From its resemblance to isatoxime, the authors consider the following constitution probable,

$$C_6H_4\left<\begin{array}{l}CO.C(N.OH)\\ N : C(OH)—\end{array}\right>.$$

By the action of zinc-dust on its solution in glacial acetic acid, *acetyldihydroxytetrahydroquinoline*, $C_{11}H_{13}NO_3$, is obtained, crystallising in long colourless silky needles. When exposed to the air in a moist state, it is rapidly oxidised to a violet-red product, from which the original substance can be obtained by reduction. Acetyldihydroxytetrahydroquinole is very sparingly soluble in cold water, alcohol and ether, moderately in glacial acetic acid, especially on warming; it dissolves in alkali to a violet solution or in excess of the latter to a blue solution, acids reprecipitating it in reddish coloured flocks which gradually become white.

On reducing nitroso-γ-hydroxycarbostyril by means of a saturated solution of stannous chloride in concentrated hydrochloric acid, and subsequently decomposing the tin salt with hydrogen sulphide, a compound of the formula, $C_9H_7NO_3$, is obtained, which is probably *β-γ-dihydroxycarbostyril*,  $C_6H_4<\begin{matrix}C(OH):C(OH)\\N:C(OH)\text{——}\end{matrix}>$. It crystallises in long colourless needles, very sparingly soluble in water, ether and benzene, readily in alcohol. Heated to 260°, it becomes converted into a brown substance infusible at 310°. With dilute alkalis it yields a blue solution, which becomes decolorised on exposure to the air with formation of a violet precipitate. On adding soda to its solution in alcohol and ether, a deep blue flocculent gelatinous precipitate is produced. When finely powdered β-γ-dihydroxycarbostyril is treated with a solution of ferric chloride in hydrochloric acid at 70—80°, a reddish-yellow liquid is obtained from which *quinisatic acid*,

$$NH_2.C_6H_4.CO.CO.COOH,$$

crystallises out on cooling. It is moderately soluble in cold water, very readily in hot water, from which it crystallises in pale straw-coloured prisms. The *alkali salts* are nearly colourless and readily soluble; the *silver salt* forms a yellowish-green unstable precipitate. On reducing a solution in glacial acetic acid with zinc-dust, and exposing the filtrate to the air, an indigo-blue coloured precipitate is formed, insoluble in water, ether, and chloroform, but soluble in alcohol, the supernatant liquid assuming a green coloration. Both colours are destroyed by acids, but reproduced on adding an alkali. On heating crystallised quinisatic acid for a short time at 120—125° water is given off, and the red anhydride, *quinisatin*, $C_9H_5NO_3$, formed: this readily combines with water forming quinisatic acid. It darkens in colour above 125°, melting between 255° and 260°. Soda solution dissolves it to a reddish-yellow solution, which is rapidly decolorised. It forms compounds with aniline and benzene, which are soluble in alkalis, but reprecipitated by carbonic anhydride, showing that quinisatin is not a carboxylic acid. Its formula is probably either  $C_6H_4\left<\begin{matrix}CO.CO\\ \quad\ |\\ NH.CO\end{matrix}\right.$ or $C_6H_4\left<\begin{matrix}CO.CO\\ \quad\ |\\ N:C(OH)\end{matrix}\right.$. A. K. M.

So-called Pyrocressol. By H. SCHWARTZ (*Ber.*, **16**, 2141—2145).—In this paper the author mentions that the results of vapour-density determination of the so-called pyrocressol were not in accordance with those obtained in the combustion analyses: the latter corresponded with a formula $C_{28}H_{26}O_2$, the former to $C_{15}H_{11}O$ (comp. *Ber.*, **16**, 1056). Both have been repeated, and the latter formula confirmed; pyrocressol, therefore, may have the constitution of a ditolyl or dibenzyl ketone, $C_6H_4Me.CO.C_6H_4Me$ or $CH_2Ph.CO.CH_2Ph$, although its properties are not in accordance with either of these substances. Similarly, it is shown that the α-pyrocressol oxide obtained by the oxidation of pyrocressol with chromic acid has the empirical formula $C_{15}H_{12}O_2$; it forms a tetranitro-derivative, $C_{15}H_8(NO_2)_4O_2$, crystallising in golden needles, and a tetrabrom-derivative $C_{15}H_8Br_4O_2$, crystallising in long white leaflets melting at 215°. V. H. V.

Derivatives of α- and β-Naphthol. By E FRIEDLÄNDER (*Ber.*, **16**, 2075—2092).—The monohydroxy-phenols readily react with the monamines yielding the diamines with elimination of water; the best dehydrating agent for effecting this change is calcium chloride, and from the author's experiments it follows that the greatest yield is obtained when 1 mol. of the phenol and 2 mols. of the amine are heated with 1 mol. of calcium chloride. In this communication, the various compounds obtained by the action of aniline and the three toluidines on α- and β-naphthols are described.

Phenyl-β-naphthylamine, $C_{10}H_7.NHPh$, crystallises in white needles melting at 108°; *phenyl-α-naphthylamine* in white leaflets melting at 60°.

Paratolyl-β-naphthylamine, $C_{10}H_7.NH.C_7H_7$, forms white glistening leaflets melting at 102°; its acetyl and benzoyl-derivatives crystallise in needles; with excess of bromine a tetrabrom-compound is obtained, which forms glistening needles melting at 168°. *Paratolyl-α-naphthylamine* forms white prisms melting at 79°; *orthotolyl-α-naphthylamine* glistening needles melting at 95°. *Orthotolyl-β-naphthylamine* crystallises from petroleum in white leaflets melting at 96°; its *picrate* in reddish-brown needles, and its *benzoyl*-derivative in leaflets.

All the above-mentioned amines give colour-reactions with nitric and chromic acids; when heated with hydrochloric acid they are reconverted into the corresponding phenol and the hydrochloride of the amine. V. H. V.

Naphthalene-derivatives. III. By F. GRAEFF (*Ber.*, **16**, 2246—2255).—The action of nitric acid on naphthonitril takes place in two stages, nitronaphthonitril being first formed, and the CN-group subsequently converted into COOH, so that it is possible to stop the action after the first phase, and obtain nitronaphthonitril. For the nitration of the α-compound (20 grams) a mixture of 50 c.c. fuming nitric acid, sp. gr. 1·48, with 200 c.c. nitric acid, sp. gr. 1·3, is recommended, whilst for the β-compound 150 c.c. of the stronger acid to 100 c.c. of the weaker acid are employed. α-Naphthonitril yields three mononitro-derivatives, the chief product melting at 205° as previously stated (Abstr., 1881, 882). Another more soluble nitronaphthonitril melts at 152—153°, whilst the third compound, which has not yet been obtained pure, melts between 100° and 130°. A mononitro-derivative melting at 172—173° is readily obtained from β-naphthonitril, but the chief product melts between 95° and 120°.

Nitro-α-naphthonitril, $C_{10}H_6NO_2.CN$ (m. p. 152—153°), is more readily soluble in boiling water than its isomeride melting at 205°, very sparingly in light petroleum, more readily in carbon bisulphide, moderately in alcohol and glacial acetic acid, and very readily in benzene and in chloroform. It crystallises in yellowish coloured needles from alcohol, ether, and glacial acetic acid, and in lustrous scales from light petroleum. Nitro-β-naphthonitril (m. p. 172—173°) is very sparingly soluble in hot light petroleum, and sparingly in alcohol and glacial acetic acid, from which it separates either in single long crystals of golden lustre or in fern-like clusters; it is moderately soluble in ether and carbon bisulphide, more readily in benzene, and extremely soluble in chloroform. It may be obtained in large nearly white needles of great purity by sublimation. These nitronaphthonitrils are saponified by heating them with concentrated hydrochloric acid for five hours at 150—160°.

Nitro-α-naphthoic acid (m. p. 241—242°), obtained from the nitronaphthonitril melting at 205°, is moderately soluble in hot alcohol and glacial acetic acid, less so in ether and chloroform, still more sparingly in benzene and carbon bisulphide, and very sparingly in light petroleum and in water. It crystallises from spirit in flat, concentrically-grouped needles, and sublimes in the form of splendid lustrous scales.

The *potassium salt*, $C_{10}H_6NO_2.COOK + H_2O$, forms hard yellowish coloured crystals of a vitreous lustre. On boiling the acid with an excess of barium carbonate, a sparingly soluble *basic salt*,

$$5[(C_{10}H_6NO_2.COO)_2Ba],BaO + 10H_2O,$$

is obtained.

The *silver salt* forms a yellowish amorphous precipitate sparingly soluble in water; the *lead salt* resembles the silver salt and separates from its solution in boiling water in small wart-like forms; the *copper salt* is sparingly soluble in water, from which it separates in small bluish-green crystals; the *methyl-derivative* forms small yellow needles melting at 109—110°, and readily soluble in alcohol; the *ethyl-derivative* is much more sparingly soluble in alcohol, and crystallises in long, slender, well-formed needles melting at 93°; the *isopropyl-derivative* forms lustrous crystals melting at 101·5°, and sparingly soluble in alcohol.

Nitro-α-naphthoic acid melting at 255° dissolves readily in most solvents, and sublimes in long colourless needles. For want of material it has not been further examined.

Nitro-β-naphthoic acid melts at 295°, and in most of its properties resembles the acid melting at 241—242°. It is insoluble in water, sparingly soluble in ether, light petroleum, benzene, chloroform and carbon bisulphide, moderately in hot alcohol and glacial acetic acid; it sublimes in small nearly colourless needles. The *potassium salt*, $C_{10}H_6NO_2.COOK + H_2O$, forms small clusters of lustrous needles very readily soluble in water. On boiling the acid with barium carbonate, two salts are obtained, a more sparingly soluble *acid* salt,

$$6[(C_{10}H_6NO_2.COO)_2Ba],C_{10}H_6NO_2.COOH + 24H_2O,$$

crystallising in small lustrous scales, and a more soluble *normal* salt also crystallising in scales. The *methyl-derivative* is sparingly soluble in alcohol, from which it crystallises in clusters of large bright yellow needles, melting at 112°; the *ethyl-derivative* is readily soluble in alcohol, and crystallises in large well-formed dark yellow needles melting at 109°; the *isopropyl-derivative* forms long silky needles melting at 75—76°, and readily soluble in alcohol. This acid appears to be the same as that obtained by Ekstrand (*Ber.*, **12**, 1395) from β-naphthoic acid, but which melted at 280° owing to the presence of impurities. A. K. M.

Reduction of Dichlorophenanthrone. By B. LACHOWICZ (*J. pr. Chem.* [2], **28**, 168—175).—The preparation and properties of dichlorphenanthrone (phenanthrenedichloroketone) have already been described by the author (Abstr., 1883, 666). The formation of resinous bye-products is minimised by adding excess of benzene to the phenanthraquinone before running in the phosphoric chloride. Nitric acid readily converts it into the nitro-derivatives of anthraquinone.

Monochlorphenanthrone, $C_{14}H_9OCl$, is obtained by the reduction of dichlorophenanthrone with iron and acetic acid; it crystallises in large yellow prisms, melts at 122—123°, is readily soluble in alcohol, ether, benzene, light petroleum, &c. It dissolves without decomposition in alkalis, and is not decomposed by long boiling with alcoholic ammonia. By heating with nitric acid of sp. gr. 1·3 it yields *nitrophenanthroquinone*, $C_{14}H_7NO_4$, crystallising in orange-yellow plates, melting at 281—282°, and soluble in glacial acetic acid and nitric acid.

Phenanthrone, $C_{14}H_{10}O$, is obtained by the long-continued action of nascent hydrogen on dichloranthrone, best by gradually adding iron filings to a solution of dichloranthrone in glacial acetic acid heated to 100—110°. Too strong heating leads to the formation of resinous products. It crystallises in brilliant brownish-red tables, melts at 148—149°, resembles the monochloro-derivative in solubilities, and like it, is not decomposed by aqueous alkalis.

The authors consider that phenanthrone has the structural formula  $\begin{array}{l} C_6H_4.CH_2 \\ | \quad\ \ | \\ C_6H_4.CO \end{array}$, whilst the isomeric compound obtained by Japp and Streatfeild from ethyl phenanthroxyleneisocrotonate (Trans., 1883, 33) may probably be represented by  $\left.\begin{array}{l} C_6H_4.CH \\ | \quad\ \ | \\ C_6H_4.CH \end{array}\right\rangle O$.

A. J. G.

Coloured Essential Oils. By K. HOCK (*Arch. Pharm.* [3], 21, 17—18).—The essential oils of chamomile, wormwood, and millefolium, although differing in colour, were found by the author to have the same absorption-spectrum, namely, three bands in the red and orange. When these oils were submitted to fractional distillation, in each case the portion which distilled at 260° was deep blue, and yielded the same absorption-bands with great distinctness. The blue oils obtained from *Matricaria chamomilla*, *Ferula sumbul*, *Nectandra puchury*, *Inula helenium*, *Pogostemon patschuly*, also by the dry distillation of galbanum, guaiacum, and asafœtida resins, as well as a blue product from oil of valerian, gave the same characteristic absorption-spectrum. From these results, the author concludes that all these blue oils contain the same colouring-matter, *azulene*, which in some cases is present in the plant from which the oil is obtained, in others, is produced by the action of water on some constituent of the plant during distillation, and sometimes is formed by destructive distillation. In the case of those essential oils from which the blue portion was obtained by distillation, an oil oxidised by keeping appeared to yield a larger quantity of the blue product than the same quantity of the fresh oil.

W. R. D.

Destructive Distillation of Colophony. By A. RENARD (*Compt. rend.*, **97**, 111—112).—When colophony is introduced into an earthenware retort heated to dull redness it is decomposed, and yields a large quantity of combustible gas rich in hydrogen, and a black, somewhat fluid tar, mixed with a small quantity of water. The tar when distilled at a temperature rising to 300° yields a resin which solidifies on cooling, and a liquid which contains benzene and its homologues, a small quantity of naphthalene, and other oils which have not been studied. The residue from the distillation of this liquid is mixed with the resin, and the mixture distilled as far as possible. A residue of coke is left, and an oil was obtained which becomes semi-solid on cooling. This oil contains two isomeric hydrocarbons, *colophanthrenes*, which have the following composition:—

	White.		Yellow.
Carbon	93·02	93·20	93·20
Hydrogen........	7·18	7·01	6·71

The yellow colophanthrene is very slightly soluble in alcohol, from which it separates in yellow crystals with a greenish fluorescence. It boils at about 360°, and by repeated crystallisation from alcohol it appears to be converted into the white isomeride. The white colophanthrene is much more soluble in alcohol, from which it is deposited in brilliant white crystals, with a violet fluorescence. It melts at about 87°, boils at about 340°, and by repeated distillation is partially converted into the yellow isomeride. It also acquires an orange-yellow tint when exposed to light. Both hydrocarbons begin to decompose at the boiling point of sulphur (440°). When oxidised by chromic acid in acetic acid solution, they both yield carbonic anhydride and a diketone, which yields a sulphonic acid. The potassium salt of this acid when heated in a sealed tube at about 170° with a concentrated solution of potassium hydroxide is converted into a deep violet substance; this dissolves in water, and is decomposed by hydrochloric acid, yielding a colouring-matter, which imparts to cotton mordanted with alumina a shade similar to that given by alizarin. C. H. B.

Extraction of Colouring-matters by a Solution of Borax. By R. PALM (*Chem. News*, **48**, 114).—For the extraction of alizarin and purpurin from garancin, the author digests the garancin with a cold saturated borax solution until a deep blood-red solution is obtained; this is filtered, and precipitated with sulphuric, hydrochloric, or acetic acid. The precipitate is boiled with a saturated solution of alum, filtered, and cooled; the alizarin and purpurin then deposited are filtered off, and a further quantity of the colouring-matter is precipitated from the filtrate on adding sulphuric acid. The author also employs borax solution for the extraction of santalin from sanders wood, and violet colouring-matter not identical with carmine from cochineal. D. A. L.

Cochineal Dye-stuffs. By H. FÜRTH (*Ber.*, **16**, 2169—2171).—By acting on carmine with sulphuric acid, Liebermann and v. Dorp have obtained a brown amorphous dye-stuff, ruficoccine, $C_{16}H_{10}O_6$, which on distillation with zinc-dust is converted into an anthracene-like hydrocarbon of composition $C_{16}H_{12}$ (*Annalen*, **163**, 97). The author has succeeded in obtaining this hydrocarbon not only from coccinine, a quinone derivative of carmine, but also directly from carmine. This hydrocarbon, which condenses in small green-gold leaflets when coccinine or carmine are distilled with zinc-dust, melts at 186°, and is soluble in ether, alcohol, and benzene. By heating acetic chloride and coccinine in sealed tubes at 100°, an acetyl-derivative is obtained, which forms small golden crystals insoluble in water, soluble in alcohol; it cannot be sublimed without decomposition. As coccinine yields a C_{16} hydrocarbon on distillation, the composition $C_{14}H_{12}O_5$, assigned to it by Hlasiwetz and Grabowsky, must be altered to $C_{16}H_{14}O_6$, and its acetyl-compound will then be a tetra-derivative, $C_{16}H_{10}O_2\overline{Ac}_4$. Coccinine is thus a tetrahydroxy-quinone, $C_{16}H_{10}O_2(OH)_2$, which formula is in accordance with its quinone-like characteristics.

V. H. V.

Preparation of Diquinoline. By R. C. TRESSIDER (*Chem. News*, **48**, 31).—Quinoline hydrochloride is heated with an equal weight of zinc chloride at 350° for five or six hours, the flask being fitted with a reflux arrangement. Soda is added to the product until the zinc hydroxide first precipitated is redissolved, the mixture is steam distilled to remove any unchanged quinoline, and the residue which is black and solid is well washed with water, boiled with a large quantity of alcohol, and filtered hot. The filtrate is decolorised with animal charcoal, and again filtered hot: on cooling, diquinoline separates out, and is recrystallised from alcohol. The yield is not large.

D. A. L.

Hydroxycinchonic Acid. By W. KÖNIGS and G. KÖRNER (*Ber.*, **16**, 2152—2160).—By fusing cinchonic acid with potash, one of the authors has obtained a hydroxycinchonic acid, $C_9H_5N(OH).COOH$ (Abstr., 1879, 472); this acid is converted into a chloro-derivative, $C_9H_5ClN.COOH$, by phosphorus pentachloride, and by heating with hydriodic acid and phosphorus into the amorphous hydroquinoline, $(C_9H_9N)_2$. This last reaction shows that the hydroxyl-group is not in the benzene, but in the pyridine nucleus; and in the present communication this supposition is confirmed, and it is further shown that hydroxycinchonic acid is a carboxyl-derivative of carbostyril.

The authors were unable to obtain a hydroxyquinoline by distilling hydroxycinchonic acid with bases; but on heating its silver salt, $C_9H_5(OH).COOAg$, in a current of carbonic anhydride, a sublimate was formed crystallising in needles, and having the characteristic properties of carbostyril.

Chlorocinchonic acid, when heated with sodium alcoholate, yields *ethoxycinchonic acid*, $C_9H_5N(OEt)COOH$, which crystallises in hairy needles melting at 145°, soluble in hot water, alcohol, and dilute mineral acids; its *silver* and *lead* salts are sparingly soluble precipitates, of which the former is an acid salt of composition

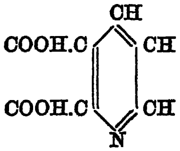
$$C_9H_5N(OEt).COOAg,C_9H_5N(OEt).COOH;$$

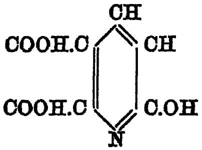
its platinochloride, $[C_9H_5N(OEt),COOH]_2.H_2PtCl_6$, is crystalline.

When ethoxycinchonic acid is heated to a temperature slightly above its melting point, it is transformed into the isomeric ethyl salt of hydroxycinchonic acid, $C_9H_5N(OH).COOEt$, also obtained by the action of ethyl iodide on silver hydroxycinchonate. This salt crystallises in needles melting at 206°, and, unlike its isomeride, is insoluble in dilute acids or alkalis. The intermolecular change of the ethoxy-acid into the ethyl salt of the hydroxy-acid probably prevents the elimination of carbonic anhydride from the acid, when it is heated with lime. When the silver hydrogen salt is heated in a current of carbonic anhydride, ethylcarbostyril and the ethyl salt of ethoxycinchonic acid are produced. The latter substance, which can also be prepared from ethyl iodide and the silver salt, crystallises in fine needles melting at 86°.

From these researches it follows that hydroxy- and ethoxy-cinchonic acids are derived from carbostyril, and as cinchonic acid is converted into pyridine tricarboxylic acid by oxidation with potassium permanganate, the carboxyl-group is in the pyridene nucleus.

In cinchonic and hydroxycinchonic acids, the N-atom and the carbon to which the COOH-group is united, are probably in the para-position to one another. The authors have also succeeded in converting quinolinic, or pyrididinecarboxylic acid, into hydroxyquinolinic acid by melting the former with potash. The relations of these acids is evident from the following formulæ:—





The latter forms colourless crystals melting at 254° of strongly marked acid properties; its aqueous solution gives a deep red coloration with ferric chloride, and voluminous precipitates with copper, lead, and silver salts. Its hydrogen barium salt crystallises in tufts of needles; its hydrogen silver salt, when heated in a current of carbonic anhydride yields a compound having all the characteristic properties of oxypyride, C_5H_5NO. V. H. V.

Oxidation of Morphine. By L. BARTH and H. WEIDEL (*Monatsh. Chem.*, 4, 700—703).—The action of most oxidising agents on morphine does not yield very definite results; potassium permanganate however in slightly alkaline solution acts on it somewhat more energetically, yielding as chief product a light-brownish uncrystallisable acid syrup, which forms amorphous salts, and when mixed with cupric acetate, remains clear at first, but becomes turbid on boiling, depositing a blue-green flocculent precipitate, which redissolves on cooling. This result is like that which is obtained by similar treatment of cinchomeronic and pyridine-tricarboxylic acids. Morphine subjected to dry distillation with lime yields a basic oil having a decided odour of pyridine. Arsenic acid acts but slowly on morphine even in sealed tubes, yielding a base which appears to contain one methyl-group less and one hydroxyl-group less than morphine; the action is however variable and so are the products. When morphine is heated with potassium hydroxide till the surface of the melt begins to glow, and the product, after cooling, is acidulated, brown-black non-nitrogenous flocks are deposited, and a solution is obtained from which ether extracts a considerable quantity of substance; and on expelling the ether, digesting the residue with water, precipitating the filtrate with lead acetate, decomposing the precipitate with hydrogen sulphide, evaporating, and repeatedly crystallising the residue, a product is obtained, consisting of protocatechuic acid. The filtrate freed from lead and evaporated yields more protocatechuic acid, together with another acid which crystallises in prisms, and gives no colour-reaction with iron salts.

When the melting with potash was conducted in a silver retort, and the vapours were received in dilute hydrochloric acid, methylamine was obtained, together with a small quantity of another base.

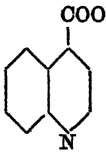
The absence of aromatic compounds amongst the products formed by oxidising morphine with permanganate, and the non-occurrence of derivatives of pyridine (or quinoline) in the oxidation of this alkaloid with caustic alkali, seem to show that the mode of combination of the aromatic and of the pyridine- (or quinoline-) groups in it, is different from that which exists in narcotine, which, it is well known, is easily resolved into its two principal constituents. H. W.

Constitution of Quinine and Quinidine. By Z. H. SKRAUP (*Monatsh. Chem.*, 4, 695—699).—The author has already shown (Abstr., 1882, 279) that these two alkaloids, when oxidised by chromic acid, yield carbonic anhydride and quininic acid, $C_{11}H_9NO_3$, which latter, when heated with hydrochloric acid, gives methyl chloride and xanthoquinic acid, $C_{10}H_7NO_3$, resolvable by heat into CO_2 and a hydroxyquinoline, $C_9H_7NO = C_9H_6(OH)NO_2$; further that quininic acid is converted by oxidation with permanganate into a pyridine-tricarboxylic acid, $C_5H_2N(COOH)_3$, identical with that which is obtained from cinchoninic acid: hence it is probable that quininic acid is a derivative of quinoline, and that its methyl-group is situated in the benzene-residue of the quinoline-molecule; hence also it may be inferred that the hydroxyquinoline obtained from xanthoquinic acid has its hydroxyl-group situated in the benzene residue. According to existing views there should be only four hydroxyquinolines thus constituted. Three are already known, and the main object of the present investigation is to ascertain whether the hydroxyquinoline obtained in the manner just mentioned is identical with either of these three, or consists of the hitherto unknown fourth modification.

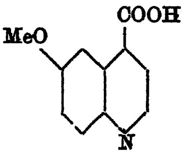
Xanthoquinic acid is for the most part resolved at 310° into carbonic anhydride and a hydroxyquinoline, which when purified by conversion into platinochloride, &c., crystallises from absolute alcohol in slender white prisms, soluble in alcohol without coloration, the solution however acquiring, on addition of water, a faint yellow colour, which disappears on further addition of alcohol. This behaviour distinguishes the hydroxyquinoline in question from the *meta*-modification, the alcoholic solution of which exhibits a splendid green fluorescence. From the *ortho*-modification it is distinguished by giving, on addition of ferric chloride to its alcoholic solution, not a green, but a reddish coloration. With *para*-hydroxyquinoline on the other hand it agrees very nearly in its melting point (194°), and further in the yellow coloration of its alcoholic solution by ferric chloride; in giving with picric acid slender yellow prisms melting at 235—235·5°; with cupric acetate, first a fine blue-green colour, then gradually violet prisms which dissolve in boiling alcohol with a fine leaf-green colour, and remain unaltered on evaporation.

This hydroxyquinoline dissolves readily when gently heated with four times its weight of strong nitric acid, and the solution, when quickly cooled and cautiously diluted with cold water, deposits orange-red crystals, easily soluble in hot water, the solution slowly mixed with potash-lye, depositing yellowish prisms, which, after recrystallisation from dilute alcohol, melt, like nitro-*p*-hydroxyquinoline, at 140—141°. The alcoholic solution, mixed with cupric acetate, first turns bright green, and then deposits a copper-brown precipitate, or if a trace of alkali be added, a green precipitate. The barium salt of the nitro-compound forms orange-red needles, slightly soluble in cold, much more freely in boiling water.

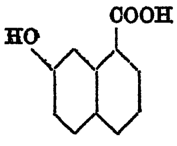
Cinchoninic, quininic, and xanthoquinic acids may be represented by the following constitutional formulæ:—



Cinchonic acid.



Quininic acid.



Xanthoquinic acid.

H. W.

Cinchonamine. By ARNAUD (*Compt. rend.*, **97**, 174—176. See also Abstr., 1882, p. 229).—Cinchonamine, $C_{19}H_{24}N_2O$, exists in *Remijia purdiana*, but is not contained in *R. pedunculata*, which contains quinine. To extract cinchonamine, the finely powdered bark is exhausted with very dilute sulphuric acid, the solution filtered, boiled, and precipitated with milk of lime. The precipitate is dried on porous tiles, and digested with boiling ether. The ethereal solution is decanted from undissolved resinous substances, &c., washed with dilute hydrochloric acid, which removes the cinchonamine, and the acid solution of cinchonamine hydrochloride is evaporated to crystallisation. The hydrochloride is dissolved in boiling dilute acid, filtered through animal charcoal, and recrystallised. The free base is obtained by adding ammonia to a solution of the hydrochloride, and crystallising the alkaloïd from boiling ether. An alcoholic solution of the alkaloïd is dextrogyrate, its rotatory power at 97° being

$[\alpha]_D = 122\cdot2°$. According to Dr. Laborde, cinchonamine is highly poisonous, even in very small doses.

The salts of cinchonamine generally crystallise readily, and are but slightly soluble in water, especially in presence of free acid. They dissolve in hot alcohol, from which they crystallise on cooling. The *hydrochloride* crystallises from an acid solution in thin, brilliant, anhydrous, prismatic lamellæ, very slightly soluble in acidulated water. From a neutral aqueous solution, the salt crystallises in opaque flattened prisms containing 1 mol. H_2O. These crystals effloresce, and are much more soluble in water than the anhydrous salt. This property of the hydrochloride to crystallise in an anhydrous condition from acid solutions furnishes a method of separating cinchonamine from all the alkaloids with which it is associated in *R. purdiana.* The *hydrobromide* forms brilliant, slender, anhydrous needles, slightly soluble in cold water, much more soluble in hot water. The *hydriodide* crystallises in micaceous plates, almost insoluble in cold water. The *nitrate* is only slightly soluble in cold alcohol, but is much more soluble in hot alcohol, from which it crystallises in hard, thick, short prisms. This salt is slightly soluble in pure water, but is insoluble in acidulated water, and is precipitated on adding nitric acid to even a dilute aqueous solution of any cinchonamine salt. The precipitate is at first flocculent, but, on standing, it rapidly becomes crystalline, the crystals being small prisms, which polarise light. At 15°, 100 parts of alcohol of 94° dissolve 0·825 part of the salt; 100 parts of water at the same temperature dissolve 0·2 part of salt. The *sulphate* can be purified by crystallisation from alcohol. A solution of the salt in water containing 1 mol. H_2SO_4 has a rotatory power at 15° $[\alpha]_D = +\ 43\cdot5$; at 25° $[\alpha]_D = +\ 42\cdot2$. The *formate* crystallises with difficulty. The *acetate* is very soluble in water, from which it is deposited as a resinous mass on evaporation. By spontaneous evaporation of the aqueous solution the salt is obtained in deliquescent crystalline concretions. The *oxalate* does not crystallise from an aqueous solution, but is deposited in a resinous form. The *tartrate* forms a crystalline powder consisting of small hexagonal prisms which polarise light. 100 parts of water at 15° dissolve 1·150 parts of the salt. The *malate* forms brilliant nacreous plates, very slightly soluble in cold water, but somewhat soluble in boiling water. The crystals retain 1 mol. H_2O at 120°, but melt and become anhydrous at 160°. 100 parts of water at 15° dissolve 1 part of malate. The *citrate* is deposited from a boiling solution on cooling as a resinous mass, which gradually becomes crystalline, forming concretions composed of brilliant prisms which polarise light. 100 parts of water at 16° dissolve 1·950 parts of the citrate. C. H. B.

Conversion of Brucine into Strychnine. By HANRIOT (*Compt. rend.*, **97**, 267—268).—The author has repeated Sonnenschein's experiments (*Ber.*, 8, 212), and finds that strychnine is not produced by the action of nitric acid on pure brucine. Sonnenschein's experiments were probably made with impure brucine. Brucine has the power of completely masking the ordinary reaction for strychnine (with sulphuric acid and dichromate), even when the latter is present to the extent of 50 per cent. It is evident therefore that the presence of strychnine in many samples of brucine may easily have been overlooked, and this will probably account for the confusion which exists as to the physiological action of brucine. Morphine, quinine, methyl alcohol, and many other substances also have the property of masking the strychnine reaction. C. H. B.

Products of the Bacterial Fermentation of Albuminoïds. By A. Gautier and A. Étard (*Compt. rend.*, **97**, 263—267. See also Abstr., 1882, 1115; and 1883, 100 and 224.)—The authors have previously shown that the putrefaction of albuminoïds results in the formation of leucines, glucoproteïns, nitrogenous and non-nitrogenous acids, phenol, skatole, indole, tyrosine, trimethylamine, ammonia, and ptomaïnes. Whatever the variety of the ferment and the source of the putrefying flesh, the principal ptomaïnes formed are constant in properties and composition.

The liquid and solid putrid matter is distilled in a vacuum at a low temperature. The distillate (A) contains ammonium carbonate, phenol, skatole, trimethylamine, and volatile fatty acids; the residue is treated successively with ether and alcohol. The ethereal solution (B) contains ptomaïnes and a fatty acid, and holds in suspension very light, brilliant, white nacreous plates. The alcoholic solution (C) contains fatty acids and crystallisable nitrogenous compounds. The residue insoluble in ether and alcohol is boiled with very dilute hydrochloric acid out of contact with air, the solution evaporated and treated with alcohol (D).

The ethereal solution (B) when distilled leaves a brown oil, from which a large quantity of fatty acid crystallises out. The mother-liquor is acidified with sulphuric acid, saturated with potash, and agitated with ether, which dissolves the ptomaïnes. A solution of the ptomaïnes from beef treated in the cold with platinum tetrachloride, care being taken to avoid an excess, yields a precipitate of the composition $(C_8H_3N)_2,H_2PtCl_6$. It is the platinochloride of a hydrocollidine, identical with the base previously obtained from fish (*loc. cit.*). The mother-liquor from this platinochloride contains another platinochloride, which forms yellowish crystals of the composition C, 28·73; H, 5·8; N, 7·19; Pt, 27·93. It is partially decomposed at 100° with development of the hawthorn-like odour of its alkaloïd.

The brilliant plates held in suspension by the ethereal solution consist of the calcium salt of amido-stearic acid, $C_{18}H_{35}(NH_2)O_2$. This is almost insoluble in all solvents, but is dissolved slightly by alcohol. When treated with hydrochloric acid, it yields amido-stearic acid, which is insoluble in water, only slightly soluble in cold alcohol, but readily in hot alcohol, from which it crystallises in aggregated needles on cooling. It melts at 63°, and when heated at about 140° it loses 1 mol. of water, and yields the anhydride, $C_{18}H_{35}NO$. The amido-stearic acid is obtained from beef: the nacreous plates obtained from putrid fish are soluble in alcohol and in potash, but are insoluble in water and acids. By treatment with inorganic acids they yield an acid of the composition, $C_8H_{20}N_2O_3$. When they are fused with potassium hydroxide, ammonia is given off, and a mixture of alkaline caprylate, caproate, and acetate is formed.

The alcoholic solution (C) contains the greater part of the leucines and leucoproteïns. After evaporation, the residue is treated with inorganic acids, the aqueous liquid separated from the liberated fatty acids, concentrated by evaporation, and treated with alcohol, which dissolves out leucines and leuceïnes, particularly those containing C_5 and C_6. The principal compound thus obtained from putrid fish forms white rhomboidal lamellæ, somewhat soluble in water, and somewhat easily sublimed; it has the composition $C_{11}H_{26}N_2O_6$, and appears to be the hydroxide of the glucoprotein, $C_{11}H_{22}N_2O_4$, obtained by Schützenberger from the products of the decomposition of albuminoïds by baryta. It has the general properties of amido-acids, and dissolves in dilute alkalis; when fused with potassium hydroxide, it yields hydrogen, ammonia, and potassium carbonate, butyrate, and valerate, a portion splitting up at the same time into the corresponding leucines and leuceines. When distilled at about 280°, it yields an amylamine boiling at 92—93°, which is probably formed together with amido-valeric acid in accordance with the equation $C_{11}H_{26}N_2O_6 = C_5H_{13}N + C_5H_9NO_2 + CO_2 + 2H_2O$. C. H. B.

Albumin, Nucleïn, and Plastin. By E. ZACHARIAS (*Bied. Centr.*, 1883, 405—407).—The principal portions of the nitrogenous substances of plant cells, insoluble in alcohol, consist of albumin, nuclein, and plastin, the two latter are attacked but slightly, or not at all, by the gastric juices; on the contrary, they readily dissolve albumin. Plastin is insoluble in very dilute solutions of alkalis, nuclein is easily soluble in these menstrua; plastin and nuclein are the soluble and insoluble nucleins of other authors. The supposition of Schimpers that the substance from which starch is produced is similar to albumin, at least to a great degree, the author believes he has confirmed by researches on the leaves of *Tradescantia virginea* and orchis.

Albumin diminishes and plastin increases in the protoplasm of the cells examined; according to Hartig's reaction. sections soaked in a dilute solution of potassium ferrocyanide, and then transferred to a very dilute solution of ferric chloride, show the nucleus deep blue, whilst in the ducts no trace of a blue colour is visible. When portions of the epidermis of the leaves of those plants are so treated, the starch material becomes intensely blue, the cell protoplasm remains colourless, or is coloured only in points. The nuclei show a blue coloration, as also the nucleoli; the plastin is colourless or very slightly coloured.

The author does not think that the chemical constitution of the nuclei and nucleoli can be ascertained from these reactions, but they are aids to that knowledge. J. F.

Physiological Chemistry.

Influence of Respiration on Elimination. By F. PENZOLDT and R. FLEISCHER (*Bied. Centr.*, 1883, 285).—Want of oxygen sufficient to induce the dyspnœic condition, causes an increased excretion of urine and urea, as also of phosphoric acid; the after-action is lowering of phosphoric acid, but raising of urea, the absolute result being no change in the total excretion of acid and urea, and no separation of sugar or albumin. If, however, the animal is fasting, then whilst there is a want of oxygen, there is a slight increase in urine, a considerable rise in urea and phosphoric acid; during the after-action urea still increases, but phosphoric acid decreases, so that there is an absolute increase in the excretion of urea, but no phosphoric acid, albumin, sugar, nor allantoïn. When no dyspnœa accompanied the want of oxygen, then a well-nourished dog excreted more urine and phosphoric acid, but less urea, whilst during the after-action there was an increase in water, urea, phosphoric and sulphuric acids. On the whole, an absolute increase of these four compounds with traces of albumin; the case was similar when a fasting dog was experimented on, save that sodium chloride behaved as urea.

The diminished supply of oxygen when accompanied by dyspnœic action affects birds, and causes them to excrete an excess of uric acid. Apnœa causes a rise of urea, a fall of phosphoric acid, and afterwards a considerable increase of both. Increased elimination of water is accompanied by a lowered excretion of urea. Increased muscular action induces great increase of urea, at first a large decrease, later on an increase, and on the whole a slight absolute increase of phosphoric acid. Reduction of the temperature of the body is followed by increase of urea. E. W. P.

Exhalation of Carbonic Acid by Frogs. By H. AUBERT (*Bied. Centr.*, 1883, 427).—The author finds that the process of exhalation is as active in an atmosphere which is deprived of oxygen as in one which contains it. The same observation has been made by Pflüger, and can only be explained on the supposition that the process depends on the decomposition of organic compounds independent of the presence of atmospheric oxygen. J. F.

Alteration of Cane-sugar in the Human Stomach. By W. LEUBE (*Bied. Centr.*, 1883, 427).—100 c.c. of a 10—15 per cent. cane-sugar solution were introduced into an empty stomach seven hours after a previous meal, or in the morning before the subject had eaten, the stomach having been previously rinsed and the rinsings tested with Trommer's test to negative reaction. Half an hour after introducing the sugar, there was no reaction, or very trifling, whereas in a known unhealthy stomach the reaction was considerable. The explanation appears to be that in the healthy stomach the inverted sugar is absorbed, which is not the case in the unhealthy one. The gastric juices of both healthy and sick persons cause the inversion of cane-sugar equally outside the body, but if a solution is introduced in equal parts into the stomachs of living subjects and withdrawn half an hour afterwards, the difference in the reducing power is most marked, the healthy stomach showing no reaction, whilst the unhealthy does very strongly. J. F.

Comparative Value of Artificial and Natural Butter as Articles of Food. By A. Mayer (*Landw. Versuchs.-Stat.*, 29, 215—232).—In estimating the value of any article of food, the points to be dwelt on are chiefly its nutritive qualities, taste, and action on the system, whether injurious or otherwise. In the case of butters of various origin, the last two points are easily settled, as a positively injurious influence has never been seriously ascribed to artificial butter. The nutritive qualities of butter were therefore the subject of this investigation.

Experiments were made with a man and a boy, who received a certain quantity of food per diem, as to whether artificial or natural butter was the more easily absorbed by the system. The first three days they were fed with various mixtures of bread, milk, eggs, and vegetables, together with natural butter; then followed two days' rest with ordinary diet, and afterwards three days with precisely the same diet as before, with the exception that artificial was substituted for natural butter. On each successive day of the experiment the solid evacuations were collected and analysed, commencing 24 hours after the beginning of the experiment. The amount of fat in these was estimated, and hence the quantity of fat absorbed into the system was found. This quantity is given in percentage of the whole amount in the food in the table below:—

	Day of experiment.		
	1.	2.	3.
Man.			
Natural butter	97·0	99·4	98·7
Artificial „	94·6	97·9	96·7
Boy.			
Natural butter	97·8	94·8	98·7
Artificial „	95·3	94·6	97·6

On the average, therefore, about 1·6 per cent. less of the artificial butter was absorbed than of the natural. As this quantity is, however, very small in comparison to the total amount absorbed, the difference in value of the two substances as articles of food can be set down as only trifling, and except in cases of illness may be overlooked with safety. J. K. C.

Digestive Fluid and Digestive Power of the Horse. By Ellenberger and Hofmeister (*Bied. Centr.*, 1883, 386—389).—It being difficult to obtain the natural digestive fluid of the horse, an artificial one was prepared by cutting up the coating of the stomach containing the ducts into very small bits; it was then washed and neutralised, either at once or after treatment with alcohol, dried, and left from 24 hours to eight days in contact with an extracting fluid, which treatment dissolves out all the ferments and acids. The fluids used were:—1. Water; 2, glycerol; 3, 0·2 to 0·5 per cent. HCl; 4, 0·2 to 0·5 per cent. lactic acid; 5, 0·2 to 0·5 HCl in glycerol; 6, same proportion lactic acid in glycerol.

The extract obtained from the part near the intestine contained more mucin, acids, and ferments, and dissolved albumin more easily than the extract from the region of the pylorus.

The extract from the whole stomach contains both hydrochloric and lactic acids, but not more than 0·04 per cent. apparently. It also contains a very active ferment, which alters albuminous substances to peptones, and so changes gelatin that it becomes easily diffusible and loses its properties. The ferment is sparingly soluble in water, glycerol, hydrochloric acid, or in alkaline solutions, and it is precipitated by alcohol, lead acetate, carbonate of magnesia, &c. It is only active in presence of acids, and is destroyed by putrefaction and alcoholic yeasts. Lactic ferments do not influence its activity when the lactic acid is not too highly concentrated. Its activity is greatest in presence of 0·15 to 0·5 per cent. hydrochloric acid; too much or too little acid impedes the action of the pepsin, much lactic acid in the stomach disturbs the digestion through irritation of the coating of the stomach.

Pepsin must be present in certain quantity in the digestive fluid; its activity increases according to its quantity up to a certain point, when further quantity is injurious. It works only in presence of water, and best at a temperature of 37° to 55°; raising and lowering the temperature disturbs the operation; at 60° it becomes quite inert. Pure gastric juice contains rennet, lactic acid, fat and starch ferment, the two latter in unimportant quantity.

The gastric juice of the horse does not dissolve cellulose, and with difficulty the substance of bone or horn, but acts readily on muscle, sinew, fat, and flesh. Pepsin extract may be preserved for a long time in weak carbolic or salicylic acid solution, and even in pure glycerol without losing its properties. J. F.

Milk Secretion. By SCHMIDT (*Bied. Centr.*, 1883, 382—386).—The author, after reviewing much of the previous literature of the subject, reports the result of his own investigations on the activity of the milk glands of the cow: the experimental animal was of Dutch breed, middle aged, yielding 12 litres of milk daily. The experiments were conducted thus: 500 c.c. were taken from the two hinder spins of the udder at the commencement of the morning milking, and the same quantity from the same spins at the conclusion of the milking; both were carefully analysed according to the usual methods. Only the results of the first day's analysis are given, the others differing slightly, if at all, and not affecting the author's conclusions. 100 grams of the milk contained—

	First milk.	Last milk.
Total solids	9·20 grams.	13·64 grams.
Caseïn	2·24 ,,	2·11 ,,
Albumin	0·31 ,,	0·29 ,,
Peptone	0·10 ,,	0·12 ,,
Fat	0·76 ,,	5·60 ,,
Sugar	5·08 ,,	4·92 ,,
Ash	0·69 ,,	0·66 ,,

It will be seen that the difference between the total solids consists almost entirely in the fat, which is almost absent from the first milk; this is explained by the theory that the fat corpuscles of the milk adhere to the walls of the ducts, and besides that in the udder itself a certain separation takes place. The author had an opportunity of examining the udder of a cow killed immediately after milking, and found that the ducts did actually contain a notable residue of rich milk.

The fat excepted, the great body of milk secreted by a cow appears to have a tolerably uniform composition, and the separation of the fat in the udder to be a mechanical operation, and that the whole of the fat is rarely obtained in the milking. J. F.

Percentage of Fat in Milk of Cows of Different Breeds. (*Bied. Centr.*, 1883, 285.)—Pure Simmenthal gave 13 per cent. cream, after 12 hours' standing; Dutch, 7 per cent. cream, after 24 hours, 8 per cent.; cross between Simmenthal and Graubünden, 12 per cent., after 24 hours, 12·5 per cent.; cross of Dutch and Simmenthal, 9 to 9·5 per cent.; pure Graubünden, 13 per cent.; cross between Dutch and Graubünden, 10 per cent. E. W. P.

Excretory Product from the Liver of the Cuttle Fish. By A. B. Griffiths (*Chem. News*, **48**, 37).—The author observed some peculiar roundish masses of a dark-coloured substance in the anterior portion of the liver of the cuttle fish; some of these were collected and examined. When ignited, they charred, and left an ash, which contained copper. The following are the results of observations made under the microscope: the masses were stained brown by a solution of iodine in potassium iodide; potash dissolved them; a red colour was produced with Millon's reagent; and nitric acid produced a yellow coloration, which was turned red by potash. On boiling them with hydrochloric acid, a blue colour is formed, which changes to violet, and finally becomes brown. On heating them with solid potash, ammonia is evolved. By boiling a solution of the substance in potash with lead hydroxide, lead sulphide is produced. From these results the author infers that these masses are albuminoïd in character, and assuming them to be deposited from the secretion, it is evident that the secretion must contain albumin, and as the pancreatic fluid in higher animals is one of the few secretions which contain soluble albumin, the author is of opinion that this investigation supplies further support to the supposition that the liver of the cephalopod is not a true liver, but is pancreatic in function. The copper is derived from the blood. The dark colour of the masses was a very thin superficial covering. D. A. L.

Behaviour of Blood with Ozone. By BINY (*Bied. Centr.*, 1883, 283).—The red corpuscles in blood are unaffected by remaining for an hour in contact with ozone, unless the quantity of blood is small, or the duration of contact long; then a gradual change of colour and shape occurs. Ozonised air passed through blood is not completely altered. E. W. P.

Cattle Disease occasioned by Town Sewage. (*Bied. Centr.*, 1883, 285.)—The death of many cows was occasioned by fungoid growths in the grass of meadows irrigated with sewage. E. W. P.

Observations on Different Diseases of Animals. By ROLOFF and others (*Bied. Centr.*, 1883, 389—393).—Experiments were made at the Veterinary School, Berlin, by Roloff, on the protective inoculation of cattle against lung disease. Two cows, two heifers, and two calves were inoculated with the preparation and placed in infected stables; none of them took the disease, but neither did a non-inoculated animal placed in the same stable: the experiment was therefore abortive. Opinions of other observers are cited on the question of protective inoculation against this particular disease. Pasteur finds that the specific poison cannot be cultivated in chicken or veal broth; that it preserves its vitality when kept at a high temperature in a dry room, and does not produce micrococci, but that, when kept without such precaution, it does produce them and loses its vitality.

If the poison is fouled by the addition of a few cow hairs before use, it is harmless; the portion kept at ordinary temperatures reproduces itself in the inoculated animal, and lymph taken from that animal communicates it to others After six to eight weeks from taking the poison from an infected animal, it loses its vitality: a calf into whose jugular vein such old poison was injected, withstood it. The discovery of the bacillus of glanders by Löfler and Schütz is next noticed; the rods were isolated from sections of a diseased organ, and cultivated in the blood of horses and sheep. It was tried on rabbits, mice, and guinea-pigs with success, but white mice did not take the infection. The material used for inoculation was cultivated for eight to ten weeks, and then used on two horses, one two years old, the other 20 years. Both died with all the symptoms of virulent glanders in about 12 days.

Pasteur and Thullier report the discovery of the microbe which causes swine fever, a disease by which, in the year 1882, farmers of the Rhone Valley lost 20,000 animals. The microbe is very minute and liable to be overlooked even when the greatest care is used in its observation; it resembles that of chicken cholera, and is of the form of the figure 8. Inoculation by a very small quantity communicates the disease; poultry are not affected, but rabbits die. The infection has been cultivated and weakened, so as by its inoculation to protect swine from fatal effects. Pasteur hopes soon to prevent the heavy losses sustained from this cause.

The remainder of the paper relates to osteoporosis, or bone weakening in animals, horses and swine particularly. Pütz attributes it to continued feeding on bran and other fodder poor in lime.

J. F.

Cattle Plague and Protective Inoculation. By KOCH and others (*Bied. Centr.*, 1883, 394—398).—Koch considers that Pasteur's mode of procedure is not quite correct, but liable to yield uncertain results. He thinks that the bacilli of the disease are propagated independently of animals; that they exist on dead vegetable substances, and probably on low marshy soils, on the surface of the earth; and he says that animals have been known to take the disease in such places where no diseased carcases had been buried. He denies the agency of earthworms in bringing the disease germs to the surface, for the plague appears in countries where the low temperature of the soil does not permit the existence of earthworms. He also denies Pasteur's assertion that the eating of the prickly fodder wounds the mouth and facilitates the taking of the disease.

The weakening of the poison, and the protection given by inoculation, has been successful only with horned cattle and sheep, and Koch doubts if the lymph is as successful, even with those animals, as Pasteur believes. The most carefully conducted experiments made with it in Germany show a loss of 10 to 15 per cent. of the inoculated animals, and there is danger to men by its employment. Koch does not undervalue the researches of Pasteur, but wishes to point out deficiencies in this particular case, which any day may be supplied. Instances are given of the deaths of sheep from plague, which had been duly inoculated. Dr. Azary gives results of numerous inoculations by Pasteur's fluid in the neighbourhood of Buda Pest, chiefly with sheep, also with horned cattle and horses; some losses took place, but on the whole the operations were successful. Arloing and others have experimented on the duration of the protective influence, and found it lasted at least 16 months; and that calves born of inoculated cows were not liable to disease for some time after their birth.

J. F.

Chemistry of Vegetable Physiology and Agriculture.

Occurrence of the Higher Fatty Acids in the Free State in Vegetable Fats. By E. SCHMIDT and H. ROEMER (*Arch. Pharm.* [3], 21, 34—38).

The Fat of Cocculus indicus.—The fat which is contained in the seeds of this plant was dissolved in alcohol and precipitated with an alcoholic solution of barium acetate, by which means the free fatty acids were separated from the glycerides with which they are associated in the original fat. After boiling for some time, the barium precipitate was filtered off, and when dry boiled with light petroleum. The nearly pure barium salt thus obtained was decomposed with hydrochloric acid. In this way 39 per cent. of free fatty acid was yielded by the original fat. By this means and by repeated crystallisation of the original fat from alcohol, as well as by distillation under diminished pressure, and also by partial precipitation with barium acetate, an acid was obtained which was recognised by analysis and physical properties as stearic acid. The substance obtained from *Cocculus indicus*, known as *menispermin*, was found by the authors to consist of stearic acid.

The Fat of Myristica moschata.—This fat, commonly known as nutmeg butter, or oil of mace, contains from 3—4 per cent. of free fatty acid, which was separated by fractional distillation under diminished pressure. At 248° the distillate, after recrystallisation from alcohol, yielded an acid, the formula of which was $C_{14}H_{28}O_2$, agreeing in its properties with myristic acid. The distillate, which came over at a higher temperature, was partially precipitated with barium acetate, and the acid which was recrystallised from alcohol, and analysed, gave numbers agreeing with the formula $C_{18}H_{36}O_2$, and was identical in physical properties with stearic acid.

The Fat of Laurus nobilis.—This fat, when distilled under diminished pressure, yielded a distillate, by the fractional precipitation of which an acid was obtained, which appeared to be palmitic acid.

W. R. D.

Chemistry of the Nucleus. By A. KOSSEL (*Bied. Centr.*, 1883, 401—404).—The regular relations between phosphoric acid and nitrogenous matters, which have been noticed both in vegetable and animal cells, have given rise to the idea of a compound of albumin and phosphates or phosphoric acid. In all the discussions on the subject, it seems to have been overlooked that lecithin and nuclein are organic phosphorus-compounds, which are sufficient to explain these appearances. Among the products of their decomposition, the author found a body which had almost the identical percentage composition of albumin. The usual mode of estimating nucleïn is by its resistance to the action of pepsin, but the author considers this liable to great error, and prefers a plan of his own. He found this phosphorganic compound in the organs examined—in the spleen, liver, pancreas, kidneys, testicles, brain, embryonic and grown muscles of animals, pus, and in human dropsical and healthy blood. According to experiments made with hens, doves, and yeast, the author regards nucleïn as a reserve material on which the organs subsist, or from which they draw supplies, to be incorrect; he finds hypoxanthine and xanthine to be characteristic decomposition products of nucleïn, and guanine accompanies them in many organs; this by oxidation yields guanidine and urea. The fact that a substance exists in most animal organs, which furnishes urea by simple oxidation, he thinks important from a physiological point of view.

J. F.

Flowers of Rosa Centifolia. By NIEDERSTADT (*Landw. Versuchs.-Stat.*, 29, 251—252).—Red roses were found to contain 86 per cent.

of water, 3·64 per cent. nitrogen, and 3·5 per cent. ash; in white roses were found 91·7 per cent. water, 3·16 per cent. nitrogen, and 3·9 per cent. ash. The composition of the ash of each is given below:—

	Red roses.	White roses.
Potash	43·81	42·05
Soda	1·12	1·53
Lime	6·02	8·05
Magnesia	6·27	6·41
Ferric oxide and Alumina	1·05	1·97
Phosphoric acid	16·47	11·32
Sulphuric acid	7·81	5·07
Silica	1·49	2 40
Chlorine	0·69	4·28
Carbonic acid	15·38	17·83

J. K. C.

Ash of Leaves of Plants Grown in the Earth under Water-culture. By C. Councler (*Landw. Versuchs.-Stat.*, **29**, 241—245).—Several samples of *Acer negundo* were grown in a glass house, Nobbe's method of water-culture being used. The leaves were collected after falling, dried and analysed. At the same time leaves were carefully gathered from young trees of the same kind in a neighbouring wood, to compare with those obtained by water-culture. The percentage of pure ash in the leaves varied considerably, nearly twice as much being obtained from those grown by water-culture. In 100 parts ash were found—

	Water-culture.	Soil.
Potash	45·52	33·91
Soda	0·58	0·66
Lime	14·92	27·23
Magnesia	3·55	4·71
Ferric oxide	0·91	0 92
Alumina	—	4·00
Phosphoric acid	12·21	3·43
Sulphuric acid	18 30	7·29
Silica	4·00	17·85

The leaves of the soil plants contained, therefore, nearly twice as much lime, and more than four times as much silica as those of the plants grown by water-culture, whilst the latter contain much larger quantities of potash, phosphoric and sulphuric acids. These differences are no doubt in great part due to the soil in which the plants were grown; it is very rich in potash, but comparatively poor in phosphates. J. K. C.

Examination of an Apple-must and of the Cider obtained therefrom. By R. Kayser (*Dingl. polyt. J.*, **248**, 347).—Borsdorf apples were cut into small pieces and pressed. The resulting must was then tested before and after fermentation. 100 c.c. gave—

	Must (filtered).	Cider.
Alcohol	—	5·80 c.c.
Extract	16·25 g.	2·36 g.
Mineral matter (ash)	0·35	0·31
Malic acid	0·33	0 31
Acetic acid	—	0·080
Sugar	12·50	0·750
Pectins	0·62	traces
Potash	0·106	0·105
Lime	0·025	0·024
Magnesia	0·018	0·018
Phosphoric acid	0·024	0·022
Sulphuric acid	0·009	0·008
Glycerol	—	0·680

Tartaric and citric acids were not present: hence cider can be distinguished from wine by the entire absence of tartaric acid, and by the larger amount of lime which it contains. By a judicious addition of tartaric acid or of wine containing much acid, a product can be obtained, which it would be difficult to distinguish from real wine.

D. B.

Analysis of "Tobacco Stems" from Virginia. By C. G. Memminger (*Chem. News*, **48**, 110).—"Tobacco stems" consist of the midribs of tobacco leaves from which the membranous portions have been stripped. The analytical results are as follow:—

In original substance.	
Moisture at 100°	17·52
Total ash, excluding CO_2	16·47
CO_2 determined	6 87
(CO_2 calculated = 6·73)	
Organic matter (by diff.)	59·41
	100·00

In organic matter.	
Nicotine	1·30
N as nicotine	0·22
N as nitrate	0·45
N as albuminoid (by diff.)	1·51
Total N	2·18

In ash.

K_2O.	Na_2O.	CaO.	MgO.	Al_2O_3.	Fe_2O_3.	
42·95	6·53	24·56	6·20	0·04	0·84	per cent.

Mn_3O_4.	SiO_2.	P_2O_5.	SO_3.	Cl.	
0 09	6·18	4·80	3·10	6·04	per cent.

D. A. L.

Phylloxera. By Henneguy and others (*Bied. Centr.*, 1883, 272—274).—Henneguy found the galls on many American pines, especially *Pinus riparia*, and but seldom on native vines; in large galls, several young insects have been found besides the egg producers, and Henneguy found thiocarbonate a good specific against the attacks. E. Cheysson approves of carbon bisulphide. A. Guillamont states that a mixture of 10 parts wood-ashes, 10 ferrous sulphate, and 2 coal-tar, is a good specific for destroying the phylloxera. E. W. P.

Valuation of Fodder. By A. EMMERLING (*Bied. Centr.*, 1883, 252—255).—The relative value of albuminoïds to fat and to carbohydrates is taken as 5 : 5 : 1. Multiplying each of these factors by the corresponding figures representing the digestible material in the food, we obtain a figure representing the sum of nutrient units. As a standard, rye is employed thus: Albuminoïds, 9·9 per cent.; fat, 1·6; carbohydrates, 65·4, which figures, when treated as above, $9·9 \times 5 + 1·6 \times 5 + 65·4 \times 1$, produce 122 9 n. u.; and, taking 8 marks per centner as the market value of rye, 1 n. u. costs 6·5 pfennigs. Employing this method the feeding value of any material may be calculated; for example, in earth-nut cake we have albuminoids 45, fat 7, carbohydrates 25, of which the digestible coefficients are 90·9, 85·7, and 98 1 respectively, giving digestible matter present to the extent of 40·9, 6·0, and 24·5. Then $40·9 \times 5 + 6 \times 5 + 24·5 = 259$ n.u.; and having laid down a table of the value of nutrient units for grain and other foods, which units vary according as the price of rye rises or falls, the author shows that when rye is at 8 marks the value of these 259 n.u. of earth-nut cake is 10·10 marks; but this cake only costs 9 marks, consequently there is a gain in using it. A similar method is employed to calculate the value of foods for manures, employing in this case the factors 0·5 for N, 0·2 for P_2O_5, and 0·1 for K_2O: by this he shows the manurial value of a centner of earth-nut cake to be 4·04 marks, and this, with the exception of cotton-cake, is the most valuable of all foods. E. W. P.

Examination of Clover at different Stages of Growth. By J. P. KALLEN and A. STUTZER (*Bied. Centr.*, 1883, 410—411).—Part of a series of experiments made in order to ascertain the period at which grasses contain most nutritive matter, with a view to harvesting them at such times. A field sown with red clover and different grasses, chiefly English rye-grass, was the subject of experiment: a square meter was cut on 17th, 24th, 31st May, and 20th June, and examined. The results are given in a table, and the recommendation is made to cut at the end of May or early in June. J. F.

New Fodder Plant. By F. T. (*Bied. Centr.*, 1883, 287).—*Lavatera arborea* yields an oily seed, which after expression of the oil forms a good cake for cattle, and good fibre for paper making, rope, and cord. The plant is biennial, and crops well. E. W. P.

Feeding Horses with Earth-nut Meal. By C. FREYTAG and BECKE (*Bied. Centr.*, 1883, 284).—Earth-nut meal may well replace two-thirds of the oats generally given to horses. E. W. P.

Storage of Acorns. By LODEMAN (*Bied. Centr.*, 1883, 286).—Collect as late as possible, pile in heaps 30 c.m. high, cover with leaves and pine twigs; in the spring remove the covering to retard germination. E. W. P.

Undecorticated Cotton-seed Meal. By DIETRICH (*Bied. Centr.*, 1883, 428).—A considerable quantity of this article has lately been sent from England to Germany; it is less valuable than the meal made from the decorticated seed, and is of a dark colour. Two samples had the following composition:—

	1.	2.
Proteïd matter............	23·56	23·06
Fat......................	6·26	7·01
Non-nitrogenous extract....	24·94	27·12
Cellulose	25·73	25·53
Mineral matters	8·15	6·59
Water....................	11·36	10·69

J. F.

Cultivation and Preservation of Potatoes. By MÄRCKER and others (*Bied. Centr.*, 1883, 268—270).—Stappaerts removes all eyes save three, and by setting only large sets obtains a higher yield. which ripens early. Märcker has preserved potatoes in a silo, when the nutrient ratio is increased by fermentation from 1 : 10 to 1 : 17·6; much of the albuminoid and amido-constituents are lost. L. Nagy enumerates and classifies the sorts of potatoes; he divides them into 12 principal classes, with 30 sub-classes. E. W. P.

Experiments on Potatoes with different Manures. By E. W. PREVOST and R. SWANWICK (*Trans. Highl. and Agr. Soc.*, Scotland, 1882, 283—299).—In these experiments the actions of "bone," "mineral," superphosphates, and insoluble phosphates (85·5 per cent. Ca_32PO_4) were employed, likewise an addition of ammonium sulphate, kainite, and potashes to the phosphates was made, with the results as hereinafter stated. The potato employed was the Champion, and the soil divided into plots of $\frac{1}{112}$ acre, contained 62 per cent. sand, Al_2O_3 8·114, K_2O 0·764, N 0·39, NH_3 and P_2O_5 0·284; all the plots were in triplicate. The "unaided" phosphates produced nearly equal crops, but the addition of 2 cwt. Am_2SO_4 caused the bone super to produce the highest yield obtained, viz., 12 tons 12 cwt., whilst the blank plots only yielded 7 tons 4 cwt., and insoluble phosphate with ammonia 9 tons 15 cwt. The addition of potash to the mixture of "super" and ammonia rather lowered the yield, and but little difference was noticed when kainite or potashes were employed. This however was not the case with the insoluble phosphate, for then potashes increased the yield by a tenth. Farmyard manure gave only a moderate yield. In the second portion of this paper are the analyses of the potatoes as produced under the above conditions: the highest percentage of starch was found in potatoes grown with bone superphosphate, and taking the average of all the plots, it appears that the further addition of ammonia or kainite lowers the percentage, which is however raised again by potashes; but there is a great difference between the percentage of starch from the bone super plot and from the "insoluble" plot, the former being 25·6, the latter only 21·96. The expenses of the whole experiments are detailed, as also the value of the various crops, and we find that whether we judge the value of the manure by the total crop it yields or by the production of starch, the mixture of bone superphosphate with ammonia was the most satisfactory. The effect on the amount of nitrogen present is also detailed, not merely as total nitrogen, but as nitrogen in amides and in albumin; ammonia increases the albuminoid nitrogen, but the increase is somewhat counteracted by potash, the unmanured plot containing least. The amides were likewise increased by ammonia (av. = 0·1399 N), but again kainite exercised a lowering action: an extraneous experiment is here referred to, which points to the conclusion that the amide nitrogen is much decreased as the ratio of potash to "super" increases. Phosphates and ammonia produce the highest ash (1·31), whilst in the superphosphate plots the percentage is reduced almost to that found in the blank plot (0·995); this is in accordance with the results found by Fleischer (*Bied. Centr.*, 1880), what has been said for ash holds good for fibre. Attempts were made to estimate the percentage of starch by the method recommended by Heidepriem (*Landw. Versuchs.-Stat.*, **20**), but they were fruitless, as the results were very far from the truth, and therefore untrustworthy. E. W. P.

Influence of Manuring on the Composition of Potatoes. By M. MÄRCKER (*Bied. Centr.*, 1883, 365—366).—Four plots of ground, each half a morgen loamy marl, on which barley and clover had been previously grown, were planted with "alcohol" potatoes; one plot was left unmanured, the other three each received 20 lbs. of soluble phosphoric acid, and different quantities of Chili saltpetre, the first 100 lbs., the second 200 lbs., the third 300 lbs. The yield per morgen was—

	Unmanured plot.	100 lbs.	200 lbs.	300 lbs.
Centner	112·0	28·0	124·5	139 0

the use of the saltpetre had therefore increased the gross weight of the crop, but the percentage of dry matter and starch did not correspond, being—

Dry matter	24·80	23·50	22 50	20·90
Starch per cent. ..	77·51	77·07	73·95	63·64

the use of large quantities of saltpetre having reduced the net quantity of starch, the actual amounts obtained being—

Plot 1.	Plot 2.	Plot 3.	Plot 4.	
21·58	23·18	20·74	18·43	centner.

J. F.

Artificial Manures in Potato-growing. By S. GURADZE (*Bied. Centr.*, 1883, 377—379).—The author reports five experiments as to the effect of different chemical manures on the growth of potatoes, combined in different proportions; they consisted of a newly introduced potash magnesia (containing 50 per cent. potassium sulphate, and 34 per cent. magnesium sulphate) superphosphate, and Chili saltpetre. All the experimental plots but two received a considerable quantity of stable manure, in addition to the artificial. The crops were in all cases exceptionally good, and the plants healthy; the proportion of starch in the tubers good, and the value of the increased production repaying the extra cost of the manures employed. The author strongly recommends the use of artificial fertilisers in the growing of potatoes. J. F.

Manuring Experiments with Rye and Wheat. By M. Märcker (*Bied. Centr.*, 1883, 373—377).—The first experiments noted were made with rye, on a good sandy soil, in order to observe the effects of phosphoric acid in bone-meal and in purely mineral phosphates, blood-meal being added to the latter equal to the nitrogen in the bone-meal. The quantity of phosphoric acid used was 10 kilos. per morgen, applied in autumn. The experiments were carried out by five farmers, independently of each other; the results were slightly in favour of the mineral phosphate with blood-meal. Steamed bone-meal produced good crops, the net result of the experiment being that a nitrogenous manure mixed with phosphate is most useful. Similar experiments were made on light and poor sandy soils with a different result, the steamed and fermented bone-meal giving the best crops, the other manures not repaying the extra cost. Certain plots of wheat were manured with Chili saltpetre, and others with ammonium sulphate, with a view of testing their manurial value. The manures were applied at different periods, the Chili saltpetre was found greatly superior, and the superiority was most marked when it was applied in May. The yield of both grain and straw was considerably larger than from all the other plots. J. F.

Manuring Vines. By A. Stutzer (*Bied. Centr.*, 1883, 381—382). —Vineyards in the Ahrthal have generally been manured with stable manure. The author found that a compost containing 7 per cent. soluble phosphoric acid, 6 per cent. potash, and 2½ to 3 per cent. nitrogen, applied in 100 gram doses to each vine, produced an average increase of 20 per cent. grapes more than the stable manured plants, and that the must was also richer in sugar. The cost of the manure and labour was not greater than that of the stable manure employed; the wood of the vines was stronger and healthier. J. F.

Manuring Beet. By Holdefleiss (*Bied. Centr.*, 1883, 380—381).—The author recommends a moderate use of stable manure supplemented by Chili saltpetre as being most suitable for the full production of sugar in the beet. Manures which are too rich in nitrogen, such as sheep dung, or even too much Chili saltpetre, are decidedly injurious. In the absence of stable manure, a mixture of superphosphate with the saltpetre should be employed. J. F.

Influence of Soil, Size of Seed, Period of Sowing, &c., on the Quality and Yield of Sugar-Beet. By G. Marek (*Bied. Centr.*, 1883, 263—268).—The weakest growth was in sandy soil, better on sandy loam, strong on clay and humous sand, and luxuriant on moorland; as regards the leaf growth, this was most abundant on the humous soil, and this class of land also is most suitable for a heavy crop; but the opposite is the case as regards sp. gr. of juice, for there the clay lands are most advisable, and this is true for the percentage of sugar: the size of seed is not of much importance. The highest yield is obtained when the crop is put in between the middle of April and end of May. It is advisable on all accounts to sow on the flat with 40 : 20—25 cm., and on the ridge distance 45 : 20—25, and the highest results, both yield and sugar, are obtained by sowing on the ridge by Bertel's method, which consists in throwing up ridges 44 cm. apart, rolling them, and employing a combined manure and turnip drill. E. W. P.

Ammonia in Rain-water. By HOUZEAU (*Bied. Centr.*, 1883, 425).—The principal agents which increase or diminish the amount of ammonia are light and heat. In July the observer was not able to detect even a trace of it in rain-water. He found that water exposed to the action of sunlight for a long time lost a large part of its ammonia. The amount of rainfall also has an influence; the smaller the amount the more ammonia it contains. J. F.

Origin of Combined Terrestrial Nitrogen. By A. MÜNTZ and E. AUBIN (*Compt. rend.*, **97**, 240—243).—The principal source of combined nitrogen appears to be nitric acid and oxides of nitrogen, formed by the action of atmospheric electricity on the nitrogen in the air. The main causes producing a diminution in the amount of combined nitrogen are, rapid combustion, which operates only to a limited extent; slow combustion, which is the most important cause of all; and the reduction of nitrates in water and soils, which plays a very insignificant part. In order to ascertain whether these increasing and diminishing forces are in equilibrium, it is necessary to determine the amount of nitric acid in the rain-water on different parts of the earth's surface, and especially in tropical regions. The accurate estimation of nitrates can be performed only in a properly appointed laboratory, and it is advisable therefore, to collect the samples of rain-water in such a way that they can be transported to a distance. The authors recommend to evaporate the rain-water to small bulk with potassium hydroxide, out of contact with air and products of combustion. The concentrated liquid is mixed with alcohol, and the authors find that in this condition it may be preserved for any length of time without undergoing any alteration. To apply this method to river water, &c., 3—5 litres of the water are evaporated to about 30 c.c., and mixed with 60 c.c. of alcohol.

Many cases of rapid combustion are accompanied by the formation of considerable quantities of nitric acid. The authors find that when 1 gram of hydrogen burns in air, 0·001 gram of nitric acid is produced, whilst the combustion of 1 gram of magnesium is accompanied by the formation of 0·1 gram of nitric acid. It is probable, therefore, that a large quantity of nitrates were formed in the earlier stages of the earth's history during the process of cooling, and the luxuriant development of animal and vegetable life in prehistoric times was possibly due to the presence on the earth's surface of a large quantity of combined nitrogen in an assimilable form. It would appear, therefore, that the total amount of combined terrestrial nitrogen is gradually diminishing, unless the sources of loss are balanced by the action of atmospheric electricity. C. H. B.

The Lupitz Method of Cultivation. By Schultz and others (*Bied. Centr.*, 1883, 232—243).—Schultz considers that the cultivation of lupines is the cheapest method of supplying the soil with nitrogen, as they abstract this constituent from the air. According to his experiments a soil in which lupines had grown showed an amount of nitrogen double that in grass land, and more than that found in potato and rye land. According to Schultz all that is necessary for a good crop of lupines is the addition of kainite; phosphates do not give a satisfactory result. Drechsler criticising Schultz's statements, shows that lupines do not add nitrogen to the soil, but rather, like all large-leafed crops, even when they draw their supplies of nitrogen from the subsoil, are consumers of nitrogen instead of collectors, and he also considers that the Lupitz system, unless nitrogen is added to the land, cannot last. Blomeyer's opinion is that the leguminosæ are "nitrogen collectors," and for this reason, that they keep the surface of the soil moist, and so prevent the volatilisation of ammoniacal compounds. Märcker is unable to answer the question whence the excess of nitrogen which is present in the Lupitz soil is derived, for 675 lbs. N have in 15 years been withdrawn, and only that nitrogen added from the usual natural, viz., the atmospheric, not artificial sources. It is possible that the deep rooting lupines may separate nitrogen from solutions which are too dilute for other plants, and the retention of nitrates on the surface soil may be due to the shelter afforded by the foliage, preventing loss by rainfall. He believes that by the continued use of kainite the nitrogen in time will be lost, and that though phosphates are now useless, they will hereafter be required; in the 15 years 1000—2000 kilos. lime per hectare have been removed, by reason of the potash manure, so that this constituent will before long be required. Märcker believes that potassium chloride as carnallite is a better manure than the sulphate as kainite.

E. W. P.

Moss and Turf Fibre as Cattle Litter. By M. Fleischer and others (*Bied. Centr.*, 1883, 368—373).—The use of so-called "moss litter" obtained from certain bogs in Northern Germany has become very general. The authors of this paper have examined samples of ordinary fibrous peat, separated artificially, and intended as substitutes for the former, one sample procured from Würtemburg, the other from a Silesian bog. They found that air-dried samples containing 20 per cent. of moisture, absorbed 6⅓—9⅓ times their weight of water, and their power of absorbing carbonate of ammonia for 1000 parts of moss, 13—16 parts of ammonium carbonate.

The manurial value of the different samples is given. 1000 parts of each contain—

	Wurtemburg fibre.	Silesian fibre.	North German moss.
Nitrogen	22·0 parts	29·0 parts	9·0 parts
Phosphoric acid..	0·6 „	0·6 „	0·4 „
Lime	17·2 „	31·0 „	2·0 „

The two samples of fibrous turf are consequently much more valuable as manure than the moss; and containing much lime, their nitrogen is probably more readily decomposed, and available for plant nutrition.

Analysis of turf fibre employed as absorbents in public and private middens in Bremen, and in horse stables, yielded the following results, calculated to 1000 parts of the dry substance:—

	Public latrines.	Private latrines.	Stables.
Nitrogen........	46·6	27·8	17·3
Mineral matters..	118·8	?	167·0
Potash..........	23·3	9·3	7·9
Phosphoric acid..	18·7	10·6	7·0

The samples were free from smell, and although containing a considerable amount of moisture, formed a compact and portable mass.

The remainder of the paper is occupied with experiments on various crops with the moss after being used as litter, and in all cases the results were satisfactory. J. F.

Sea Mud. By M. Fleischer, A. Konig, and B. Kissling (*Bied. Centr.*, 1883, 243—250).—Mud is deposited at the mouths of most rivers, which it is advantageous to the harbour authorities and to the farmer to remove. Analyses show that with but slight variation the deposits are of the same composition, the principal variant being sand. This mud when exposed to the air dries to a firm compact and plastic mass, and at the same time that it loses water, it also diminishes in volume; in one case the ratio of loss of water to loss of volume was 1 : 0·55. The changes effected by long storage are of considerable importance to the agriculturist, for the physical character changes, the mud becoming more pulverulent, and consequently more easily applied to the land, and this is especially the case after frost; also water being lost and volume reduced, transport expenses are lowered, chlorides are lost, ferrous oxide and sulphide become oxidised, plant and animal remains become more decomposed, and but little, if any, nitrogen is lost. Further changes are induced by frost and thawing, for the dry matter is raised from 45·6—65·06 per cent., and the whole becomes still more friable, and a higher percentage of soluble sulphate and lime is obtained. E. W. P.

Destruction and Utilisation of the Bodies of Animals which have Died from Contagious Diseases, especially from Anthrax. By A. Girard (*Compt. rend.*, 97, 74—77).—The body, without removal of the skin, is dissolved in the cold in concentrated sulphuric acid of about 60°. Complete solution takes place with comparative rapidity, and the acid can be used repeatedly until its degree of concentration is diminished to 43°. Direct experiments have proved that all germs are destroyed in the process of solution. The acid liquid obtained contains a considerable proportion of nitrogen, and has the power of readily attacking natural phosphates yielding highly nitrogenous superphosphates. A layer of fatty matter floats on the surface of the acid solution, and may be removed and purified.

C. H. B.

Guano recently discovered in Australia. By A. B. GRIFFITHS (*Bied. Centr.*, 1883, 427).—The following is the analysis of two samples:—

	No. 1.	No 2.
Nitrogenous organic matter and ammoniacal salts	46·72	46·73
Phosphoric acid	15·02	15·10
Lime	18·00	17·99
Alkaline salts	1·42	1·41
Sand	2 71	2·71
Water	15·92	16 07
	99·79	100·01

J. F.

Manurial Value of Sewer Slime. By M. FLEISCHER (*Bied. Centr.*, 1883, 426—427).—In Bremen several sewers connected with houses, and containing much urine, are led into a small stream with a gentle fall; the solids precipitate, and are removed for agricultural purposes. An analysis of a sample yields the following:—

	Dry.	With 15 per cent. of water.
Potash	6·3	3·5
Lime	17·2	9·5
Phosphoric acid	8·0	4·4
Total nitrogen	11·6	6·4

The reaction is acid, and it contains soluble iron salts; ignited in a platinum capsule sulphurous acid is evolved. The wet material when heaped up yields a drier mass of 50—60 per cent.; it must be exposed a long while to the air in consequence of the sulphur compounds.

Another sample drawn from a pond into which the night soil from a part of the city was for a long time allowed to flow. This sample also gave an acid reaction. The addition of hydrochloric acid causes evolution of sulphuretted hydrogen.

This sample yielded in 1000 parts—

	Fresh.	Dried at 100°.
Water	889·70	—
Combustible matter	27·20	251·0
Nitrogen	1·46	13·2
Insoluble in HCl	54·25	498·8
Potash	0·98	8·9
Soda	0·34	3·1
Lime	1·91	17·3
Magnesia	1·35	12·2
Iron and alumina	18·25	165·5
Phosphoric acid	0·52	4·7
Sulphuric acid	3·65	33·1

J. F.

Constituents and Properties of some Water Plants. By NIEDERSTADT (*Landw. Versuchs.-Stat.*, **29**, 247—250).

Stratiotes aloides.—The use of this as manure has been followed by exceedingly good results, better in fact than with any other ordinary manure. Analysis of the ash shows that it is very rich in alkalis and phosphates. It contains 19·5 per cent. of ash, and 15·7 per cent. protein. In the ash was found 14·2 per cent. soda, 15·9 per cent. potash, and 11·4 per cent. phosphoric acid.

Nymphæa alba.—The leaves of this plant yielded 11·1 per cent. of ash, consisting chiefly of alkaline chlorides and calcium carbonate, and the same may be said of the ash of the leaves of *Nuphar luteum*. The flowers of these plants contained large quantities of chloride and phosphate of potassium. J. K. C.

Kainite as Potato Manure. By M. FLEISCHER (*Bied. Centr.*, 1883, 366—367).—These experiments were made at the instance of the Central Moor Commission, in order to learn the effects of early and late applications of kainite to potatoes. Four plots were manured with precipitated phosphate and Chili saltpetre; to one no potash salt was applied; No. 2 received kainite in September; No. 3 kainite in December, and No. 4 immediately previous to planting, the effect of the kainite was remarkable, the average of the crop taken off the three plots on which it was used, being three times as great as that from the other plot. The yield of the three plots treated with kainite was nearly alike, but the flavour of the September manured plot was best; the yield of starch, however, determined by König's sp. gr. method, was:—

September plot.	December plot.	At sowing.
100	67	64

Similar experiments were made by Wildt in 1882. The time of applying the kainite did not appear to affect the gross weight of the crop, but the starch percentage was greatly diminished by late applications. When the kainite was applied at the under-mentioned periods the net yield of starch and its proportion, taking the highest figure as 100, were:—

	Autumn.	Early spring.	Four weeks before planting.	At planting.
Centner ..	20·9	18·8	18·1	17·5
	100	90	87	84

The author ascribes the loss of starch to the presence of chlorides. J. F.

Analytical Chemistry.

Estimation of Chlorine, Sulphuric Acid, and Chromium in Presence of Organic Matter. By C. T. Pomeroy (*Chem. News*, **48**, 41—42).—To determine these substances in the presence of organic matter, it is first of all necessary to remove the latter by ignition with an alkaline carbonate and nitrate; some of the nitrate is thereby reduced to nitrite, which, during subsequent operations, reduces the chromates, and interferes with the estimation of chlorine; moreover, if the sulphuric acid is precipitated in this solution, the barium sulphate always retains chromic oxide. To obviate these difficulties the mass from the fusion with alkaline carbonate and nitrate is dissolved and filtered; potassium nitrite and nitric acid in excess are added to the filtrate, which is allowed to stand 12 hours in the cold. 'On adding ammonia and boiling, the chromium hydroxide is thrown down; it should be filtered off hot, washed with hot water, and estimated as usual. The sulphuric acid is precipitated from the filtrate from the chromium hydroxide by means of barium nitrate, and the chlorine estimated in the filtrate from the barium sulphate in the usual way. The published results agree very well. In the analysis of ordinary chrome yellow, even the lead passes entirely into solution when sufficient sodium nitrite and nitric acid are added, and the mass boiled. D. A. L.

Formation of Methylene-blue as a Reaction for Hydrogen Sulphide. By E. Fischer (*Ber.*, 16, 2234—2236).—To test for hydrogen sulphide in aqueous solution, the latter is treated with one-fiftieth volume of concentrated hydrochloric acid, a few grains of paramidodimethylaniline sulphate are added, and when this is dissolved, 1—2 drops of a dilute solution of ferric chloride. In the case of a solution containing 0·00009 gr. hydrogen sulphide in a litre of water, coloration took place in a few minutes, and in half an hour the liquid had assumed a strong blue colour, which lasted for days. A solution of the same strength, but without hydrochloric acid, yielded only a light brown coloration with lead acetate. In a solution containing 0·0000182 gr. hydrogen sulphide in a litre of water, the methylene-blue reaction still gave a distinct blue coloration, whilst no effect was produced either by lead acetate or sodium nitroprusside. This reaction is recommended as the most delicate and certain test for neutral or acid solutions of hydrogen sulphide. Paramidodimethylaniline is most conveniently prepared from commercial helianthin, $Me_2N.C_6H_4.N:N.C_6H_4.SO_3H$; this is finely powdered, mixed with 5 parts of water and an excess of ammonium sulphide; the mixture is frequently agitated, and when (after about 24 hours) the reduction is complete the amidodimethylaniline can be extracted with ether; the ethereal solution is then agitated with a little white lead suspended in water, and the filtrate treated with an ethereal solution of concentrated sulphuric acid. The ether is separated from the crystalline sulphate, and this is heated with absolute alcohol until it is converted into slender white needles, which after being washed with alcohol can be pressed and dried on a water-bath.

A. K. M.

Volumetric Estimation of Phosphoric Acid. By G. C. Caldwell (*Chem. News*, **48**, 61—62).—The author finds Pemberton's method (Abstr., 1882, 1318) efficient; he has introduced an improvement to facilitate the final test filtrations. A test-tube is fitted with a double-bored cork, through which pass two tubes, a short one bent at right angles and a longer one bent at a convenient angle for introduction into a beaker; the bore of the tube is 1 mm., the end of the longer one has a conical enlargement or mouth with a diameter of 5 mm. To prepare the apparatus for use a perforated platinum cone is fixed in this mouth, and while suction is applied to the short bent tube, the mouth of the tube with the cone is just dipped into very thin asbestos pulp and then into water, the suction being continued until the water comes through quite clear. The apparatus is now ready for use; suction is again applied, the filter dipped into the liquid to be tested, and when the desired quantity of filtered solution is obtained, the filter is withdrawn; the suction must be sustained all the time to prevent the cone and asbestos from falling out. The liquid is treated in the test-tube, and then returned to the beaker. Before the next test is made the filter and tube are washed by a small quantity of the liquid, which is drawn through the filter and returned to the beaker.

D. A. L.

Quantitative Separation of Potash and Soda from Ferric Oxide, Alumina, Lime, and Magnesia in Silicates. By W. Knop (*Chem. News*, **48**, 110—111). The new method is based on the formation of alkaline silicofluorides insoluble in acidulated mixtures of alcohol and ether, by the combined action of hydrochloric and hydrofluoric acids on silicates. When the alkalis are in excess it is necessary to add silica before treatment with the acids.

The weighed substance, mixed with a small quantity of water, and, if necessary, silica also, is treated, in a platinum capsule, with fuming hydrofluoric acid, evaporated to dryness, treated with strong hydrochloric acid and absolute alcohol, and after some time with excess of ether. In 12 hours' time the silicofluorides are filtered off, washed with alcohol, dried, and removed from the filter, which is incinerated. The ash and the precipitate are mixed together in a crucible with concentrated sulphuric acid, and as soon as the evolution of silicon fluoride ceases the crucible is ignited at a low temperature, so as to leave the alkalis as acid sulphates. The mass is treated with ammonia, evaporated to a paste, rendered alkaline with ammonia, and after an hour, to ensure complete separation of iron and alumina, is treated with ammonium carbonate solution and left for 12 hours. The iron, alumina, lime, and magnesia, are filtered off and washed with ammonium carbonate, &c. The filtrate is evaporated to dryness—a quantity of ammonium hydrogen tartrate equal to the ammonium sulphate present being added to prevent spurting—and ignited. The residue is taken up with water, tested with ammonium carbonate for iron, &c., and the solution is then evaporated to dryness and weighed.

D. A. L.

Methods of Analysing Columbates by means of Hydrofluoric Acid. Separation of Thoria from the other Oxides. Estimation of Didymium. By J. L. Smith (*Chem. News*, **48**, 13—15; 29—31).—After a review of the work done on this class of minerals by Rose, Hermann, Marignac, &c., the author observes that they have special interest, because there are always some of the rarer earths associated with them, and the reasons amongst others which have prevented their being more perfectly studied are, firstly, the scarcity of the minerals, and secondly, the difficulty attached to the process of decomposing them. The first obstacle was removed by the discovery of large quantities of columbite and samarskite in the United States, and the second is set aside by the methods described in this paper.

In a previous communication (*Amer. J. Sci.*, 1877, 360), the author has described these minerals, columbites and tantalites from the United States, both as regards their mineralogy and their chemical composition, but owing to the defects in the manner of working, he could neither give the relative proportions of columbic and tantalic acids, nor could he detect conclusively cerium or thorium. All doubt on this head has been dispelled by the use of his new method.

Analysis of Samarskite (and other Columbates containing Earthy Oxides).—5 grams of the finely powdered mineral dried at 150° (loss by ignition is determined in a separate quantity) are placed in a platinum capsule (50 c.c. capacity is sufficiently large) moistened with water and treated with 4 to 5 c.c. of concentrated hydrofluoric acid; after two or three minutes, a second and similar quantity of this acid is added, and the whole well stirred; vigorous action soon sets in, and in 5 or 10 minutes all black specks have disappeared, showing the decomposition to be so far complete. The capsule is now heated on a water-bath; the contents consist of a clear *solution* (A) containing the metallic acids, iron and manganese, and an *insoluble portion* (B) containing the earths and uranium oxide. These two parts are but very slightly intermixed. The contents of the capsule are mixed with 30 c.c. of water, warmed, filtered on a gutta-percha or silver funnel, the filtrate being received in a platinum capsule, and washed with hot water containing a few drops of hydrofluoric acid. The *solution* is evaporated over a water-bath, and before it is dry, is treated with excess of concentrated sulphuric acid to decompose the fluorides; it is heated until nearly all the sulphuric acid is driven off, and when cool is washed into a glass flask and boiled with very dilute hydrochloric acid. The whole mass is then filtered and washed with hot water. The precipitate, consisting of columbic, tantalic, and small quantities of tungstic and stannic acids is dried, ignited and weighed; subsequently the tungstic and stannic acids are separated in the manner recommended by Rose, and the columbic and tantalic acids by Marignac's method. The filtrate contains iron and manganese, which are estimated in the usual manner. The *insoluble portion* is washed into a platinum capsule, treated with a sufficient quantity of concentrated sulphuric acid to decompose the fluorides, heated carefully until nearly all the sulphuric acid is driven off, and when cool is warmed with 50 c.c. of water, in which all dissolves to a green solution, except perhaps a very minute quantity belonging to portion A. The green solution is heated, and after the addition of a little nitric acid, is poured into a beaker and made up to about 250 c.c. with water. It is now nearly neutralised with ammonia, and the earths precipitated with ammonium oxalate or oxalic acid. After six or eight hours, the *earthy oxalates* (C) are filtered off and washed. The solution contains all the uranium with a trace of iron; both are estimated; the iron is precipitated as sulphide, and the uranium estimated by the ordinary method. The *earthy oxalates* are dried, ignited, and weighed. The powder, which is of a pale yellow colour, is dissolved in nitric acid, evaporated to a syrup, and before it solidifies is mixed with a concentrated solution of sodium sulphate, and subsequently small crystals of the sulphate are added (50 c.c. of the solution and 4 grams of the crystals for 1 or 2 grams of mineral), a precipitate (D) soon begins to form. After 24 hours it is very abundant and is filtered off and washed with concentrated sodium sulphate solution. The filtrate containing yttrium and erbium is treated with oxalic acid or ammonium oxalate, the precipitated oxalates ignited, redissolved, reprecipitated, ignited, and weighed. The oxides are dissolved in dilute sulphuric acid, evaporated carefully, and heated until the weight is constant: then from the weight of oxide and of sulphate, the relative proportion of yttria and erbia is found by Bahn and Bunsen's formula. The sodium sulphate precipitates are separated by fractional precipitation; they are washed with solution of the salt, dissolved in very diluted hydrochloric acid, nearly neutralised with ammonia, precipitated by ammonium oxalate, ignited, redissolved, reprecipitated, and weighed.

No cerium was found in the first precipitate, but instead a dark oxide soluble in very dilute nitric acid, which the author called mosandrum oxide. In the precipitate D are found the other cerium oxides and thoria. After being treated in the usual manner with hydrochloric acid, ammonia, oxalic acid, &c., and ignited, the resulting oxides dissolved in dilute nitric acid, thus again showing absence of cerium oxide. This fact was now confirmed by treating the nitric acid solution with caustic soda and chlorine, no indications of cerium were obtained, all the oxides passing into solution with the exception of a small quantity of thoria, which forms 0·8 per cent. of the mineral. Some experiments were now conducted on a large scale, lead vessels, capable of working more than a kilo of mineral at a time, were employed instead of platinum ones. The conduct of the process is the same as described above, the earthy fluorides are decomposed with sulphuric acid, &c., and after the separation of uranium oxide, &c., the solution is boiled up with steam, nearly neutralised, and the oxalates precipitated. The yttria is separated as above described; the thoria can be separated quantitatively by treating the solution with large quantities of soda and passing chlorine for two or three hours as above described, or less completely by dissolving the earths, separated by the sodium sulphate, in nitric acid, concentrating the solution on a water-bath, diluting abundantly, boiling with a current of steam, and adding sufficient ammonia to the boiling solution to precipitate about $\frac{1}{6}$

of the oxides present. The gelatinous precipitate containing all the thoria and a little of the other oxides, is filtered off, washed, and dissolved in dilute sulphuric acid; this sulphate of thoria can be easily purified by the usual methods. The filtrate from the thoria contained a mere trace of thoria, and no lanthanum, therefore the only oxide of the cerium series to be looked for was didymium, which the author recognised by the spectroscope.

Quantitative Estimation of Didymium.—Solutions of didymum oxide of known strength are placed in tubes of uniform diameter, these are compared before the spectroscope with similar tubes containing a nitric acid solution of the oxides to be tested, until the bands produced by the tubes correspond in intensity; the author in this manner arrived at the quantity of didymium in solution. From these results it is evident that the samarskite examined by the author contained thoria, and other mixed oxides in place of the cerium oxide.

Columbite and tantalite are more difficult to decompose than samarskite. They must be very finely pulverised; to effect this with tantalite, the powder in the mortar is covered with (95 per cent. commercial) absolute alcohol, and the trituration continued under these circumstances. The trituration of 1 gram of columbite requires a quarter of an hour; 1 gram of tantalite 20 minutes. They are then decomposed by heating with hydrofluoric acid of the usual strength used by the author, and treated as described above. D. A. L.

Dialysis of Arable Land. By A. PETERMAN (*Bied. Centr.*, 1883, 361—364).—The employment of strong mineral acids in the analysis of soils has led the author to think that substances pass into solution and are estimated, which under the ordinary conditions of cultivation are not attacked, and are useless to the plant. He has, therefore, tried a system of dialysis with distilled water, which he believes follows better the processes of nature. The dialyser employed was somewhat, but not materially different from the ordinary apparatus. It was found that after a dialysate of 10 days, not only the soluble salts but a notable proportion of organic matter had passed into the distilled water, colouring it yellow, yielding a dark brown residue after cautious evaporation, and a carbonaceous residue on ignition. This substance is different from the *matière noire* of Grandeau, which does not pass through parchment-paper. The author refers to old experiments of Risler made in 1858, showing that plants derive a portion of their carbon from the soil, and not entirely from the atmosphere. J. F.

Titration of Copper by Means of Potassium Cyanide. By J. J. and C. BERINGER (*Chem. News*, **48**, 111—113).—The authors have studied some of the conditions which affect the accuracy of this method for the determination of copper, and publish the results, &c., in this paper.

Effect of Manner of Working.—The result is not so much affected by the time occupied in the entire titration as it is by the rate with which the last 2 or 3 c.c. are run in. The manner of finishing is, therefore, of paramount importance; and in order to obtain concordant results, a fictitious finishing point must be adopted.

Effect of Variations of Temperature.

It is evident that sodium salts are less objectionable than ammonium salts; and by neutralising with soda instead of ammonia, ammonium salts are avoided. Therefore if only a slight excess of soda be employed, whilst the temperature and mode of working are the same, the present question is greatly simplified, the only matter to be considered being the effects of the relative quantities of reagents:

these may be summed up thus; when the copper, ammonia, and volume of liquid vary, but retain their relative proportions, the quantity of cyanide used is proportional to the copper present. If, however, the copper and volume are constant, whilst the ammonia increases, more cyanide is required. On the other hand, if the ammonia and copper are constant, whilst the bulk increases, less cyanide is necessary. Hence the authors inferred that by adding water and ammonia in proper proportions these errors might be got rid of. They have employed successfully 15 c.c. of 0·880 ammonia to each 300 c.c. of liquid, in slightly alkaline solution, titrating with the necessary precautions. D. A. L.

Colorimetric Estimation of Gold. By A. CARNOT (*Compt. rend.*, **97**, 169—170. (See below.)

New Reactions of Gold. By A. CARNOT (*Compt. rend*, **97**, 105—108).—A dilute solution of auric chloride is mixed with a small quantity of arsenic acid, two or three drops of ferric chloride solution, and the same quantity of hydrochloric acid diluted with 100 c.c. of water, and a fragment of zinc are added. A purple colour is soon developed in the neighbourhood of the zinc, and on agitation the liquid acquires a rose or purple tint. The same colour is also immediately produced if, instead of zinc, the solution be mixed with a few drops of an acid solution of ferrous chloride, or of the solution obtained by acting on metallic iron with arsenic and hydrochloric acids. This reaction succeeds with less than 0·0001 gram of gold in 100 c.c. of water. With phosphoric acid in place of arsenic acid, a violet or bluish coloration is obtained. Hydrochloric acid alone gives a less intense rose coloration. Hydrogen gas, mixed with small quantities of hydrogen sulphide, may be used instead of zinc or ferrous chloride.

The rose or purple liquid is perfectly transparent, can be filtered without being decolorised, and is unaltered at the end of three months. It is, therefore, a true solution, and is not a liquid holding finely-divided gold in suspension. If the solution is not distinctly acid, or if it be mixed with certain salts, especially ammonium salts, a flocculent purple precipitate is slowly deposited. If the liquid is too acid, the reaction does not take place, but finely-divided gold is precipitated. The same decomposition occurs if the reducing agent is added too rapidly, or if the precipitate, when once formed, is redissolved in hydrochloric acid. If the reducing agent is added gradually, a considerable excess appears to have no action on the rose or purple compound. The precipitate has a composition corresponding with the formula $Au_2O,19Fe_2O_3,15AsO_5$. It would appear, therefore, that the action of the reducing agent is only partial, aurous oxide and ferric oxide being formed. The ferric chloride, the presence of which is essential, in all probability acts as a restrainer of the reducing action. C. H. B.

Estimation of Arsenic: Pearce's Process. By O. J. FROST (*Chem. News*, **48**, 85—86. Compare Abstr., 1883, 1034—1035).—In this process, the finely-powdered substance is fused with six to ten times its weight of the sodium carbonate and potassium nitrate mixture and then proceed as described (*loc. cit.*), the solution, however, instead of being evaporated to dryness, is exactly neutralised with ammonia and nitric acid, and filtered, if necessary. Excess of neutral silver nitrate solution is now added; the silver arsenate filtered off and washed with cold water, and the filtrate tested to see that precipitation is complete. The amount of silver is determined and the arsenic calculated from it. This is best effected by dissolving the arsenate on the filter in dilute nitric acid (any chloride is thus left behind), and titrating the filtrate for silver, with thiocyanate. Good results have been obtained by this method, which the author states can be worked in half an hour. Molybdic and phosphoric acids interfere with the process; antimony does not, on account of the insolubility of sodium antimonate.

D. A. L.

Volumetric Method for the Estimation of Arsenic. By A. H. Low (*Chem. News*, **48**, 85).—A defence of Pearce's process (see last abstract) against some criticisms made by McCay. The author considers that dissolving the precipitated silver arsenate in dilute nitric acid and titrating the silver is better than determining the excess of silver as McCay does (Abstr., 1883, 1035), for any chlorine present as impurity in the reagents would have no effect in the first case, because any silver chloride present would not be dissolved, but would lower the results in the latter method. He also recommends the use of a platinum instead of porcelain crucible for the fusion, as it can be more easily cooled, and, from experience, he states that it remains apparently uninjured, even after many times using. D. A. L.

Test for Bismuth Subnitrate. (*Dingl. polyt. J.*, **248**, 260.)—According to Hager, bismuth subnitrate and bismuth subarsenate dissolve in eight parts of nitric acid of sp. gr. 1·185, forming clear solutions; the latter is, however, not completely soluble in a solution saturated with bismuth nitrate. Hence, by treating 0·5 gram of the subnitrate with 4 grams nitric acid, a clear solution should be obtained within half an hour, otherwise arsenate is present. D. B.

Estimation of Manganese in Iron Ores. (*Dingl. polyt. J.*, **248**, 259.)—Zulkowsky recommends incineration of the manganous sulphide precipitate in a platinum capsule, and moistening the residue with aqueous sulphurous acid. The solution is evaporated on a water-bath, the residue taken up with water and two to three drops of dilute nitric acid, and titrated with potassium permanganate. For this purpose, the solution is transferred to a flask, diluted with water to 150 to 200 c.c., and boiled. To the hot solution, potassium permanganate is added from a burette, and the mixture boiled after each addition until the supernatant liquid shows a pale red colour. According to the formula $3MnO + Mn_2O_7 = 5MnO_2$, 1 c.c of a decinormal solution of potassium permanganate corresponds with 1·65 mgrm. manganese.

D. B.

Volumetric Method of Estimating Manganese, especially in Iron and Steel. By R. Schoffel and E. Donath (*Dingl. polyt. J.*, **248**, 421—424).—To conduct this method, a solution of sodium carbonate is required, which does not reduce potassium permanganate even on boiling; also a solution of potassium permanganate of known strength. For this purpose sodium hydrogen carbonate is converted into the normal carbonate by strongly heating it. A saturated solution of the carbonate is then prepared, which is heated to boiling and treated with a solution of potassium permanganate until the mixture assumes a faint reddish colour, which remains on continued boiling. The fluid is kept in well-stoppered bottles, and although its colour soon disappears, it no longer affects potassium permanganate. The solution of potassium permanganate is titrated with pure iron wire or with ammonium ferrous sulphate. As this reaction is illustrated by the equation $10FeO + Mn_2O_7 = 5Fe_2O_3 + 2MnO$, and the equation which explains the action of potassium permanganate on the manganese salt is $3MnO + Mn_2O_7 = 5MnO_2$, 10 atoms of iron correspond with 3 atoms of manganese; so that by multiplying the iron value by 0·2946, the permanganate value is obtained.

For the analysis of samples rich in manganese, such as pig iron, spiegeleisen, and ferromanganese, 2 to 1 grams,—for poorer samples, 4 to 3 grams,—are dissolved in boiling hydrochloric acid. The mixture is allowed to cool, treated with a small amount of potassium chlorate, and again boiled until all chlorine has been expelled. The solution, if too acid, is evaporated to a small bulk, partly neutralised with sodium carbonate, and made up to 100 c.c. 50 to 60 c.c. of the solution of sodium carbonate are then transferred to a flask holding 700 to 800 c.c., diluted with 400 to 500 c.c. distilled water heated to boiling, and treated with standard potassium permanganate. The test solution is then run in from a burette, the mixture being stirred all the while. From the instant the colour becomes fainter, the solution should be added with caution, and the mixture allowed to settle from time to time. The operation is concluded as soon as the red colour of the fluid has disappeared. The amount of permanganate solution used should be so regulated that one-half, or at least one-third of the test solution is required, otherwise the results will be vitiated too much by the limits of error. D. B.

Suspended Matter in Water. By E. Marchand (*Compt. rend.*, **97**, 49—50).—The water under examination is placed in a flask surrounded by black paper, in which are cut two opposite rectangular apertures, and a beam of light is passed through the water. This method of examination reveals the existence of a large number of suspended particles which are invisible under ordinary conditions, but which the author has found to exist in large numbers in all forms of natural water, and even in distilled water which has been exposed for some time to the air. Some of these particles are vacuoles containing water or gas, others have a shape resembling that of discoïdal diatoms. They have a sp. gr. higher than that of sea-water (in which they are very abundant), and they are not attacked by dilute acids or alkalis. Amongst these suspended corpuscles are germs of *Euglenea*, a fact which explains the development of green growths in all places exposed to light and moisture, and they also include organisms which probably play an important part in the oxidation of the organic matter contained in water. Although some of them have a diameter as great as 2 mm., they are so flexible that they pass through the closest filters, and when taken into the body they can pass through the kidneys, and are found in the urine. C. H. B.

Test for Glycerol and Woody Fibre (*Dingl. polyt. J.*, **248**, 259.)—According to Reichl, minute quantities of glycerol can be detected by boiling the solution to be examined with a small amount of pyrogallol and a few drops of sulphuric acid diluted with an equal volume of water; this causes the formation of a red colour, which is changed to purple on adding stannic chloride. Carbohydrates and certain alcohols must be absent, as they produce similar colours. By boiling woody fibre in a solution of stannic chloride mixed wih a few drops of pyrogallol, a fine purple colour is formed. This reaction can be used as a means of dyeing wood. D. B.

Valuation of Sugar-beets by their Density. By A. v. WACHTEL (*Bied. Centr.*, 1883, 421—422).—The custom of valuing beet-roots by their weight is a rough and ready rule; the beet-juice on analysis frequently shows considerable differences. The author recommends Krocker's process, that is, to prepare several mixtures of calcium chloride or cane-sugar solutions of different sp. gr., then with a sampling tool to take pieces out of the root, placing them in solutions of different densities until they float. Considerable differences are caused by the manner in which the roots are cleansed for sampling, roots which are brushed and wiped showing a greater percentage of sugar than those cleaned with warm water. J. F.

Detection of Silver Cyanide. By C. L. BLOXAM (*Chem. News*, **48**, 49).—The following test is of use in qualitative work. Precipitated silver cyanide appears amorphous under the microscope; if, however, it is treated with ammonia and warmed, it forms needles. Silver chloride, treated in similar manner, forms octohedrons. In a mixture of the two, both constituents can be recognised in this way. Silver thiocyanate also forms needles under like conditions, the absence of thiocyanic acid must therefore be ascertained by the iron test. Silver cyanide also crystallises when boiled with a strong solution of sodium carbonate, or when moistened with strong nitric acid and warmed. Silver cyanide can be separated from silver chloride by treating the mixture with hot dilute nitric acid in which the cyanide is soluble. If the solution is cooled, and the tube containing it is kept still, the cyanide separates in a semi-transparent gelatinous form; if, however, the tube is agitated, the precipitate collects suddenly into opaque masses (generally) of microscopic needles. D. A. L.

Reactions with Silver Cyanide, Ferrocyanide, and Ferricyanide. By C. L. BLOXAM (*Chem. News*, **48**, 73—74).—When white silver ferrocyanide is shaken with ammonia it forms an opalescent liquid. When heated it becomes brownish-grey in colour, and metallic silver is deposited. When treated with nitric acid, the grey precipitate yields a solution of silver nitrate and ferric nitrate, leaving a residue of ferric oxide, mixed with a little silver ferricyanide. No cyanide could be detected in this precipitate by means of ammonium sulphide. With hydrochloric acid, a solution containing both ferrous and ferric chlorides is obtained.

The ammoniacal solution neutralised with nitric acid yielded silver and ammonium cyanide. When silver ferrocyanide is treated with a cold strong potash solution, a heavy brown precipitate forms. The supernatant liquid is colourless, stains paper brown, and on being heated deposits silver; it contains a trace of potassium cyanide, but no ferro- or ferri-cyanide. The brown precipitate contains metallic silver, and silver ferro- and ferri-cyanide. Apparently, then, a part of the silver ferrocyanide is converted into ferricyanide with separation of silver; and the ferricyanide thus formed forms a compound with the unchanged ferrocyanide, which compound is not decomposed by cold potash or warm ammonia. Boiling with potash entirely decomposes the ferrocyanide, yielding a solution of potassium and silver cyanide, and leaving a residue of ferrous and ferric oxides and silver. By boiling together precipitated silver oxide, silver ferrocyanide, and water, the colour changes from brown to black, and silver and silver cyanide and ferricyanide are produced. When silver ferricyanide is treated with potash in the cold it becomes black, yielding silver oxide and potassium ferricyanide; on boiling, the black precipitate changes to pink, and ammonia is evolved, but on continuing to boil the precipitate again becomes black. The pink precipitate contains a compound of silver cyanide with silver ferricyanide insoluble in ammonia, along with silver cyanide, silver ferrocyanide, and ferric oxide. The pink precipitate can be exactly reproduced by boiling silver oxide with potassium ferricyanide, on continuing the ebullition ammonia is evolved and the precipitate becomes black. The filtrate from the pink precipitate contains potassium cyanide and silver ferrocyanide in large quantities, and small quantities of silver cyanide and potassium formate. The final black precipitate consists of metallic silver and ferric oxide; the filtrate from it contains the same constituents as the pink precipitate filtrate, with the exception that there is no potassium formate, but instead silver ferricyanide. When ammoniacal solutions of silver cyanide and silver ferricyanide are boiled together, a buff precipitate is produced, which behaves like the above-mentioned pink precipitate (thus synthesising the compound of silver cyanide with silver ferricyanide). The potassium cyanide then reduces the remaining silver ferricyanide to ferrocyanide thus: $2Ag_6Fe_2Cy_{12} + 4KCN + 4H_2O = 3Ag_4FeCy_6 + K_4FeCy_6 + 2HCN + 2CO_2 + 2NH_3$. When silver oxide and silver ferrocyanide are boiled together, the pink precipitate, silver cyanide, and ferric oxide are produced: $Ag_6Fe_2Cy_{12} + 3Ag_2O = 12AgCy + Fe_2O_3$. Several equations are given to illustrate the reactions which probably take place during these changes. D. A. L.

Test for Gallic Acid. By S. YOUNG (*Chem. News*, **48**, 31—32).—When aqueous gallic acid is treated with potassium cyanide solution, a red coloration is produced, which disappears in a short time if the liquid remains undisturbed. If, however, the liquid is shaken energetically the colour reappears, but again disappears on standing. The colour can be reproduced in this manner from 15 to 20 times, the solution finally becoming brownish-yellow. Pure tannic acid, free from gallic, is not coloured by potassium cyanide. D. A. L.

Examination of Fatty Almond Oil. By H. HAGER (*Dingl. polyt. J.*, **248**, 524).—The author draws attention to the fact that the oil obtained from bitter almonds differs from that of sweet almonds by the elaïdin test, as it gives only a small amount of solid elaïdin. For the examination of the oil, 1 gram is treated in a small porcelain dish with 4 drops of concentrated sulphuric acid, and the mixture stirred together with a glass rod. A yellow colour rapidly changing to yellow-red appears, which is soon converted into a permanent brown with green tinge, or green with brown tinge. By mixing equal volumes of fuming nitric acid and water with 7 vols. of almond oil, and agitating the mixture, the oil from sweet almonds gives a white colour, whilst that from bitter almonds yields light to dark-yellow shades. D. B.

Butter Analysis. By A. v. BASTELAER (*Bied. Centr.*, 1883, 419).—In order to determine the relations of water, fat, caseïn, and salt, the author takes 10 grams from the centre of a butter sample, places it in a porcelain dish of 5 or 6 cm. diameter; dried at 100—120° to constant weight, the loss is water; the residue is extracted with rectified benzene, the first portion poured on without stirring to allow the caseïn to separate, the last two portions stirred up with a glass rod, and again dried; the loss shows fat; residue ignited is caseïn by loss; the ash is salt. The limits of a large number of determinations are given:—

Pure butter fat......	75 to 85 per cent.
Water	9 to 15 „
Caseïn	1 to 3 „
Sodium chloride	5 to 10 „

J. F.

Tests for Vegetable Alkaloïds. By R. PALM (*Chem. News*, **48**, 65—66).—The author has shown previously that the alkaloids are precipitated by solutions of alkaline sulphides or persulphides, and moreover that in contact with a solution of sodium thioantimonate, solutions of the alkaloïd salts form characteristically coloured precipitates consisting of the alkaloid hydrosulphides mixed with antimony sulphide. When the solutions of the alkaloïd and reagent are dilute, these precipitates appear as colourless turbidities, which become yellow on exposure to the air; whilst with concentrated solutions they are yellow to reddish-brown, and in saturated solutions they form resinous masses. The precipitation is more complete in dilute solutions, and is accelerated by gently heating, or by the addition of strong alcohol. In most cases the yellow precipitates are dissolved by excess of the thioantimonate; they are, with few exceptions, amorphous, and dilute acids only partially separate the alkaloïd from them. The chemical composition of the precipitates has not been determined. Sodium thioantimonate produces the following changes with the alkaloïds referred to. With quinine sulphate in dilute neutral solutions, a white turbidity; in stronger solutions, yellow flocks, which on shaking form resinous lumps, and become darker. When hot solutions of the quinine salt and reagent are mixed, resinous masses form at once, which when dry fall to a fine yellow powder like lead iodide. With cinchonine sulphate, in dilute solutions, dark yellow (leather colour) flocks form at once; they do not coagulate either on standing or heating. With quinidine sulphate, the effect is almost exactly the same as with the quinine salt, with the exception that the whole of the precipitate does not become resinous, and when dry is of a darker yellow colour (an intense dark chrome-yellow): the precipitation is also more complete. With morphine hydrochloride in dilute solutions, yellow flocks are at once deposited, which are darker in strong solutions, and when dry resemble powdered gamboge in colour. With codeine hydrochloride, a flocculent precipitate is produced, which when dry resembles the quinidine precipitate in tone, being a paler yellow than the morphine precipitate. With narcotine, in concentrated hot solutions, the precipitate coagulates in resinous masses, which when dry have the colour of dry precipitated ferric hydroxide. With strychnine nitrate, the reaction is more sensitive than with all the other vegetable alkaloids, the strychnine being entirely precipitated, and moreover the precipitate is not soluble in excess of the reagent. In dilute solutions of strychnine nitrate, colourless flocks separate which become yellowish in air; in concentrated solutions, yellow flocks form which do not coagulate on standing, and when dry are of a fine intense deep golden-yellow colour. With brucine nitrate, when the reagent is added in successive portions to a moderately concentrated solution of this alkaloid salt, three distinct precipitates are obtained: 1. Reddish-yellow, which collects in resinous masses. 2. Light golden-yellow flocks. 3. Colourless flocks, which form a crust on the surface of the liquid. When the mixed precipitates are boiled with water, the greater part dissolves, leaving an amorphous deep orange residue. The solution deposits yellow crystals of the double sulphide.

With atropine sulphate in strong solutions, a yellow deposit is formed, which coagulates on shaking or heating, but when dry is not so dark as the dry morphine precipitate.

With bebeerine hydrochloride, a dark-coloured precipitate is formed which coagulates in strong, and especially in hot, solutions, and when dry is greyish-brown. The alkaloids also form double sulphides with other metallic sulphides.

Lead chloride can be used as a reagent for vegetable alkaloïds; it should be dissolved in a solution of sodium chloride, which dissolves more of the lead salt than cold water does. The precipitates are generally crystalline, and consist of a mixture of lead chloride and an alkaloïd salt. Quinine and brucine form crystalline powders; cinchonine, morphine, and codeïne small fine needles; the strychnine precipitate when dry forms a crystalline asbestos-like felted mass. The lead chloride is not so delicate a test as the thioantimonate. A strong solution of sodium chloride completely precipitates bebeerine from its solutions.

D. A. L.

Estimation of Urea. By L. Hugounenq (*Compt. rend.*, **97**, 48—49).—Urine is filtered through animal charcoal, diluted with water, and heated in sealed tubes at a temperature above 140°, the ammonium carbonate which is formed being estimated by means of standard acid with "methyl orange" as indicator. This method is applicable to albuminous urine, if the albumin is previously removed by coagulation, but it is not applicable to urine containing glucose or a notable quantity of magnesium. C. H. B.

Estimation of Gluten in Flour. By L. Reed (*Chem. News*, **48**, 63).—The proposed method of estimation is based on the fact that a yellow nitro-body is produced by the action of nitric acid on albuminoïds.

Half a gram of flour is put in a test tube, which is graduated from the bottom to about half way up into 4 parts of equal capacity, water is added up to the 4th mark, and the tube violently shaken. The contents are now temporarily transferred to a dry tube, the graduated tube is washed, and a quarter of the liquid poured back up to 1st mark, and colourless nitric acid is added up to 3rd mark. After five minutes' standing, with occasional shaking, the liquid is filtered through a dry filter into a dry receptacle; a standard flour is treated in the same way, and the clear yellow solutions are examined colorimetrically, the qualities of the flours being inversely as the heights of equal colour. D. A. L.

Technical Chemistry.

Heat of Combustion of Coal. By Scheurer-Kestner (*Compt. rend.*, **97**, 268—271).—A criticism of Bunte and Stohmann's experiments (Munich, 1879, 1880, 1882). C. H. B.

Influence of Artificial Lighting on the Atmosphere of Dwellings. By F. Fischer (*Dingl. polyt. J.*, **248**, 375—379).—The author shows that the preference given to solar oil or rock oil as illuminating agents is not only based on grounds of economy, but depends on the fact that these oils contaminate the air of rooms less largely than coal-gas. Gas is, however, a more convenient and effective illuminant. The use of regenerative gas-burners, or of the electric light especially in the form of incandescent lamps worked from accumulators, is strongly recommended, as little or no heat is given off, whilst the atmosphere is not contaminated with injurious substances. D. B.

Chemical Composition of the Water of the Danube above Vienna in the year 1878. By J. F. Wolfbauer (*Monatsh. Chem.*, **4**, 417—435).—This paper gives the results of a series of analyses of Danube water made in the year 1878, chiefly with the view of ascertaining the value of the water for irrigating a tract of land known as the Marchfeld, situated between the rivers Danube and March. For this purpose 23 samples of water were taken at Grafenstein, about 20 kilometers above Vienna, at intervals of 16 days from January 20, 1878, to January 16, 1879, the height of the river being observed at each taking. The quantities of solid constituents of the water in the forms of dissolved and of suspended matter (mud) were then determined in each sample, and the several samples were submitted to chemical analysis. The results are given in the following table,

TABLE I.—*Average Chemical Composition and Hardness of Danube Water in Four Periods of the Year* 1878.

which shows the average composition of the Danube water in four seasons of the year 1878, together with the average for the whole year; also the degrees of hardness according to Fehling's scale, in which 1° of hardness indicates the presence of 1 part by weight of calcium oxide in 100,000 parts of water.

The numbers in Table I show that the minima of dissolved substances and of hardness occur in the spring and early summer months, when the river is swollen by rainfalls and by the melting of the Alpine snows. The variations in the proportion of mud at different seasons are much greater than those of dissolved matters, the minimum 0·96 per cent. being observed on the 11th of December, and the maximum 3·383 on the 6th of July. The water is clearest from the beginning of October to the middle of January, from which time till the beginning of autumn incessant fluctuations take place in the height of the river, and in the quantity of mud which it carries along. The general result of all these observations is that as the river rises, it becomes more muddy and softer, and as it sinks, it becomes clearer and harder.

TABLE II.—*Average Quantity and Composition of the Mud.*

	In form of:				
	Organic matter and chem. comb. water (loss by ignition).	Carbonates, soluble silicates, &c., soluble in nitric acid.	Argillaceous substance, disintegrable by strong sulphuric acid.	Sand.	Total.

The preceding data afford the means of estimating the quantities of mud and of plant-constituents which the water of the Danube is capable of yielding for irrigation. According to the proposed scheme for irrigating the Marchfeld, 1·2 litre of water per second would be made to flow over each hectare of surface, during the normal irrigation period, from April to September inclusive.

This amounts to 18,000 kilos. per hectare, or, in other words, the depth of the layer of water added daily to the soil would amount to 10 mm. With this quantity of water there would be added to the soil—

Floating particles (mud)		2500 kilos.
Dissolved matter (total)................		2800
Potash, dissolved............	31 kilos.	62
„ in the form of zeolitic silicates and clay	31 kilos.	
Phosphoric acid		4·1
Sodium nitrate........................		46·0

For the better appreciation of these numbers, it may be added that the quantity of potash thus added to the soil might be estimated to increase the production of hay by 4000 kilos. per hectare. The phosphoric acid in the water may be roughly estimated as equivalent to the production of 970 kilos. per hectare. H. W.

Organisms in the Air around Carlsberg. By E. C. Hansen (*Bied. Centr.*, 1883, 279—283) —By employing sterilised hopped beer-wort the author has examined the air in various localities at Carlsberg, including the fermenting cellars of a brewery. He gives a long list of the various organisms found, and states that all the organisms found in different parts of the brewery were also found in a garden, excepting *Sacch. glutinis* and *sarcina*, *Ba. spirilla* and *spirochetis* were never found. Grains should not remain in a brewery, as bacteria proceed from them, which may set up acid fermentation. Alcohol ferments proceed from ripe fruits and the soil, and of these ferments mildew is the most abundant and saccharomyces the least frequent. E. W. P.

Coking of Coal with Conversion of its Nitrogen into Ammonia. By Scheurer-Kestner (*Comp. rend.*, **97**, 179—182).—The loss of heat-producing power resulting from the preliminary coking of coal is only compensated by the value of the condensed ammonia compounds when the price of the original coal is extremely low. C. H. B.

Manufacture of Sulphuric Acid free from Arsenic and Selenium. By H. Borntráger (*Dingl. polyt. J.*, **248**, 380).—With the view to facilitate the drying and roasting operations, the author recommends to filter-press the iron sulphide formed in the manufacture of sulphuric acid from the soda residues of the Leblanc process by the aid of spent pyrites (*ibid.*, **243**, 151) instead of draining it on filters. It is also suggested to utilise the resulting liquors for the preparation of sodium thiosulphate, as they are free from metallic sulphides. D. B.

Manufacture of Sulphuric Acid. By H. Pemberton (*Dingl. polyt. J.*, **248**, 424),—The author has experimented on the manufacture of sulphuric acid from sulphur, with the view of determining the relation between the consumption of nitre and the chamber-space. His results are of interest, as they include a system which works with Gay-Lussac towers. From the amount of denitrated Gay-Lussac acid, the quantity of nitre which passed through the chambers for 100 parts of sulphur is calculated. The percentage of nitre consumption found is 15·6, which includes 3·5 per cent. of nitre lost.

Hurter, in his dynamic theory of the manufacture of sulphuric acid, found that the product of chamber-space into nitre consumption is approximately a constant number when the chamber-space corresponds to 1 per cent. of loss of nitre for works not using Gay-Lussac towers. The chamber-space is inversely proportional to the nitrogen compounds present, provided, however, that the loss of sulphur is the same, and the same strength of acid is made. For works making weak acid the necessary chamber-space is much smaller.

The following results by Hurter are yearly averages of five English works using pyrites. The author's numbers refer to works where sulphur is exclusively used. The two are not, however, comparative, as in the author's case the loss of sulphur and the concentration of the acid is not shown:—

Hurter's Results (only Pyrites).

	Chamber space for 1 pound of sulphur. cubic feet.	Nitre used for 100 sulphur.	Product of nitre, consumption into chamber space.	Acid produced from 100 sulphur.	Sp. gr. of acid.
A....	32·3	10·0	323	431	1·55
B....	29·8	11·2	334	392	1·65
C....	24·5	12·0	294	345	1·65
D....	22·3	13·7	305	386	1·65
E....	22·8	9·5	217	405	1·50

Pemberton's Results (Sulphur).

1....	26·8	10·0	268	—	—
2....	29·8	9·0	268	—	—
3....	35·7	8·0	285	—	—
4....	19·2	15·6	300	—	—

In the case of A and E the acid is much weaker; the produce from A is larger, and the chamber-space in the case of E much smaller. No. 4 was worked with Gay-Lussac towers, the loss of nitre being 3·5 per cent. D. B.

Formation of Sodium Sulphate in Bricks. By G. CHRISTEL (*Arch. Pharm.* [3], 21, 39—41).—The author found that a mass of effloresced salt, which appeared upon some bricks in cold weather, consisted of sodium sulphate with a trace of sodium carbonate. The principal chemical constituents of the materials used in the manufacture of the bricks were aluminium silicate, iron pyrites, and sodium silicate. The author supposes that the formation of sodium sulphate may be due to one or all of the following reactions:—(1.) The iron pyrites, under the influence of heat in presence of water, absorbed oxygen, forming iron sulphate and sulphuric acid; the latter acting on sodium silicate would form sodium sulphate; the sulphuric acid formed in the above manner would also act on aluminium silicate, giving rise to sodium alum, which, when heated, would yield alumina and sodium sulphate. (3) The existence of calcium sulphate or other sulphate in the original materials, which, during manufacture, would act on a sodium salt yielding sodium sulphate by double decomposition. W. R. D.

New Process for Producing a Bronze-coloured Surface on Iron. By L. MAYER (*Dingl. polyt. J.*, 248, 249).—The cleaned objects are exposed to the vapours of a heated mixture of concentrated hydrochloric and nitric acid (1 : 1) for a few minutes, and heated to a temperature of 300—350°, the heating being continued until the bronze colour appears. The objects are then cooled, rubbed with vaseline, and heated, until the latter begins to decompose. This operation is then repeated. A bronzy oxide coating is obtained by using acetic acid in conjunction with the above-mentioned acids. By varying the proportions of the different acids, it is possible to obtain light or dark brown shades. The author has coated iron T-bars in this manner and exposed them for about a year to the atmosphere of his laboratory without the slightest change or sign of corrosion.

D. B.

Production of a Gold-coloured or Green Surface on Brass. By C. PUSCHER (*Dingl. polyt. J.*, **248**, 304).—40 grams of caustic soda, 40 of milk-sugar, and 1 litre of water, are boiled together for 15 minutes. 40 grams of a cold saturated solution of sulphate of copper are then added gradually, the mixture being stirred continually. The solution is then cooled to 75°. A short immersion of the articles to be coated results in the formation of a gold colour. A longer digestion yields a bluish-green tint, whilst after a very long immersion iridescent colours are obtained. D. B.

Adulteration of Cement. (*Dingl. polyt. J.*, **248**, 245—249).—At the sixth general meeting of the Society of German Cement Manufacturers, held in Berlin, a long discussion on the adulteration of Portland cement took place, and the following propositions were unanimously agreed to:—

(1.) Portland cement is a product formed by intimately mixing lime and alumina, burning the mixture to the point at which the mass begins to slag, and disintegrating it to the fineness of flour.

(2.) Every product which is formed in a different manner or receives foreign additions during or after burning, is not to be regarded as Portland cement. Additions of 2 per cent. of gypsum are, however, admissible.

(3.) The sale of cement containing foreign substances as Portland cement is an imposition on the consumers.

(4.) Good Portland cement is not improved by mixing foreign substances like calcium silicate (ground blast-furnace slag) trass, ground clay, slate, limestone, &c., with it. But supposing it could be shown that such additions were of advantage, they should not be allowed, as the consumer cannot control the quantity or quality sufficiently to enable him to guard himself against fraud.

(5.) Every addition is therefore to be regarded as the commencement of the preparation of mortar, and concerns, not the manufacturer, but the consumer.

(6.) As the test which is used at the present time is unavailable when Portland cement is adulterated with foreign substances, and the character of cement is altered when such additions are made, it is useless to apply the same in comparing mixed with unmixed cement.

D. B.

Metallurgy of Nickel. By W. P. Blake (*Chem. News*, **48**, 87—89).—In an interesting address, the author remarks that for many years after its discovery nickel was produced only as a bye-product in the working of cobalt ores, and even when it came into use, it appeared only as an alloy, and until 1876, when Wharton in America investigated the subject and produced considerable quantities of the metal, pure nickel was as rare as thallium is at the present time. Subsequently Fleitman improved and cheapened the refining operations, and reduced the liability to the presence of blow-holes in nickel castings, by adding a very small quantity of magnesium to the molten metal in the pot. By this means the carbonic anhydride is destroyed, magnesia and graphite being formed. Since then large quantities of the pure metal have been produced, and many uses found for it. Nickel welds well with iron, and the two metals when rolled together at the proper temperature, become so firmly united that they may be rolled down together to any thinness. There are all thicknesses of nickel upon iron.

In scrap or waste, the nickel is recovered by dissolving away the iron with sulphuric acid. Formerly nickel plates, &c., were beaten directly under the hammer: hence there was a great loss by scaling, as with iron, but now this is avoided by covering the nickel with a thin sheet of iron, which is afterwards dissolved off. This nickelled iron is extremely useful; the coating is much more firmly attached, and hence more durable than the electrically deposited nickel, whilst for domestic purposes, for covers, saucepans, &c., it surpasses *tinned* iron or copper, for the nickel is not only lighter, harder, and stronger, but is also less liable to tarnish and corrode, so that it can always be kept polished. It moreover will wear longer, and cannot be melted off by overheating. D. A. L.

Novelties in the Iron Industry. (*Dingl. polyt. J.*, **248**, 498—509.)—In a paper read at the August meeting of Mechanical Engineers, Cochrane referred to the working of blast furnaces, and especially to the effect which the position of the tuyeres has on the working of the furnace. The position of the tuyeres if badly chosen may often annul the saving effected by working with large furnaces and a specially hot blast. By drawing back the tuyeres a great advantage is gained; thus by increasing the distance of the tuyeres from 1·83 meters to 2·13 the make of iron was raised from an average of 483 tons to 599 tons, the consumption of coke being practically the same in both cases (603 tons).

According to Delafond, the dephosphorisation of pig-iron in basic lined open hearths has the following advantages over the converter. The preparation and maintenance of the basic lining is not attended with the same difficulties. The addition of lime and the removal of slag can be effected at any period of the operation.

Gautier states that the pressing of fluid steel during the process of cooling is conducted at the Whitworth Steel Works by pouring the fluid metal into moulds composed of a series of superposed steel rings lined with a refractory material. The moulds are placed on wheels, and when full are run under the hydraulic presses. A refractory stone prevents the ram of the press from being welded together with the steel. The pressure used is equal to 600 atmospheres. Steel prepared by compression is said to gain considerably in hardness.

The longer the surface of a casting is allowed to remain in the fluid state, the more uniformly will it contract on cooling, and the smaller will be the number of hollow spaces which are formed. Krupp has utilised this circumstance in practice by surrounding the upper sides of the castings with fluid slag or sand.

Gmelin recommends the use of a jacketted cylinder cooled by water for the walls of cupolas.

Dufrené has patented a new arrangement in cupolas heated by gas, the generator being in direct communication with the furnace. In the lower part of the collecting space immediately above the opening through which the fire gases enter, an intermediate hearth is arranged, consisting of a series of barrelled ribs, so as to allow the flame to pass into the charge which is placed on the hearth.

Besson has modified the construction of cupolas by connecting the chamber of the furnace with a separate iron hearth and a special combustion space, which is said to accelerate the fusion.

Reusch works up scrap iron by heating it to redness in a furnace with a reducing flame, whereupon it is pressed into moulds and rolled out to bars, plates, &c. D. B.

Red Wine Manufacture in Germany. By NESSLER (*Bied. Centr.*, 1883, 422—423.)—The growth of a taste for red wines in Germany, and the planting of new vineyards to supply it in the vine districts, has induced the author to publish the recommendations contained in the present paper. They relate to situation of the vineyard, and the descriptions of grapes which should be grown; he discusses the kind of vats which should be used, and recommends a large chamber or other place which can be kept at a uniform temperature of 16—20°, in which the process of fermentation should be carried on independent of outside temperature: he cautions the wine maker against the use of unripe or spoiled grapes. J. F.

Extractive Matter in Tyrolese Wine, 1883 Vintage. By A. HENECKE (*Bied. Centr.*, 1883, 426).—It is the custom to examine the yearly averages of wines grown in the district; as those of 1882 were of inferior quality to those of many previous years, it was expected that the extractive matter would have been very low. The reverse was the case, however. and the author endeavours to explain this by supposing that in plentiful years the poor and spoiled bunches are left, the superior chosen for wine making. During the year in question, there were few choice bunches, and the decayed or unripe grapes yielded a large extract. The wine of the year was thick and mucilaginous, cleared badly, and developed bacteria in quantity. He attributes it to the low proportion of alcohol in the wine. J. F.

Preservation of Wines. By E. HOUDART (*Compt. rend.*, **97**, 55). The second fermentation of light wines rich in sugar, such as the "vins de coupage," when kept in casks for daily consumption, may be prevented by carefully heating the wine to 55—60° in a specially constructed apparatus, and storing it in casks previously well washed with boiling water. The air which enters the cask when the wine is drawn off, is filtered through cotton-wool. This treatment does not appreciably affect the composition, colour, flavour, nor any other property of the wine. C. H. B.

Wine and its Examination. (*Dingl. polyt. J.*, **248**, 293—296.) According to Maumené, œnocyanin, the colouring matter of wine, is colourless at the commencement of the ripening of grapes, and is rendered blue by oxidation; iron takes no part in this change.

For the preparation of wine from roots, Brin recommends the following method. Beetroots are boiled, triturated and pressed; the juice is brought into fermenting vats provided with steam pipes and fermented with yeast, malt, or apple-juice. The requisite quantity of tannic acid is then added, the mixture allowed to settle, filtered, and the product treated like ordinary grape-wine. This product is said to form a suitable adulterant for red wines. Turnips yield a white coloured wine when treated in a similar manner; it is, however, advisable to add a small quantity of nitric acid to the mass at the beginning of the fermentation.

Lorraine Wines.—Weigelt has prepared a number of wines from grapes of the year 1881, and examined the same with the following results:—

* Red and white grapes.

Fresenius and Borgmann (*Zeitschr. Anal. Chem.*, 1883, 46) give a description of their investigation on pure grape wines.

Borgmann confirms the assumption that wine which contains less than 7 pts. glycerol for 100 pts. alcohol, has been treated with alcohol.

D. B.

Preparation of Spirit and Pressed Yeast. (*Dingl. polyt. J.*, **248**, 464—469.)—At the annual meeting of the Society of German Spirit Manufacturers, the more recent experience gained in the manufacture of spirit and pressed yeast was discussed.

Delbrück treated of the improvements which have been effected in the manufacture of spirit by the introduction of new mashing apparatus. Referring to the preliminary mashing vats used for mixing the malt and the stuff coming from the steamers, both of which are introduced at different temperatures, it is stated that the main object is to obtain perfect agitation, so that no differences of temperature can be noticed at any period of the mashing. With regard to the mode of cooling, a very advantageous arrangement is the use of an exhauster, although cooling by means of water is more trustworthy.

According to Märker, Goutart's mashing apparatus is the most perfect in mechanical construction and working power; a very concentrated mash is obtained by its use.

Francke discussed in detail the conditions necessary to produce the highest yield of yeast. D. B.

Bread Making. By V. Marcano (*Compt. rend.*, **96**, 1733—1734).—In experiments on bread-making made in Venezuela, the author found that the fermenting paste is free from *saccharomyces*, but contains a large number of moving sphero-bacteria. During fermentation, the gluten and a small portion of the albuminoïds are partially dissolved and converted into peptones not precipitable by tannin. These results agree with those of Chicandard (Abstr., 1883, 1179), but the author found that contrary to the statement of this chemist, the paste at the commencement of fermentation contained a considerable proportion of erythro-dextrins and a relatively small quantity of soluble starch, whilst at a later stage it also contained a notable proportion of achroo-dextrins. In Venezuela, the bread is made from a mixture of flour and starch which is comparatively poor in gluten. The bacterium does not attack the starch until after it has destroyed the albuminoïds, hence the necessity for using a very active ferment developed by means of maize, potatoes, &c. Similar fermentation takes place whenever any grain, fruit, root, &c., is exposed to the air in the tropics. If European yeast is placed in moistened starch, the yeast gradually disappears, and is replaced by bacteria. Attempts to repeat these experiments in Paris have yielded negative results, the starch always remaining unattacked. It would appear, therefore, that in all experiments on fermentation, it is necessary to take into account the local conditions, which may exert great influence on the nature and progress of the change. C. H. B.

Fermentation of Bread. By L. Boutroux (*Compt. rend.*, **97**, 116—119).—Leaven from rye-bread made at a farm at a considerable distance from a brewery was found to contain bacteria and four other distinct organisms, viz., *Mycoderma vini*, two distinct species of yeast different from that of beer and wine, and an organism which appears to be *Saccharomyces minor*, but which has no power as a ferment. The bacteria were very abundant, but the other organisms could only be recognised by careful cultivation, and it would appear therefore that the bacteria are the principal agents of fermentation, the other organisms playing a secondary and comparatively insignificant part.

C. H. B.

Percentage of Sugar in Beet. By K. STAMMER and P. DEGENER (*Bied. Centr.*, 1883, 274—278).—Stammer has introduced a pulper which enables a higher percentage of sugar to be obtained in the manufacture of beet-sugar, and he shows the gain obtained by successive pressings of the pulp. Beets which have gone to seed and others which have withered, are by no means wanting in sugar. After the mash has been extracted with 50 per cent. alcohol, it still yields sugar to 75 per cent. alcohol. Degener describes his method for estimating the value of roots, which method yields higher results than that of Scheibler, as modified by Seckel. E. W. P.

Strontia Process. By C. SCHEIBLER (*Dingl. polyt. J.*, **248**, 426—428).—The author mixes a 20 to 25 per cent. solution of pure cane-sugar heated to 70° to 75° with strontium hydroxide in the proportion of 1 mol. sugar to 1 mol. $SrH_2O_2,8H_2O$, stirring the liquor continually. On cooling, a supersaturated solution of strontium monosaccharate is obtained, from which, after some time, either unaltered strontium hydroxide crystallises out or monosaccharate separates according as the saturated solution has been treated with a few crystals of strontium hydroxide, or a small amount of monosaccharate. The saccharate, $C_{12}H_{22}O_{11}SrO,5H_2O$, is formed in the cold by introducing the requisite quantity of finely-divided strontium hydroxide into a cold sugar solution, with constant agitation. The author utilises this reaction for the recovery of sugar from molasses. He dissolves 0·5 k. of strontium hydroxide in 1·5 k. of boiling water, and mixes it with 1 k. molasses. The clear solution is allowed to cool and stirred frequently, small quantities of monosaccharate being added at the same time. After 12 to 24 hours, the strontium saccharate has crystallised out; it is freed from the mother-liquor by filter presses, and washed with water or a cold saturated solution of strontium hydroxide. In order to recover the sugar which remains in the liquors, an excess of strontium hydroxide is added, and the mixture boiled for some time: thus nearly all the sugar is precipitated as strontium disaccharate; the strontium hydroxide remaining in solution is precipitated with carbonic anhydride. The disaccharate which is saturated with mother-liquor is converted into monosaccharate by dissolving it in molasses and adding a hot saturated solution of strontium hydroxide (1 mol. total sugar requires 1·25 mols. strontium hydroxide). The strontium monosaccharate is separated in the manner just described. From the latter, the sugar is recovered by the ordinary methods, or the strontium hydroxide may be first partly separated as such and again used for a further operation. For this purpose the saccharate is dissolved in hot, but not boiling water, and the solution allowed to cool without agitating it, when strontium hydroxide crystallises out.

The author has determined the solubility of strontium monosaccharate in water at different temperatures. The following table gives the solubilities to 60°, the temperature at which the decomposition of the saccharate commences:—

Temperature.	One litre contains—				Sp. gr. of the monosaccharate solution at +17·5°.	Corresponds with degrees, Brix.
	Monosaccharate, $C_{12}H_{22}O_{11}SrO$.	Sugar.	Strontium oxide, SrO.	Crystalline strontium hydroxide, $H_2SrO_2.8H_2O$.

D. B.

Preparation of Potato Starch. (*Dingl. polyt. J.*, **248**, 381.)—Nitykowski has made a series of comparative tests on the cultivation of potatoes. He found that the recent heavy rains have reduced the total yield of potatoes by about 25 per cent. of the average of the last ten years. Thirty-seven varieties were examined, the yield ranging from 9697 kilos. per 5000 square meters (containing 19·16 per cent. starch, equal to 1858 kilos.) to 4167 kilos. (containing 16·38 per cent. starch, equal to 683 kilos. starch per 5000 square meters). The so-called "alcohol potatoes" proved to be the most mealy and richly flavoured. The yield was 7500 kilos. per 5000 square meters (containing 19·26 per cent. starch, equal to 1445 kilos.).

Märker states that potatoes rich in starch should be used for seed. Samples of a Saxon variety of potatoes were analysed, and a great difference was found in the amount of starch present. In experimenting on the effects of different manures on the potato, it was shown that the produce was increased with potassium salts, especially the chlorides, whilst the amount of starch was diminished. Märker strongly condemns the manufacture of starch without the utilisation of the refuse water for the irrigation of meadows and arable land, as this water contains valuable fertilisers.

According to Saare, the great loss in the manufacture of starch is due to the want of efficient disintegrating machines. D. B.

Experiments with Nielsen and Petersen's Centrifugal Separator. By W. Fleischmann (*Bied. Centr.*, 1883, 411—415).—A description of the machine and some results of working with it; the yield of cream is good; and rate of revolution being but 1600 revolutions per minute against 4232 revolutions in the Laval separator, there is considerably less danger of accident. In eight experiments, where the temperature of the milk was gradually increased from 5° to 40°, the fat left in the skim milk decreased from 0·8508 in the first to 0·2229 in the eighth, which the author takes to prove the beneficial influence of a temperature of 40°. Suggestions are made for improvements or additional appliances, but would not be understood without a long description. J. F.

Comparison of Various Systems of Butter-making. By N. Fjord and others (*Bied. Centr.*, 1883, 415—416).—The authors have for a year compared five different systems of butter-making: the ice process; cooling by water at 10°; churning; and the centrifugal machine of Nielsen and Petersen. The yield from all processes varied considerably, but the centrifugal showed the best; and whereas the average of the ice process required 27·5 lbs. of milk to make 1 lb. of butter, the centrifugal required 3 lbs. of milk less. J. F.

Faults in Butter Manufacture. By Otto (*Bied. Centr.*, 1883, 417).—The author draws attention to certain precautions which should be taken not only in butter-making, but with the milk from which butter is made, as many mistakes do not show themselves until after the butter has been stored some time.

Cows should not be irrationally fed; they should not be constantly fed on one material, but on various descriptions of fodder in reasonable variety. The milk of old cows which is slightly bitter should only be used in moderate proportion with other milks. Ventilation of stables must be carefully attended to, the cows kept clean, and the milk quickly removed from the stable lest it should acquire a bad flavour. The locality of the dairy should be carefully attended to. A free current of fresh air should play around it, and the floor should not be made of a porous material, such as bricks. The cleansing of the vessels is of the greatest importance. The rancidity of butter is frequently due to want of attention to this; they should be cleaned with soda, steam, &c. The souring of the cream should not be continued longer than 24 hours, or the butter will have a slightly bitter taste.

J. F.

Fixing Indigo on Cotton. By SCHLIEPER and BAUM (*Chem. News*, **48**, 64—65).—For this purpose, the indigo is ground up for two days with caustic soda and water; it is then mixed with a mixture of British gum, maize starch, water, and caustic soda, and the whole heated at 55° in a water-bath, well stirred, and cooled immediately. The colour ought now to be gelatinous, and is printed on the cloth, which is prepared with glucose and well dried. The dyed cloth is then steamed for 10—15 minutes. Light or dark shades are obtained by using more or less indigo with more or less soda. The *only* good *resist* is precipitated sulphur, and thickening. A *yellow resist* is formed with cadmium chloride, precipitated sulphur, and thickening. A *red resist* is made of red liquor, tin-crystals, calcined starch, and precipitated sulphur. *Light blue*, the cloth prepared with glucose, is printed with caustic soda, thickened with dextrin and maize starch, steamed for 15 seconds, and padded with indigo colour. In using the red resist, the soda must be removed, or the cloth must be passed into ammonium chloride. An indigo colour is easily discharged on Turkey-reds. For a Turkey-red mordant, heat gelatinous alumina with caustic soda, add water, neutralise with hydrochloric acid, and add more water. For padding, this mixture is also used in a more dilute form; it is dried and aged on the cloth, then passed through lukewarm chalk water, which converts the sodium into calcium aluminate. This mordant can withstand the action of sulphuric acid without losing much of its depth, and on this property the production of indigo discharge styles is founded. For the production of indigo Turkey-red, the cloth previously mordanted for, or dyed with alizarin, is saturated with glucose. The indigo is now printed on, the fabric steamed, washed, exposed to the air for a few minutes, passed into sulphuric acid (8° B.) for about 20 seconds, washed, passed into weak sodium carbonate, and again washed. The red pieces are soaped at a boil, the alizarin is dissolved, and the blue colour appears. To obtain white on Turkey-red or indigo-blue, a dark blue and strong soda-lye are printed on before proceeding as indicated, or a strong lye is printed on the Turkey-red mordant, then steam, dry, and print on the indigo.

Process for preparing a Mineral White. (*Dingl. polyt. J.*, **248**, 260.)—According to Cobley, a solution of magnesium sulphate is converted into magnesium chloride by the addition of calcium chloride. 10 per cent. of aluminium chloride are then added. Calcium hydroxide throws down a white precipitate from the mixed solution. A cheaper white is obtained by precipitating a solution of the corresponding sulphates with calcium hydroxide. D. B.

General and Physical Chemistry.

Photographic Investigations of the Ultra-Violet Spark Spectra emitted by Metallic Elements and their Combinations under Varying Conditions. By W. N. HARTLEY (*Chem. News*, **48**, 195—196).—It has been shown (*Brit. Assoc. Jour.*, 1882) that the spectra of metallic solutions are the same as those from metallic electrodes, the principal difference being that short lines in the spectra from the metals become long in the spectra from solutions, whilst very short lines sometimes disappear, as for example in the case of zinc. This is probably due to the solution not being able to contain a sufficient quantity of metal to yield an image of them: thus the very short lines of the aluminium spectrum are not reproduced in solutions of the chloride unless the solutions are extremely concentrated. With regard to the short lines being lengthened by moistening iridium electrodes with calcium chloride, it has now been shown that moistening with water has the same effect: hence the supposition that a chloride of the metal was formed is untenable. The very short lines in the zinc spectrum are also lengthened by moistening the electrodes with water. This variation in the spectra appears to be due to the cooling action of the water on the negative electrode, since heating the electrodes produces a reverse result. Carbon gives two spectra in air when dry, and a third when moistened with water; the three have been photographed, but cannot be exactly described without maps. Numerous experiments have been tried to determine which non-metallic elements are capable of yielding spark spectra when they are combined with metals. Chlorides, bromides, iodides, sulphides, nitrates, sulphates, selenates, phosphates, carbonates, and cyanides yield none. Hydrochloric acid solutions of arsenites, arsenates, and antimonates yield spectra of arsenic and antimony respectively, and solutions of borates and silicates yield characteristic spectra (see below) of the non-metallic constituents; even if sodium salts are employed no metallic lines appear in the case of borates, and with silicates only the strongest sodium line ($\lambda = 3301$) is visible, even in concentrated solutions.

Spark.		Carbon spectra lines (Liveing and Dewar).	
Boron (wave-lengths).	Silicon (wave-lengths).	Spark.	Arc.
3450·1	2881·0	—	2881·0
2497·0	2631·4	2541·0	—
2496·2	2541·0	2528·2	2528·1
	2528·1	2523·6	2523·9
	2523·5	2518·7	2518·8
	2518·5	2515·8	2515·8
	2515·5	2514·0	2514·1
	2513·7	2506·3	2506·6
	2506·3		2478·3
	2435·5		2434·8

It will be observed that these silicon lines are identical with those (annexed table) attributed by Liveing and Dewar (*Proc. Roy. Soc.*, **33**, 403) to carbon, and from many hundred spectra taken between graphite poles it is apparent that in the arc spectrum carbon yields but one line (2478·3 wave-length) in the ultra-violet.

The ultra-violet spectrum of beryllium has been obtained from the solution of its chloride, and the following lines were observed:—

Wave-lengths.	Description.
3320·1	Strong, sharp.
3129·9	Very strong, extended.
2649·4	Strong, sharp.
2493·2	Strong, sharp.
2477·7	Strong, sharp.

From these observations and the general grouping of the lines, the author feels inclined to regard beryllium as the first member of the dyad series to which barium, calcium, and strontium belong. Reasons are given for not classing beryllium with other metals.

D. A. L.

Production of Electricity by Condensation of Aqueous Vapour. By S. Kalischer (*Ann. Phys. Chem.* [2], **20**, 614—620).—The production of electricity by condensation of aqueous vapour presents a problem of considerable meteorological importance as regards the origin of atmospheric electricity. It is, however, probable that the production of electricity observed is in most cases due to the friction between the water particles and the condensing surface. In this paper the problem is examined experimentally by means of an apparatus which permitted the condensation of aqueous vapour by cooling. It consisted essentially of a series of beakers filled with ice, and covered externally with tinfoil; the beakers were placed on a plate of galvanised iron connected with a quadrant electrometer, and the whole combination was enclosed in a metallic box. Although deviations of the needles of the electrometer were observed, yet they were of the same magnitude and direction whether the beakers were filled with ice or not; and secondly, they were sometimes in one, and sometimes in the other direction.

Other experiments are described in which air was compressed in, and then allowed to expand from a vessel resembling the electric egg, the metallic stopcock of which was in connection with a quadrant electrometer. But in this case, although a pressure of 25 atmospheres was used, and the aqueous vapour fell in the form of fine dew on releasing the pressure, yet there was no development of electricity.

V. H. V.

Measurement of the Quantity of Electricity produced by a Zamboni's Pile. By E. Riecke (*Ann. Phys. Chem.* [2], **20**, 512—524).—This paper contains a series of determinations in absolute measure of the quantities of electricity produced by three Zamboni's piles containing a large number of platinum plates interposed between strips of silk. A long series of tables of those quantities obtained on days of different relative humidity are given, and formulæ for their calculation as well as for differences of potential are also quoted. V. H. V.

Influence of Galvanic Polarisation on Friction. By K. WAITZ (*Ann. Phys. Chem.* [2], **20**, 285—303).—In 1874 Edison noticed that the friction between a metallic and a porous plate moistened with some conducting liquid, was diminished when an electric current was sent through this combination from the porous to the metallic plate. Further changes in the friction are produced by variations in the intensity of the current. This fact has been practically applied in the construction of telephones and electromotographs.

In this memoir the phenomenon is more completely investigated. The apparatus consists in the main of a clay cylinder filled with acidulated water, and enclosed within a glass vessel filled with water of the same concentration. A platinum foil is introduced into the inner, and a strip of glass in the outer vessel, on which a small platinum foil is stretched; this latter is connected with a mechanical arrangement whereby the platinum foil on the glass strip can be pressed against the clay cylinder with various degrees of pressure. The whole arrangement is enclosed in circuit with two Daniell's cells, a metallic arrangement to measure the degree of pressure, and a rheostat to vary the intensity of the current. In many experiments it was found that the friction between the platinum and the porous cell is materially diminished when the intensity of the current is sufficient to decompose the acidulated water.

As the contact of the platinum and the clay was not found to be sufficiently perfect, a polished glass cylinder was substituted. The alteration of friction between glass and various metals, platinum, palladium, gold, and nickel, introduced into such solutions as sulphuric acid, potash, and soda, and potassium ferrocyanide was carefully examined: in the original memoir extensive tables are given of the results obtained in the course of the investigation. As a general result it may be stated that there is a diminution of resistance when the metallic plate is the anode, but an increase when the plate is the kathode, and the intensity insufficient to decompose the electrolytic liquid. This latter fact is contrary to the experience of Koch, who found no alteration in the case of the kathode. As the diminution of resistance appears only when bubbles of gas appear at the surface of the plate, it appears probable that the occlusion of the gas by the electrode is the cause of the phenomenon. Another hypothesis is that the formation of an electric double stratum, called forth by the polarisation on the surface of the electrodes, alters the external friction between the metallic surface and the glass on the one hand, and the glass and the liquid on the other.

Further experiments will decide between these two hypotheses, but the writer inclines to the latter. V. H. V.

Relations between Coefficients of Friction and Galvanic Conduction. By E. WIEDEMANN (*Ann. Phys. Chem.* [2], **20**, 537—538).—In connection with a remark of G. Wiedemann on certain relations existing between coefficients of friction and galvanic conduction, and the theoretical deductions drawn therefrom, a series of investigations has been made on this point. However, in order to prove how far these relations hold good, the author examined solutions of crystalline zinc sulphate in water and aqueous glycerol of various concentrations. The coefficients of friction were measured by Spring's apparatus, those of conduction by a Wheatstone's bridge.

Strength of solution $ZnSO_47H_2O$.	Ratio of coefficient of friction		Ratio of coefficient of conduction	
	In water.	In glycerol.	In water.	In glycerol.
1 per cent.........	1	68 7	1	12·1
2 „	1	29·8	1	9·52
5 „	1	6·5	1	3·68

These numbers show that the ratios existing between the coefficients of friction and conduction are not simple, and further that the nature of the solvent and also its concentration exert a most marked influence on them. V. H. V.

Galvanic Temperature Coefficient. By V. STOUHAL and C. BAROS (*Ann. Phys. Chem.* [2], **20**, 525—536).—Previous researches have not established any differences of specific resistance as factors of the temperature corresponding to known differences of composition of various forms of iron and steel. It appeared, however, probable to the writer that iron, whose coefficient of resistance varies according to its degree of hardness and temper, should also possess various temperature coefficients. In this connection it has been shown by Matthiessen and Vogt that the temperature coefficients of platinum-silver alloys decrease with the proportion of platinum; like differences have been observed by the authors in the case of German silver. Similarly it is to be expected that iron, containing various proportions of carbon, which may function as the second metal, should display similar variations. Experiments were accordingly made on steel tempered at various "heats," and specimens of bar and pig-iron.

In the case of steel the temperature coefficient of the steel varies as its coefficient of resistance continuously with the hardness of the steel, and decreases with increase of the temperature at which it is tempered.

The experiments of Matthiessen and Vogt on bar-iron, and those quoted in this memoir on pig-iron, show that the temperature coefficient varies with the proportions of carbon, and further, that the specific resistance of the latter is far greater than that of the hardest steel.

The above observations point to a marked analogy existing between alloys and steel in their galvanic relations, and to a general law that in all cases of homogeneous substances differences of specific resistance cause similar differences of temperature coefficients, increments of the former corresponding to diminutions of the latter. In alloys it is the small proportion of added metal which raises the specific resistance, in steel the carbon produces the same effect. It is also most probable that the magnetic, as the galvanic, temperature-coefficients vary with the degree of hardness in the same way.

Other experiments are also promised on the analogy existing between alloys and steel as regards their physical properties.

V. H. V.

Dependence of the Boiling Point on Pressure. By G. W. A. KAHLBAUM (*Ber.*, **16**, 2476—2484).—It has usually been assumed that a diminution of pressure of 1 cm. lowers the boiling point 1°. Experiments made in an apparatus in which the pressure could be kept constant whilst a considerable amount of liquid distilled, showed that this assumption is quite erroneous. The experiments were mainly for pressures of 5—100 mm. The nature of the variations is best shown by the results obtained with some of the fatty acids.

Formic acid.			Propionic acid.			Butyric acid.		
mm. Pressure.	Boiling point.	Sp. R.	mm. Pressure.	Boiling point.	Sp. R.	mm. Pressure.	Boiling point.	Sp. R.
24·84	21·8°	0·1071	21·31	56·5°	0·112	10·06	63·5°	0·131
27·66	22·6	0·1065	22·46	57·6	0·111	21·48	75·2	0·171
32·58	24·6	0·104	31·34	63·5	0·104	31·94	81·4	0·110
41·40	27·9	0·101	41·70	68·8	0·098	43·12	87·5	0·103
49·66	30·5	0·099	44·20	69·2	0·098	48·90	89·8	0·101
74·54	37·6	0·092	47·30	70·4	0·097	760·00	161·5	—
760·00	100·6	—	760·00	139·4	—	—	—	—

From these results it will be seen that the variations are peculiar to each substance and pressure. The figures in the third column of the tables give the ratio of the diminution of boiling point to diminution of pressure (from the boiling point at 760 mm.), termed by the author the *specific remission*. On obtaining by means of curves the specific remission for 0 mm. pressure, it appears that for the substances experimented with (lower fatty acids, alcohols, and anhydrides) *a difference in the composition of* CH_2 *corresponds with a difference of* 0·01 *in the specific remission for* 0 *mm. pressure.* A. J. G.

Heat of Combination of Carbon and Oxygen. By A. BOILLOT (*Compt. rend.*, **97**, 490—491).—Thermochemical investigations should determine the quantity of heat due to each individual constituent entering into combination or being liberated by decomposition, but, up to the present the determinations made measure only the sum or the difference of the effects due to the different constituents. In the combination of carbon and oxygen, how much heat is developed or absorbed by the carbon and oxygen respectively? Let A be the heat developed by the combination of 2 vols. of oxygen (weighing 2·666) with 2 vols.* of carbon vapour (weighing 1) to form 2 vols. of carbonic anhydride (weighing 3·666), B the heat developed by 1 vol. of oxygen combining with 2 vols. of carbonic oxide to form 2 vols. of carbonic anhydride, then A — B will be the heat developed by the union of 1 vol. of oxygen with 2 vols. of carbon vapour with formation of 2 vols. of carbonic oxide. Let x be the heat absorbed by the unit weight of carbon passing into the state of vapour occupying 2 vols., then $A - B + x$ will be the heat furnished by 1 vol. of oxygen combining with 2 vols. of carbon vapour to form 2 vols. of carbonic oxide, and $A - B + x = B$, whence $x = 2B - A$.

---

* The volume ratios and weights are given as in the original paper.

Using 6 grams of diamond, the results will be $A = 47$ cal., $A - B = 12·9$ cal., $B = 34·1$ cal., and $x = 21·2$ cal. $A + x = 68·2$ cal. will be the total heat furnished by the combination of 2 vols. of oxygen (weighing 16 grams) with 2 vols. of carbon vapour (weighing 6 grams) to form 2 vols. of carbonic anhydride (weighing 22 grams). Of these 68·2 cal., 21·2 cal. are absorbed by the carbon.

C. H. B.

Sodium Alcoholates. By De Forcrand (*Compt. rend.*, **97**, 108—111).—The heats of solution of the three known alcoholates in water at 20° are as follows:—

C_2H_5NaO, solid + 13·47 cal.
$C_2H_5NaO,2C_2H_6O$, solid + 10·46 ,,
$C_2H_5NaO,3C_2H_6O$, solid + 12·34 ,,

and the heats of formation are therefore—

$2C_2H_6O$, liquid, + Na_2O, solid, = C_2H_5NaO, solid, + H_2O liquid .... develops + 34·70 cal.
C_2H_6O, liquid + $NaHO$, solid, = C_2H_5NaO, solid, + H_2O liquid .... ,, + 0·25 ,,

It would appear, therefore, that the heat of formation of sodium alcoholate from sodium hydroxide, like that of sodium glycollate, is practically *nil.*

C_2H_5NaO, solid + $2C_2H_6O$, liquid, = $C_2H_5NaO,2C_2H_6O$, solid.................. develops + 8·06 cal.
C_2H_5NaO, solid + $3C_2H_6O$, liquid, = $C_2H_5NaO,3C_2H_6O$, solid.................. ,, + 8·64 ,,
$C_2H_5NaO,2C_2H_6O$, solid + C_2H_6O, liquid, = $C_2H_5NaO,3C_2H_6O$, solid.................. ,, + 0·58 ,,

A considerable proportion of this development of heat is due to the solidification of the alcohol. The inverse reactions give—

C_2H_5NaO, solid + H_2O liquid = C_2H_6O liquid, + $NaHO$ solid.. + 1·19 cal
$C_2H_5NaO,2C_2H_6O$, solid, + H_2O liquid = $3C_2H_6O$ liquid + $NaHO$, solid .. .. − 6·82 ,,
$C_2H_5NaO,3C_2H_6O$, solid + H_2O liquid = $4C_2H_6O$ liquid + $NaHO$, solid .... − 7·44 ,,

The decomposition of the alcoholates by water in excess takes place by reason of the development of heat which accompanies the hydration of the two products of the reaction, a development which amounts to + 17·78 or + 19·78 cal., according as the amount of alcohol is $3C_2H_6O$ or $4C_2H_6O$. From these data it follows that C_2H_6O liquid + Na solid = C_2H_5NaO solid + H gas develops + 32·13 cal., a number very similar to that developed by the action of sodium on water. Direct determination of the heat developed by the action of sodium in a large excess of alcohol gives the heat of solution of the anhydrous alcoholate in excess of alcohol as 12·65 cal., a value closely approaching the heat of solution of sodium hydroxide by water.

These results show that water and alcohol have almost equivalent functions with respect to sodium and sodium oxide. This fact and the dissociation of the secondary hydrates and alcoholates explain the equilibrium which is established in liquids containing alcohol, water, and sodium oxide. C. H. B.

Aqueous Solution. By J. A. Groshans (*Ann. Phys. Chem.* [2], 20, 492—512).—The sp. gr. of an aqueous solution of 1 mol. of a substance in 4 mols. of water can be expressed by the interpolation formula $a = 1 + \frac{\alpha a}{18(A + \lambda)}$, in which a is the molecular weight of the substance, 18 that of water, α is a constant, and $\lambda = \frac{a}{18\beta}$, where β is another constant. In this communication, certain relations existing between αa for the haloïd salts and the nitrates of certain metals are brought out. Thus, for example, the differences of the values for αa for the iodide and bromide of strontium is equal to the difference between the same values for the iodide and bromide of magnesium. The same difference exists between the values for the bromides and chlorides of magnesium and cadmium. A few examples are quoted below:—

	Value for αa.		Value for αa.
SrI_2	283·85	MgI_2........	226·93
$SrBr_2$	211·37	$MgBr_2$......	152·38
	72·48		74·55
$MgBr_2$........	152·38	$CdBr_2$	226·93
$MgCl_2$	78·47	$CdCl_2$	152·38
	73·91		74·53

Hence it follows, for these salts, that $R(I_2 - Br_2) = R(Br_2 - Cl_2$ $= I_2 - Br_2 = Br_2 - Cl_2 = 73·80$. Similarly these differences for αa are the same, not only for the non-metallic but also for the metallic radicles. Thus Pb — Ba (αa) = Cd — Mg (αa) = 72·48 to 74·55: so also Ba — Sr = Sr — Ca = 43·15. A series of analogous differences is quoted in this memoir, derived not only from the above formula, but also from modifications of it in which other constants are introduced. The compounds more especially investigated are the halogen acids and their salts together with the nitrates of the alkaline earth and the magnesium-zinc-cadmium-group. V. H. V.

Specific Gravity of Normal Salt Solutions. By C. BENDER (*Ann. Phys. Chem.* [2], **20**, 560—578).—Valson has noticed (*Compt. rend.*, **73** and **77**) certain differences existing between the sp. grs. of metallic salts containing 1 gram of salt in 1 litre. For example, there is a constant difference between the sp. grs. of the potassium and ammonium salts, whatever be the non-metallic radicle associated with them, and, conversely, there is a constant difference between the sp. grs. of the chlorides and nitrates, whatever be the metallic radicle. So that to each metallic and non-metallic radicle there can be assigned a certain value or modulus with which it may be said to enter into solution. The following table explains the above statement:—

	Cl.	Br.	I.
K	1·0444	1·0800	1·1135
NH_4	1·0157	1·0520	1·0847
	0·0287	0·0280	0·0288

	K.	Na.	NH_4.
NO_3	1·0591	1·0540	1·0307
Cl.	1·0444	1·0396	1·0157
	0·0147	0·0144	0·0150

If, then, the sp. gr. of one salt, preferably that of ammonium chloride as the lowest, be taken as a standard, then the sp. gr. of other salts can be deduced from it by means of the equation $d = d_a + m_b + m_s$, in which d_a is the sp. gr. of ammonium chloride, and $m_b.m_s$ the moduli of the metallic and non-metallic radicle respectively. Valson has also observed that similar relations exist between the refraction equivalent of the metallic salts.

From these facts, the following general law may be deduced:—*Elements or radicles, entering into combination, are endowed with certain physical constants which are independent of the chemical nature of the resultant compounds.*

It is, however, pointed out that these observations were restricted to salt solutions of the same strength, and presupposes the same coefficient of expansion for each of the salt solutions.

In this paper these observations are extended to solutions containing one or more molecules of salt; it is shown that the modulus (*vide supra*) divided by the number of molecules in solution is a constant. This statement is explained by the table below, in which μ represents the number of molecules and Δ the modulus:—

μ.	NH_4Cl.	KCl.	Δ.	$\frac{\Delta}{\mu}$	NaCl.	Δ.	$\frac{\Delta}{\mu}$
1..	1·0157	1·0444	287	287	1·0401	244	244
2..	1·0308	1·0887	579	289	1·0788	480	240
3..	1·0451	1·1317	866	289	1·1164	713	238

A series of analogous examples of a large number of metallic salts is given in the original memoir; some of the values for the modulus in $\frac{1}{10000}$ units at 0°, deduced from various experiments, are given below:—

Metal.	Δ.	Element or Radicle.	Δ.
NH_4	0	Cl.	0
K	289	Br	373
Na	238	NO_3	163
Li	78	$(SO_4)_{\frac{1}{2}}$	206
$\frac{1}{2}$Ba	735	$C_2H_3O_2$	—15
$\frac{1}{2}$Sr	500		
$\frac{1}{2}$Mg	210		
$\frac{1}{2}$Mn	356		
$\frac{1}{4}$Zn	410		
$\frac{1}{2}$Pb	1087		

From these data the following will be the general equation for calculating the sp. gr. of a salt solution containing μ molecules in solution: $d\mu = d(\mu)\sigma + \mu(m_b + m_s)$, in which $d\sigma$, m_b, and m_s represent the same values as in the equation above. Attention is drawn to the general interest attached to these relations, and to their wider application to the more complicated organic combinations. V. H. V.

A New Liquid of High Specific Gravity, Refraction Equivalent, &c. By C. ROHRBACH (*Ann. Phys. Chem.* [2], **20**, 169—174).—Schaffgotsch, Church, and Klein have proposed various liquids of high sp. gr. for the practical separation of minerals. In the present memoir, a solution of the double salt of barium and mercuric iodide is recommended for this purpose, which forms a highly refractive golden-coloured liquid of sp. gr. 3·575 to 3·588. It boils at about 145°, evolving with the steam red vapours of mercuric iodide. It has the advantage that it neither decompose carbonates, nor absorbs carbonic anhydride from the air, but readily takes up water. Tables are given of various minerals which may be separated by means of this liquid. The following refraction values for Fraunhofer's lines were obtained:—

	C.	D.	E.	F.	$\frac{nF - nC}{nC}$.
Barium mercuric iodide sp. gr. = 3·564	1·7754	1·7930	1·8065	1·8488	0·409

G and the following Fraunhofer's lines could not be measured, owing to strong absorption in the violet. The high dispersive power of the liquid is also shown by the well-defined separation of the two D lines nD_1 and nD_2. This liquid may possibly be available for other mineralogical and physical investigations. V. H. V.

Compressibility of Gases. By E. H. AMAGAT (*Ann. Chim. Phys.* [5], **28**, 456—464).—The author contradicts Cailletet's statements (*Ann. Chim. Phys.* [5], **19**), (1) that mercury absorbs oxygen at the ordinary temperature; (2) that glass manometers are distended by pressure to such an extent as to affect the accuracy of the author's determinations of the compressibility of gases (*ibid.* [4], 29).

W. C. W.

Compressibility of Air and Carbonic Anhydride at 20—300° under 1 to 8 Atmospheres' Pressure. By E. H. Amagat (*Ann. Chim. Phys.* [5], **28**, 464—480).—In order to avoid the disturbing influence arising from the tension of the vapour of mercury, a special apparatus was constructed in which the gas does not come into immediate contact with the mercury during the determination.

Air obeys Marriotte's law under a pressure of 8 atmospheres at temperatures between 20° and 300°.

Carbonic anhydride deviates from the law, but the deviation diminishes as the temperature increases, *e.g.*, the value of $\frac{pv}{p'v'}$ at 50° to 300° under different pressures is shown in the following table:—

Pressure cm.	50°.	cm.	100°.	cm.	200°.	cm.	300°.
74	1 0037	72	1 0027	71	1·0009	72	1·0003
147	1·0075	143	1·0051	141	1·0025	143	1·0015
291	1·0143	282	1·0085	250	1·0041	287	1·0017

W. C. W.

Compressibility of Rarefied Air, Hydrogen, and Carbonic Anhydride. By E. H. Amagat (*Ann. Chim. Phys.* [5], **28**, 480—499).—Gases appear to obey Marriotte's law under low pressures. Under very slight pressures, the errors of experiment are too great to permit any conclusions to be deduced from the determinations.

W. C. W.

Condensation of Carbonic Anhydride by Glass. By R. Bunsen (*Ann. Phys. Chem.* [2], **20**, 545—560).—The thickness of the layer of carbonic anhydride condensed on the surfaces of the glass is so small, that a very extended surface is required for exact measurement of the amount of gas so condensed. The best material for the examination of this phenomenon is ordinary glass-wool; the sample used in the course of the investigation was of such a degree of fineness, that 150 grams occupied a space of 100 c.c., corresponding with a thread-length of 62 geographical miles, and exposing a surface of 23 square metres. Its sp. gr. was 2·5056. In the original paper the determinations on which these figures are based are given at length. A quantity of this glass-wool was introduced into a gas apparatus, which was filled with perfectly dry carbonic anhydride, and the experiment continued for three years, observations being made from time to time.

The following results are arrived at:—(1) The gas condensation does not reach a fixed point, even after several years; (2) during the continuation of the experiment, notwithstanding instantaneous or continual changes of temperature and pressure, no giving up of the carbonic anhydride was observable; (3) within temperature of + 23° to − 8° a rise of temperature produces an acceleration, a fall a corresponding retardation of the absorption. In the three years 5·135 c.c. of carbonic anhydride under standard conditions were absorbed by 1 square metre of the glass wool.

The results of these experiments are in direct contradiction to others on the same phenomenon; this discrepancy is, however, due to the fact that in former experiments the phenomenon was supposed to be finite and not continuous.

As the chemical affinity of the silicic anhydride for the basic substances in the glass is greater than that of the carbonic anhydride, the supposition of a combination of the latter with the glass is precluded; thus it appears that the carbonic anhydride is condensed as such. The long continuation of the phenomenon can be explained by an imperfect interpenetration of the glass by the molecules of the liquid carbonic anhydride. Further experiments will be required to prove whether after a sufficiently long interval of time this interpenetration becomes a sufficiently diminishing quantity; when this point is reached, the conditions remaining the same, neither condensation nor evaporation of the liquid carbonic anhydride would take place, although either one or the other might be caused by a change of the conditions. It would thus be not altogether impossible that for every series of temperatures there would be a corresponding series of levels of the layer of the carbonic anhydride.

It was further found by experiment that atmospheric air behaves towards a glass surface exactly as carbonic anhydride.

V. H. V.

Similarity of the Behaviour of Ultramarine in a very fine State of Division to that of Metallic Sulphides in the Colloidal State. By P. Ebell (*Ber.*, 16, 2429—2432).—Ultramarine in a very finely divided state, as it is obtained by grinding and elutriation in the course of its manufacture, shows great similarity in behaviour to the colloidal metallic sulphides described by Spring (Abstr., 1883, 904). The finer parts will remain suspended in pure water for months; the liquid passes unaltered through several thicknesses of Swedish filter paper, does not show any sign of turbidity when examined in a layer 2 cm. thick, and on evaporation leaves the ultramarine in a lustrous layer on the walls of the vessel. Microscopic examination (× 1200) shows only points appearing partly colourless, partly pale blue by transmitted light, deep blue by reflected light. The addition of small quantities of salts, &c., to the liquid causes the separation of the ultramarine: on washing with pure water or very great dilution, the ultramarine passes again into suspension. The author regards it as doubtful if the copper sulphide in the so-called colloidal state is really in solution in water, or whether it is not rather in suspension in a state of division far finer than that in which ultramarine can be obtained by mechanical means.

A. J. G.

Specific Volumes of Liquid Substances. By H. Kopp (*Ber.*, 16, 2458—2460).—The author thinks it advisable to call attention to the fact that in his original paper (*Annalen*, **96**, 155) the relations between composition and specific volume as derived from the observations then accessible were not advanced as being the correct ones, but only as useful approximations.

In comparing the calculated and observed volumes, it is necessary to bear well in mind the real nature of any difference: for instance, taking methyl alcohol (cal. vol. 40·8, obs. 42·1, diff. 1·3) and amyl benzoate (cal. 240 0, obs. 247·7, diff. 7·7), there is not, as at first sight appears, a much greater divergence in the latter case, but in each case the difference is the same, = 3·2 per cent. of the calculated specific volume.

The results obtained by the later experiments with bodies whose relations to one another are now more clearly known, certainly show less agreement with a law of atomic volume than was expected from the earlier experiments; but the agreement of individual substances with many so-called laws is often more general than absolute.

A. J. G.

Inorganic Chemistry.

Critical Temperature and Pressure of Liquid Oxygen. By S. Wroblewski (*Compt. rend.*, **97**, 309—310).—When oxygen is liquefied by pressure in a bent tube surrounded by liquid ethylene which is caused to evaporate rapidly, it is found that, as the amount of liquefied oxygen increases so that it rises above the surface of the ethylene, the pressure necessary to continue liquefaction gradually increases, and when the liquid oxygen rises to a certain height in the tube, the meniscus becomes indistinct and finally disappears. These results are due to the fact that the temperature of that part of the tube above the liquid ethylene gradually increases as the distance from the ethylene increases. The disappearance of the meniscus takes place at a pressure of about 50 atmos., and on slightly reducing the pressure the meniscus reappears.

Carbonic anhydride was liquefied by pressure in a tube, the lower part of which was placed in melting ice, whilst the upper part was heated to 50°, the intermediate portions being of course at intermediate temperatures. As the liquefied gas approached the heated portion of the tube, the pressure required to continue liquefaction gradually increased until at about 76 atmos. the meniscus disappeared, but it reappeared on slightly reducing the pressure and consequently reducing the volume of the liquid.

The disappearance and reappearance of the meniscus in both cases evidently takes place at that part of the tube which is at the critical temperature for the particular gas, and the pressure observed at the time of disappearance is the critical pressure. The critical pressure for oxygen is about 50 atmos., and the critical temperature is approximately − 113°.

C. H. B.

Critical Point of Oxygen. By E. SARRAU (*Compt. rend.*, **97**, 489—490).—The critical pressure and temperature calculated by means of Clausius' formula from the results of Amagat's experiments on the compressibility of oxygen, are 48·7 atmos, and − 105·4° respectively. These values agree fairly well with Wroblewski's determinations (see preceding Abstract). C. H. B.

Conduct of Moist Phosphorus and Air towards Carbonic Oxide. By I. REMSEN and E. H. KEISER (*Chem. News*, **48**, 199—201).—In reference to the work of Hoppe-Seyler (Abstr, 1880, 3), Baumann (*ibid.*, 1882, 691), Traube (*ibid.*, 1882, 795), and Leeds (*ibid.*, 1880, 237), on the existence of an active form of oxygen distinct from ozone, the authors have repeated some of the experiments. A repetition of Traube's experiment led the authors to confirm his statement, viz., that the oxidation of palladium-hydrogen is due to the formation of hydrogen dioxide. And again, several repetitions of Leeds's and Baumann's experiments, in which great care was taken to prevent the mixed gases from inside the apparatus coming in contact with organic matter, led the authors to negative Leeds's and Baumann's conclusions; under these conditions no oxidation of carbon monoxide to dioxide took place.

In these experiments all the stoppers were covered with water or mercury, connections were made with pieces of glass tubing bent twice at right angles, so as to avoid india-rubber joints, and all necessary plugs were of asbestos. In some experiments, the asbestos plugs were replaced by cotton-wool, with the result that the gas which previously contained no carbonic anhydride, now precipitated baryta-water; this explains Leeds's error. No satisfactory explanation is given of the negative results obtained by Leeds and Baumann when no carbonic oxide was used. The authors are of opinion that the action of air and moist phosphorus on carbonic oxide furnishes no evidence of the existence of the so-called active oxygen. D. A. L.

Atomic Refraction of Sulphur. By R. NASINI (*Gazzetta*, **13**, 296—311).—Brühl's labours on atomic refraction have shown that the same element may have different atomic refractions according to its mode of union with the other elements, but up to the present time the atomic refraction of sulphur in its various compounds has not been made the object of special study.

After noticing what has been already done in determining the refractive indices of various sulphur compounds, the author points out that the questions he proposes to solve are:

1. To ascertain the value of the atomic refraction of sulphur corresponding with oxygen, where bivalent sulphur is united with two univalent groups, as in the mercaptans.

2. Its atomic refraction where the two valencies of sulphur are satisfied by the same carbon-atom.

3. To ascertain whether a variation in valency has any influence on its atomic refraction, by a study of inorganic sulphides and derivatives of carbon acids in which the sulphur is quadrivalent or sexavalent.

The experiments were all made with liquids: these for the most part were supplied by Kahlbaum, but were purified before the determinations were made. The author employed the empirical formula $\frac{n-1}{d}$ used by Landolt and Brühl, as being but little affected by variations of temperature. H. A. Lorentz and L. Lorenz have recently shown (*Wied. Ann.*, 9, 64, and 11, 70) that the formula $\frac{n^2-1}{n^2+2d}$ is the correct expression for the refractive power of a substance; it gives excellent results, and has also been used by the author. The values for this formula, calculated by Landolt from Brühl's numerous experiments, are given in the subjoined table, where r_a and r_A represent the atomic refractions of the elements with respect to the line α of the hydrogen spectrum, and with respect to the constant A of Cauchy's formula as functions of the old formula $\frac{n-1}{d}$; and r'_a and r'_A the same values for the new formula.

		$\frac{n-1}{d}$.		$\frac{n_2-1}{(n_2+2)d}$.	
		r_a.	r_A.	r'_a.	r'_A.
Carbon	C.................	5·0	4·86	2·48	2·43
Hydrogen	H.................	1·3	1·29	1·04	1·02
Oxygen (alcoholic)	O'	2·8	2·71	1·58	1·56
„ (aldehydic)	O''	3·4	3·29	2·34	2·29
Chlorine	Cl.................	9·8	9 53	6·02	5·89
Increment for each double bond.........		2·4	2·00	1·78	1·59

The determinations of the refractive index were nearly all made at 20° with a spectrometer of Bartels and Diederichs, by the method of minimum deviation, using the lines α, β, and γ of the hydrogen spectrum and the D sodium line. The sp. gr. of the substance was determined at 20°, referred to water at 4°, reducing it to a vacuum by means of the formula $d_{t4} = \frac{m}{w}(2-\lambda) + \lambda$, where m is the weight of the substance at a temperature t, w that of the water at the same temperature, and λ the mean density of the atmosphere.

The substances examined were ethyl mercaptan, EtHS; ethyl sulphide, Et_2S; ethyl bisulphide, Et_2S_2; isobutyl mercaptan, $C_4H_9.SH$; ethyl monothiocarbonate, OC(OEt)(SEt); isopentyl mercaptan, $C_5H_{11}.SH$; isopentyl sulphide, $(C_5H_{11})_2S$; diethyl dithiocarbonate, $OC(SEt)_2$; carbon bisulphide, CS_2; the compound, $CS(OEt)_2$; sulphurous anhydride, SO_2; and sulphuric acid, H_2SO_4. The results are given in three tables, and from an inspection of them it appears that the atomic refraction of sulphur, like that of oxygen, has two values, according as the two valencies are satisfied by two different univalent groups, as in mercaptan, &c., or by the same carbon-atom as in carbon bisulphide. These two values are as follows:—

	$\frac{n-1}{d}$.		$\frac{n_2-1}{(n_2+2)d}$.	
	r_a.	r_A.	r'_a	r'_A.
Sulphur with two single bonds	14·10	13·53	7·87	7·65
„ „ a double bond	15·61	15·09	9·02	8·84

In the case of the oxygenated compounds of sulphur, it would seem that the atomic refraction has only one value, although it differs considerably from those given above.

It is now established that the atomic refraction of an element may vary, not only as it is more or less closely united with other elements —that is, by single or double bonds—but also that the nature of the atoms or variation in the capacity of saturation of the element may greatly influence the value of the refraction-constant. Comparative researches on other multivalent elements, such as phosphorus and arsenic, will no doubt throw light on this most important question.

C. E. G.

Basic Sulphates. By J. Habermann (*Monatsh. Chem.*, 4, 787).— Preliminary Notice.—The basic copper sulphate, $6CuO,2SO_3,5H_2O$, which Reindel obtained as a blue-green precipitate on adding ammonia in sufficient quantity to a boiling solution of normal cupric sulphate (*Gmelin-Kraut*, 6 Aufl., vol. iii, p. 628), is also formed by boiling a solution of the normal sulphate (Pickering, *C. J.*, 1883, Abstr., 853), and the author of the present notice has obtained it by treating the solution of the normal sulphate with ammonia or with sodium carbonate in certain proportions.

Basic sulphates of nickel, cobalt, zinc, and cadmium are formed in like manner with either of these precipitants, but the salts thus obtained are not analogous in composition to the copper salt. Further details are promised.

H. W.

Action of Potassium Permanganate on certain Sulphur-compounds. By M. Hönig and E. Zatzek (*Monatsh. Chem.*, 4, 738 —752).—In this paper the authors describe a large number of experiments on the action of potassium permanganate on the thiosulphates, sulphites, and sulphides of the alkali-metals, the results of which may be summarised as follows:—

1. The thiosulphates of the alkali-metals are completely oxidised by the permanganate at ordinary temperatures, only in alkaline solution. Whatever may be the concentration of the permanganate solution, the complete oxidation of 1 part sodium thiosulphate ($Na_2S_2O_3,5H_2O$) requires 1·6366 part potassium permanganate. The

composition of the resulting precipitate is best represented by the formula $KH_3Mn_3O_8$.

2. The sulphites of the alkali-metals are completely oxidised at ordinary temperatures both in neutral and in alkaline solution. The quantity of permanganate required for oxidation of 1 part by weight of sodium sulphite (Na_2SO_3) depends on the concentration of the permanganate solution, being less in proportion as that solution is more dilute. The composition of the resulting manganese precipitate is variable, and likewise depends on the concentration of the permanganate solution.

3. The action of permanganate at ordinary temperatures on the mono- and poly-sulphides of the alkali-metals gives rise to sulphuric acid, trithionic acid, and free sulphur; at the boiling heat all or nearly all the sulphur is oxidised to sulphuric acid. H. W.

Direct Union of Nitrogen and Hydrogen. By H. B. Baker (*Chem. News*, **48**, 187—188).—This communication is a reply to Johnson (Trans., 1881, 128, 130). The author describes various experiments with Johnson's and other apparatus, and ultimately comes to the conclusion that nitrogen prepared from air, either by the removal of the oxygen by cold phosphorus, or by potassium pyrogallate, or by hydrogen in the presence of warmed platinum sponge, does not combine directly with hydrogen to form ammonia. When, however, the hydrogen was passed through a solution of silver nitrate, and subsequently through three bottles containing a saturated solution of ferrous sulphate, the author always obtained a brown coloration in the second Nessler tube.

Note.—Johnson has discontinued the use of silver nitrate for the *purification* of his hydrogen (*Chem. News*, **48**, 202). D. A. L.

Nitrogen Iodides. By A. Guyard (*Compt. rend.*, **97**, 526—531). —Nitrogen iodide in contact with water or aqueous ammonia is as sensitive to luminous vibrations as to calorific, sonorous, or material vibrations. When exposed to light, the iodide is rapidly decomposed with effervescence and gives off pure nitrogen, ammonium iodide and a small quantity of ammonium iodate being also formed. In presence of water, the decomposition usually terminates in a violent explosion, but in presence of ammonia it proceeds quietly to the end. Nitrogen iodide is as sensitive to diffused light as to direct rays, the rapidity of decomposition being proportional to the intensity of the light. The decomposition takes place equally well at 1°, 5°, 10°, or the ordinary temperature. The infra-red spectrum has no influence on the decomposition, but the visible spectrum acts powerfully, the maximum effect being produced by the yellow rays and the minimum by the violet.

Nitrogen iodide of the composition NH_2 is decomposed by light in presence of water, without explosion, in accordance with the equation $2NH_2I = NH_4I_2 + N$. Nitrogen iodide, however, rarely has this composition, and usually contains a greater or lesser proportion of other iodides. The compound therefore generally decomposes at first in accordance with the above equation, but explodes when the iodide,

NH_3I, begins to decompose. The decomposition of the typical iodide, NHI_2, in presence of ammonia, takes place in accordance with the equation $5NHI_2 + 12NH_3 = 10NH_4I + 7N$. One and the same nitrogen iodide will give off more nitrogen in presence of ammonia than in presence of water; in the first case ammonium iodide is formed, in the second the diiodide.

The decomposition of nitrogen iodide in ammonia may be used photometrically to determine the chemical and mechanical equivalent of light. The apparatus employed consists of a small flask with a long neck graduated in cubic centimeters, and provided with a stopper. The neck also carries a side tube similar to that of a Gay-Lussac burette. 1·27 gram of iodine is placed in the flask, which is then completely filled with ammonia of 22°, carefully stoppered, with exclusion of air bubbles, and exposed to light. 1·27 gram of iodine gives off 33·5 c.c. of nitrogen. The final reaction is the same whether nitrogen iodide or a mixture of iodine and ammonia is employed, and whether the mixture of iodine and ammonia is exposed to light at once, or time is given for the formation of nitrogen iodide. The decomposition takes place in accordance with the equation $13NH_3 + 10I = 10NH_4I + 3N$.

Preparation of Ammonium Iodide and Iodate.—When a mixture of iodine with excess of ammonia is exposed to light, nitrogen is given off, the free iodine entirely disappears, and ammonium iodide and iodate are formed. The ammonia is driven off and the liquid concentrated, when the ammonium iodide crystallises out, and the iodate remains in solution.

When iodine is mixed with aqueous ammonia, part of the iodine forms ammonium iodide, and the remainder is converted into nitrogen iodide. Afterwards, in presence of light and an excess of ammonia, more ammonium iodide is formed and nitrogen is given off. The first part of the change is chemical, the second photochemical. The principal reaction is represented by Odling's equation $3NH_3 + 2I_2 = 2NH_4I + NHI_2$. When the iodine is in excess, ammonium diiodide is formed, and the nitrogen iodide produced has approximately the composition NH_2I; with proper proportions of iodine and ammonia, the nitrogen iodide has approximately the composition NHI_2; with an excess of ammonia, a greater proportion of ammonium iodate is formed. Nitrogen iodide of the composition NHI_2 is but slightly affected by washing with pure water. Ammonia added to ammonium diiodide forms nitrogen iodide with the second atom of iodine.

Under ordinary conditions, $x(NH_4O) + 233(NH_4O) + I_{303} = NH_4O,IO_5 + 154NH_4I + 10(N_8H_9I_{15}) + 227HO + x(NH_4O)$,* where xNH_4O represents the excess of ammonia which must always be used, is the simplest equation which expresses the observed facts. The formula $N_8H_9I_{15}$ is approximately $8NHI_2$. With twice the excess of ammonia, about twice the amount of ammonium iodate is formed, and the nitrogen iodide consists mainly of $N_3H_4I_5$, or approximately $3NHI_2$. The formulæ given by previous investigators are probably correct, but refer to bodies prepared under different conditions.

---

* This equation is given exactly as it is in the original, it is, however, incorrect, as the two sides are $N_{233},H_{932},I_{303},O_{233} = N_{235},H_{937},I_{305},O_{233}$.

Nitrogen iodides are decomposed even by very dilute sulphuric, hydrochloric, or sulphurous acid, at first with effervescence, but afterwards with violent explosion. They dissolve in sodium thiosulphate, with formation of sodium iodide, ammonium sulphate, and free ammonia. The free ammonia is that existing in the nitrogen iodide; the ammonium in the ammonium sulphate is derived from the nitrogen existing in the nitrogen iodide in the form of triiodamine. Nitrogen iodide is partially decomposed by potassium iodide in the dark, with formation of potassium diiodide free from ammonia, and a nitrogen iodide insoluble in the alkaline iodide, that is, the iodide NHI_2 loses an equivalent, or part of an equivalent, of iodine, and yields a new iodide. When exposed to light, however, the nitrogen iodide is completely decomposed by the potassium iodide, and the liquid contains ammonium iodide. Potassium cyanide dissolves nitrogen iodide even in the dark, with evolution of nitrogen.

Nitrogen Copper Iodide.—When an ammoniacal solution of a copper salt is mixed with potassium diiodide, a brilliant, crystalline, garnet-coloured precipitate of the composition $CuI_2,2NH_3I$ is gradually deposited. When dried, this compound is very stable, but it is entirely decomposed by water, with formation of ammonium diiodide, and a bronze-coloured cupric oxyiodide, CuO_2I, which is decomposed by heat into black cupric oxide, iodine, and oxygen. The double copper nitrogen iodide is decomposed by aqueous ammonia, with formation of an ammoniacal solution of cupric iodide and a residue of an explosive nitrogen iodide free from copper. When the double iodide is heated, iodine and the products of the decomposition of nitrogen iodide are given off, and a residue of perfectly pure cuprous iodide is left. When distilled, the double iodide yields cuprous iodide, and brown, violet, and ammoniacal vapours. The brown vapours condense to a black product, decomposed by water with formation of a black crystalline nitrogen iodide, which resembles iodine in appearance, but which differs from all the other nitrogen iodides by dissolving with effervescence in a solution of potash or soda, nitrogen or hydrogen being given off, and a considerable quantity of ammonia formed.

When Schweitzer's reagent, prepared by Peligot's method, is mixed with potassium diiodide, a crystalline black double iodide of nitrogen and copper is formed, which resembles the preceding compound in its general properties, but yields an explosive cupreous residue when decomposed by washing with water. C. H. B.

White Phosphorus. By I. REMSEN and E. H. KEISER (*Chem. News*, **48**, 201—202).—In course of the experiments alluded to in this vol., p. 149, the authors had a suspicion that the phosphorus with which they were working might have contained some carbonaceous matter. To remove this the phosphorus was distilled in an atmosphere of purified hydrogen, and the vapour condensed in cold water. The distilled phosphorus presented a peculiar appearance; it floated on the surface of the water, forming a snow-white layer, and when placed in warm water changed into ordinary phosphorus. After many experiments the authors found that this variety of phosphorus could be prepared in the following manner: Sticks of phosphorus are placed in a tubulated retort, the neck of which is inclined upwards, and projects into a double-necked globular receiver, containing a layer of water and ice 1½ in. deep in the deepest part. The receiver is supported in a vessel of cold water, and the bent tube, which passes from the other neck of the receiver, dips into cold water. A glass tube is fitted into the tubulure of the retort to supply purified hydrogen, which is passed until the apparatus is filled with it; the current is then stopped, and the distillation proceeded with; this is conducted steadily so that the vapour as it issues from the retort does not condense to a liquid. In successful operations a thin white cake is found floating on the water. The apparatus is allowed to cool, the retort disconnected, and the receiver with its contents put under water to displace the hydrogen and remove the phosphorus; if this precaution is not taken, the phosphorus is liable to take fire, and give rise to an explosion of the mixture of hydrogen and air. White phosphorus is light and plastic; if it is placed on bibulous paper as it dries, it fumes, melts without taking fire, and changes to ordinary phosphorus, with which its melting point is identical. It is soluble in carbon bisulphide, and is not affected by sunlight so readily as ordinary phosphorus; a sample after a year became slightly yellow, but was otherwise unchanged. D. A. L.

Reactions of Gaseous Hydrogen Phosphide. By A. GAVAZZI (*Gazzetta*, **13**, 324—325).—On passing gaseous hydrogen phosphide through a neutral aqueous solution of platinic chloride, an ochreous yellow precipitate of the composition $PtPH_2$ is obtained: this is insoluble in water and hydrochloric acid. It ignites when heated to 100—110°, or when moistened with fuming nitric acid.

Arsenic phosphide, AsP, is formed by the action of hydrogen phosphide on a solution of arsenious anhydride in hydrochloric acid.

An aqueous solution of potassium permanganate absorbs hydrogen phosphide at a low temperature, the reaction being represented by the equations—

$$PH_3 + 2KMnO_4 = K_2HPO_3 + 2MnO_2 + H_2O$$
$$PH_3 + 2KMnO_4 = K_2HPO_4 + Mn_2O_3 + H_2O.$$

C. E. G.

Preparation of Phosphorus Oxychloride. By E. DERVIN (*Compt. rend.*, **97**, 576—578).—When phosphorus trichloride is mixed with potassium chlorate a violent reaction takes place, phosphorus oxychloride and potassium chloride being formed in accordance with the equation $KClO_3 + 3PCl_3 = 3POCl_3 + KCl$. This reaction may be utilised for the preparation of phosphorus oxychloride. 500 grams of pure phosphorus trichloride free from uncombined phosphorus are placed in a retort of 750—1000 c.c. capacity, connected with an inverted condenser, and 160 grams of finely powdered potassium chlorate is added through the tubulure in quantities of about 4 grams at a time, care being taken to wait each time until ebullition ceases before adding more chlorate. When the whole of the chlorate has been added, the liquid is distilled. The yield is very satisfactory, and the oxychloride contains but mere traces of chlorine. C. H. B.

Action of Sunlight on Phosphorous Anhydride. By A. IRVING (*Chem. News*, **48**, 173).—The author prepared his phosphorous anhydride by passing a slow current of dry air over molten phosphorus, and found that the product turned brown, and changed into free phosphorus and phosphoric anhydride when exposed in sealed tubes to direct sunlight (compare Lewes, Trans., 1884, 10). D. A. L.

Boron. By A. JOLY (*Compt. rend.*, **97**, 456—458).—The products of the reduction of boric anhydride by aluminium are: (1.) The boride, BAl, which forms golden-yellow hexagonal lamellæ, described by Deville and Wöhler. (2.) The boride, B_6Al, which forms large black lamellæ, analysed by Hampe (*Annalen*, **183**, p. 75). (3.) Yellow quadratic crystals of adamantine lustre containing carbon and aluminium. (4.) A boron carbide, or more probably several carbides formed by the alteration of the preceding compounds, at a high temperature, in presence of carbon and excess of boric anhydride. This carbide forms small black very hard crystals, with a bright metallic lustre, insoluble in boiling nitric acid. They have a sp. gr. of 2·542 at 17°, and contain 15·7 per cent. of carbon, corresponding with the formula B_4C. C. H. B.

New Silver Compounds. By T. POLECK and K. THÜMMEL (*Ber.*, **16**, 2435—2448).—Gutzeit has shown (*Pharm. Zeit.*, 1879, 263) that when gases containing arseniuretted hydrogen impinge on a piece of filter-paper moistened in its centre with one drop of a concentrated solution of silver nitrate, the wet spot assumes a lemon-yellow colour, whilst at the periphery a brownish-black ring forms, which slowly broadens towards the centre until the whole spot becomes black. If the spot, whilst still yellow, is moistened with water, it blackens over the whole surface, and at the same time shows a strongly acid reaction. Hydrogen sulphide, phosphide, and antimonide give similar results. The present paper details experiments on the chemical nature of these reactions.

Hydrogen sulphide is passed into a concentrated solution of silver nitrate (1 part $AgNO_3$ in 0·7—1·0 part water) kept constantly agitated, when a yellowish-green precipitate of the formula $Ag_2S,AgNO_3$ is obtained. The supernatant liquid has a strongly acid reaction, does not contain sulphuric acid, and yields a considerable quantity of ammonia when distilled with potash. The precipitate can be heated to 180° without decomposition, and then forms a dark-green powder. It is decomposed into silver nitrate and silver sulphide by treatment with water or alcohol. On oxidation with nitric acid of sp. gr. 1·18 an orange-red coloured powder is frequently obtained. This compound is also obtained by the action of sulphur on a boiling concentrated solution of silver nitrate, and after purification gave results corresponding with the formula Ag_2S,Ag_2SO_4. It dissolves in boiling nitric acid, is decomposed by boiling water into silver sulphide and sulphate, and by cold hydrochloric acid into silver sulphide and chloride.

Arsenic trihydride acting on dilute solution of silver nitrate has long been known to yield metallic silver, arsenious anhydride, and nitric acid; with a concentrated solution, however, the reaction is very different. The first few bubbles of gas produce a deep lemon-yellow coloration, no precipitate is formed, and the liquid acquires an acid reaction; this coloration remains for one or two days, then the liquid becomes colourless, silver is precipitated, and the solution contains arsenious and arsenic acids. If a rapid stream of arsenic trihydride be passed into a concentrated solution of silver nitrate at 0°, the whole liquid solidifies to a yellow crystalline mass, but rapidly blackens from separation of silver. Many experiments were tried to isolate the compound, but its instability was too great. Analysis by an indirect method pointed to the formula $Ag_3As.3AgNO_3$.

With concentrated solutions of silver nitrate, hydrogen phosphide gave results exactly similar in appearance to those obtained with arsenic trihydride. The composition of the yellow precipitate from indirect determinations was $Ag_3P,3AgNO_3$.

A yellow precipitate is also obtained by the action of antimony trihydride on concentrated solution of silver nitrite. It could not be isolated, but indirect determinations gave the formula $Ag_3Sb,3AgNO_3$. Unlike arsenic, phosphorus, and sulphur, metallic antimony does not yield the double compound; when it is placed in a solution of silver nitrate, Ag_3Sb is first formed, but is soon converted into antimonious oxide and silver.

A. J. G.

Silver Nitrite and Ammonia. By A. Reychler (*Ber.*, 16, 2425—2428).—On dissolving silver nitrite in concentrated aqueous ammonia heat is evolved, and the liquid soon deposits well-formed brilliant yellow prisms of the formula $AgNO_2,NH_3$, soluble in water, sparingly soluble in alcohol, nearly insoluble in ether, and melting at 70°. Long-continued heating above the melting point decomposes the compound, all the ammonia being expelled, and the residue consisting mainly of silver nitrite. On gently heating the compound with ethyl iodide, it yields silver iodide, ethyl nitrite, and ammonia.

On heating the monammonia compound with alcoholic ammonia and precipitating with ether, the diammonia compound $AgNO_2(NH_3)_2$ is obtained as a white crystalline mass, rapidly losing ammonia on exposure to air.

The finely powdered monammonia compound rapidly absorbs ammonia gas, with considerable evolution of gas, and apparently yields a triammonia compound, $AgNO_2(NH_3)_3$; it is readily soluble in water, and rapidly loses ammonia on exposure to the air.

A. J. G.

Crystallised Calcium Silicophosphate produced in the Dephosphorisation of Iron. By A. Carnot and Richard (*Compt. rend.*, **97**, 316—320).—The slag formed in working the Thomas-Gilchrist process at Joeuf (Meurthe-et-Moselle) has a brownish or blackish colour, and is more or less crystalline, some parts consisting of transparent crystalline matter, which acts strongly on polarised light, whilst other parts have a reddish colour, and resemble brown hæmatite. The surface of the slag is covered with black crystals, some of which are slender needles, whilst others are right rhombic prisms with brilliant faces. These crystals are frequently aggregated in columnar masses, which terminate in small vitreous perfectly translucid blue crystals. Similar blue crystals are found in the cavities in the slag, and appear to form one of its principal constituents. These are very constant in composition, but frequently enclose small black needles or particles, which can, however, be removed by means of a magnet. The blue crystals have the composition—

P_2O_5	SiO_2.	Al_2O_3.	CaO.	MgO.	FeO.	MnO.	
29·65	12·42	2·76	53·20	traces	1·80	traces	= 99·83.

Vanadium could not be detected. The numbers correspond with the formula $8P_2O_5,8SiO_2,Al_2O_3,FeO,36CaO$. Regarding the crystals as consisting essentially of calcium silicophosphate, the formula becomes $P_2O_5,SiO_2,5CaO$ or $Ca_3P_2O_8 + Ca_2SiO_4$. The composition of the crystalline slag is variable; it contains a lower proportion of phosphoric acid than the blue crystals, and a considerable excess of ferrous and manganese oxides.

The calcium silico-phosphate crystals belong to the rhombic system, the angles being $mm = 113° 10'$ and $e'e'$ (on p) $= 64°$. They are strongly doubly refractive, and exhibit well-marked dichroism. When the plane of their optical axis is parallel with the principal section of the Nicol's prism, they have a cobalt-blue colour; when it is perpendicular, they are almost colourless. C. H. B.

Presence of Yttrium in the Sphene of Biellese Syenite. By Cossa (*Gazzetta*, **13**, 326).—The author has found yttrium and cerium in the sphene of Biellese syenite to the amount of about 2·3 per cent. This is an important fact, as it affords additional evidence of the analogy between the syenite of Biellese and those of Planceuschengrund and Sweden. Besides showing that substances exist in the Alps which were formerly believed to be exclusively confined to Northern Europe, it proves that these rare metals are widely diffused, and their association with calcium compounds may be important in relation to their valency. C. E. G.

Separation of Gallium. By L. de Boisbaudran (*Compt. rend.*, **97**, 295—297, and 521—522).—*From Vanadium.*—(1.) The feebly acid hydrochloric acid solution is mixed with arsenious acid and an excess of acid ammonium acetate, and treated with hydrogen sulphide. Vanadium is not precipitated, but the arsenious sulphide carries down the whole of the gallium. The precipitate is washed with water containing ammonium acetate and hydrogen sulphide, and treated with aqua regia. The arsenic acid is reduced with sulphurous acid, and a current of hydrogen sulphide is passed through the strongly acid liquid, when the arsenic is precipitated alone, all the gallium remaining in solution. This is the only process which gives accurate results when used alone, and it is especially useful for separating small quantities of gallium from large quantities of vanadium. (2.) The solution is almost neutralised with ammonia, mixed gradually with an excess of ammonium sulphide, and agitated. Dilute hydrochloric acid is then added in considerable excess with constant agitation, and the precipitated vanadyl sulphide is filtered off and washed with dilute hydrochloric acid containing hydrogen sulphide. The filtrate is boiled with aqua regia to destroy ammonium salts, the nitric acid is then expelled, and precipitation repeated six or seven times. The vanadyl sulphide is also dissolved in aqua regia, and reprecipitated several times. (3.) The hydrochloric acid solution is made alkaline with ammonia, and boiled until the liquid is neutral. The precipitate is redissolved and reprecipitated two or three times; the filtrate is treated by method (1) in order to separate the last traces of gallium. (4.) The solution is mixed with sulphuric acid and ammonium sulphate in proper proportions, and the gallium alum is purified by recrystallisation. The solution contains small quantities of gallium.

If the amount of gallium is very small, process (1) is used; if the proportion of gallium is large, and that of vanadium small, the greater part of the gallium is removed in the form of alum, and the mother-liquid is treated by the following method. When the gallium and vanadium are present in approximately equal proportions, the liquid is twice boiled with ammonia (2), and the filtrate treated by (1). The precipitated gallium hydroxide is converted into alum, and the mother-liquor is again boiled with ammonia. The filtrate is treated by (1): the precipitate is mainly converted into gallium alum, and the mother-liquor is finally treated by (1).

From Tungsten.—The tungsten is converted into alkaline tungstate, and the solution evaporated almost to dryness at a gentle heat in presence of a considerable excess of hydrochloric acid, a small quantity of water is then added, and the liquid again evaporated almost to dryness. The residue is treated with a moderately large quantity of very dilute hydrochloric acid, gently heated, and the liquid filtered. The filtrate is free from tungsten; the traces of gallium in the precipitate are removed by dissolving it in ammonia, and repeating the process.

From Phosphoric Acid.—(1.) The gallium is precipitated by potassium ferrocyanide in presence of a large quantity of hydrochloric acid, and the precipitate is washed with water strongly acidified with hydrochloric acid. (2.) The solution is mixed with about one-third its volume of strong nitric acid, and the phosphoric acid precipitated by means of ammonium molybdate, the gallium and molybdenum being afterwards separated by the method previously described. (3.) The feebly acid solution is mixed with arsenious acid and ammonium acetate, and treated with hydrogen sulphide, as described above.

C. H. B.

Diffusion of Vanadium in the Mineral and Vegetable Kingdoms. By L. Ricciardi (*Gazzetta*, 13, 259—262).—After a recapitulation of the results obtained by various authors on the occurrence of vanadium in rocks and minerals, the author gives the results of his own experiments on the existence of that metal in volcanic emanations ancient and modern. These are as follows, the numbers denoting the percentage of vanadium sesquioxide found in the several substances examined :—

Lava of Vesuvius (1868)	0·0063 per cent.
„ „ (1871)	0·0075 „
„ „ (1872)	0·013 „
Ashes from Vesuvius (1872)	0·105 „
Lava of Vesuvius (1881)	0·0081 „
Lava of Etna (1669)	0·0102 „
„ „ (1879)	0·0034 „
Basalt of Pachino	0·006 „
Basalt of the Isola dei Ciclopi	0·0084 „

Scacchi has found vanadium in incrustations of the Vesuvian lava of 1631.

E. Bechi (*Atti della R. Accademia dei Lincei* [3], 3, 403 [1878–79]), after having found this element in argillaceous limestones, in schists and in sands, has established its presence in plants, especially in those growing on clay soils.

The author of the present paper has also found it in the ashes of grasses growing on the Etna lava of 1669, but the proportion was too small for quantitative estimation. Its occurrence in plants may be regarded as having some relation to the isomorphism of vanadic and phosphoric acids. H. W.

Sulphur Compounds of Molybdenum. By G. Krüss (*Ber.*, 16, 2044—2051).—According to Berzelius, molybdenum forms not only a di- and tri- but also a tetra-sulphide, MoS_4, a compound which would point to molybdenum as possessing a quantivalence of eight, and would be analogous to the uranium tetroxide. The author has succeeded in isolating this tetrasulphide by melting molybdic acid with potassium carbonate, exhausting the melt with water, and passing hydrogen sulphide into the solution when heated to the boiling point. A black powder together with a crystalline substance separates out. This mixed material is washed first with cold water, then with hot water to dissolve out the molybdenum di- and tri-sulphide, and the resultant chocolate-brown powder is heated in a current of hydrogen sulphide until its weight is constant. The result of the analysis show that this substance is *molybdenum tetrasulphide*.

The author also describes a series of compounds intermediate between the salts of molybdic and sulphomolybdic acids, which may be designated by the generic term *oxythiomolybdates*.

Ammonium orthoxythiomolybdate, prepared by passing hydrogen sulphide into an ammoniacal solution of ammonium molybdate, crystallises in golden-yellow needles of the composition $(NH_4)_2MoO_2S_2$, which was assigned to the substance by Debray. The corresponding potassium salt forms reddish-golden needles.

Besides the crystalline orthoxythiomolybdate, a number of amorphous oxysulphomolybdates are obtained by the decomposition of the molybdates by the alkaline hydrosulphide. Ammonium pyroxythiomolybdate, prepared by decomposing ammonium molybdate with ammonium hydrosulphide, is a reddish-golden precipitate having the composition $H_2Mo_2O_4S_3$ (= $2H_2MoO_2S_2$ − H_2S), which evidently stands to orthoxymolybdate in the same relation as ortho- to pyro-phosphoric acid. The corresponding sodium salt is a golden amorphous powder.

Thiomolybdates.—These compounds were obtained by Berzelius by passing hydrogen sulphide into the molybdates and evaporating the liquid; the substances formed by the process are, however, far from pure, owing to a loss of hydrogen sulphide and formation of the oxythiomolybdates. The potassium salt can best be prepared by fusing together potassium carbonate, sulphur, and a large excess of the natural molybdenum sulphide.

Dithiomolybdates.—On passing hydrogen sulphide into a solution of potassium molybdate containing a large excess of free alkali, an orange-yellow precipitate separates out; this has the composition $K_6Mo_2S_9$, or *potassium dithiomolybdate.* V. H. V.

Complex Inorganic Acids. By W. Gibbs (*Chem. News*, **48**, 155).—Two communications from the author on this subject have already appeared in this Journal (Abstr., 1882, 469, 702). In these communications only binary compounds have been referred to, and these can be represented by the general formula:—

$$mRO_3.nR'_2O_5.pR''_2O,$$

in which m = any even number from 10 to 48; R = either molybdenum or tungsten; R′ either phosphorus or arsenic; and R″ the basic radical. He has now extended the generalisation, and states that the phosphorus and arsenic may be replaced by vanadium or antimony, or possibly by niobium and tantalum; for example, well-defined and beautifully crystalline vanadio-molybdates have been obtained having the formulæ:—

$$6MoO_3,V_2O_5,2Am_2O,H_2O + 4Aq.$$
$$16MoO_3,V_2O_5,5BaO,H_2O + 28Aq.$$

Moreover, the group R'_2O_5 may be replaced by the group R_2O_3 as As_2O_3,Sb_2O_3,P_2O_3, and probably V_2O_3. Thus the formula of an ammonium phosphoroso-molybdate is—

$$24MoO_3,2P_2O_3,5Am_2O + 20Aq.$$

These R_2O_3 compounds are converted by oxidation into the salts containing the group R_2O_5. Klein has described salts containing R_2O_3; salts of this class containing hypophosphorous acid have also been obtained, such as the ammonium hypophosphomolybdate of the formula $24MoO_3,6PO_2,6Am_2O + 7Aq$. There are a great many ternary compounds of a similar character containing molybdic or tungstic oxide united with two other oxides. A great many have the general formula, $mRO_3n,R'_2O_5,pR''_2O_5,rR''_2O$, in which RO_3 = molybdic or tungstic oxide, whilst R'_2O_5 and $R''O_5$ = two different oxides of the same type; for example, P_2O_5 and V_2O_5. It has not as yet been proved that any two known oxides of the type R_2O_5 can enter together into such compounds. The following are some examples of these salts:—

$$
\begin{array}{l}
14MoO_3,8V_2O_5,P_2O_5,8Am_2O + 50Aq. \\
48MoO_3,V_2O_5,2P_2O_5,7Am_2O + 30Aq. \\
60WO_3,V_2O_5,3P_2O_5,10Am_2O + 60Aq. \\
16WO_3,3V_2O_5,P_2O_5,5Am_2O + 37Aq.
\end{array}
$$

But the compounds containing MoO_3 or WO_3 in combination with oxides of two types are still more numerous. They have the following general formulæ:—

$$
\begin{array}{c}
mRO_3,nR'_2O_5.pR''_2O_3,rR'''_2O; \\
mRO_3,nR''_2O_5,pR'_2O_3,rR'''_2O; \\
mRO_3,nR'_2O_5,pR'_2O_3,rR'''_2O;
\end{array}
$$

in which R_2O_5 may be P_2O_5, V_2O_5, As_2O_5, Sb_2O_5, and probably Nb_2O_5 and Ta_2O_5, whilst R_2O_3 may be B_2O_3, P_2O_3, V_2O_3, As_2O_3 Sb_2O_3. The author has also prepared salts belonging to the ternary compounds with the general formula $mRO_3,nR'_2O_5,pR''O_2,rR'''O_2$. None of this series containing R'_2O_3 in place of R'_2O_5 have as yet been prepared.

Quarternary compounds also exist, for the author has obtained the following in well-defined crystals:—$60WO_3,3P_2O_5,V_2O_5,VO_2,18BaO + 150H_2O$, which is reducible to the general formula:—

$$mRO_2,nR'_2O_5,pR''_2O_5,qR'''O_2,rR'''O.$$

It is evident that the possible number of various combinations in this group is very great. Besides the above types, the author has obtained other compounds containing neither molybdenum nor tungsten; for example: phospho-vanadates, arseno-vanadates, and antimony-vanadates, which are frequently crystalline, and have the general formula mR'_2O_5,nR''_2O_5,pR_2O. D. A. L.

Mineralogical Chemistry.

Brucite of Cogne, Val d'Aosta. By FRIEDEL (*Gazzetta*, 13, 278).—This mineral gave by analysis 67·06 per cent. MgO, 1·13 FeO, 29·48 H_2O, and 2·13 silica and insoluble matter, total 99·80; or deducting the silica and insoluble portion: 68·53 MgO, 1·15 FeO, and 30·13 water = 99·31, agreeing nearly with the formula MgO,H_2O or $Mg(OH)_2$, and showing that this mineral is identical with the brucites of other localities, and in particular with that of Hoboken. Like all other brucites, it is accompanied by serpentine. H. W.

Chemical Composition of Apatites. By J. A. VOELCKER (*Ber.*, 16, 2460—2464).—The formula $3Ca_3(PO_4)_2 + \left\{\begin{matrix}CaCl_2\\CaF_2\end{matrix}\right.$, usually assigned to apatite, does not appear to be founded on direct determinations of all the constituents, but to have been assumed on the strength of its isomorphism with pyromorphite, $3Pb_3(PO_4)_2 + PbCl_2$. In particular, the fluorine seems not to have been estimated, but calculated from the excess of lime beyond that required for the phosphate and chloride.

The author has determined all the constituents in several samples of apatite, and finds that the amount of fluoride and chloride is always considerably below that required by the above formula, but that there is an excess of calcium oxide present equivalent to the deficiency in the haloid salt, and that apatite must therefore be represented by the formula—

$$3Ca_3(PO_4)_2 + 1\left\{\begin{array}{l} CaCl_2. \\ CaF_2. \\ CaO. \end{array}\right.$$

The analyses were all made from crystals with completely smooth and sharp faces. A and B are Canadian apatites, D, E*a*, E*b*, and F Norwegian apatites containing no fluorine.

Formation of Albite in the Wet Way. By C. FRIEDEL and E. SARASIN (*Compt. rend.*, **97**, 290—294).—When solutions of sodium silicate and aluminium silicate in the proportions necessary to form albite are heated together in a strong steel tube at about 400°, no albite is formed, but crystals and globules of analcime separate out in considerable quantity, a certain proportion of the sodium silicate and traces of the aluminium silicate remaining in solution. If, however, the sodium silicate is added in excess to the extent indicated by this experiment, and the solution heated at about 500°, crystals of albite are obtained identical in chemical composition and physical properties with the natural crystals. The crystals are sometimes slender needles, sometimes shorter and thicker prisms, and some of them show the usual albite twinning. When the solution of sodium and aluminium silicates is mixed with potassium chloride, the results are somewhat contradictory. In the first experiment, no albite was formed, but crystals of quartz and a quantity of small crystals apparently belonging to the cubical system were obtained. In other experiments, however, both albite and orthoclase were formed simultaneously, but the two minerals did not crystallise together. Albite is formed even in liquids containing four times as much potassium as sodium, and sodium chloride even in large proportion is apparently without effect on the formation of the mineral.

C. H. B.

Rhodonite from Viù. By V. Fino (*Gazzetta*, **13**, 277).—This rhodonite is red, but is mixed with a black substance difficult to separate, probably a product of alteration. The rhodonite has a density of 3·65, hardness 5—5·6. It melts before the blowpipe, gives a brown bead with borax; with phosphorus salt a bead which is opaque when cold, and becomes red in the reducing flame. Its analysis gave—

SiO_2.	MnO.	FeO.	CaO.	Loss by ignition.	
44·31	48·77	1·53	4·44	1·25	= 100 30
44·34	48·64	1·48	4·57	1·23	= 100·16

agreeing nearly in composition with the rhodonite of S. Marcel, in which Ebelman found 46·37 SiO_2, 47·38 MnO, and 5·48 CaO.

H. W.

Artificial Production of Rhodonite and Zephroïte. By A. Gorgeu (*Compt. rend.*, **97**, 320—323).—When a current of hydrogen and carbonic anhydride charged with aqueous vapour is passed over a mixture of 10 parts manganous chloride and 1 part precipitated silica fused at a cherry-red heat, the manganous chloride is partially decomposed, yielding hydrochloric acid and manganous oxide, which dissolves in the unaltered manganous chloride and is thus brought into intimate contact with the silica. The first product is a bisilicate, which is obtained in small distinct rose-coloured crystals by treating that part of the fused mass which is insoluble in water with dilute hydrochloric acid (1 : 2). If the action of the moist gas is prolonged, and the residue after being washed with water is treated with very dilute hydrochloric acid (1 : 50), grey crystals of a normal silicate are obtained. In these experiments, the aqueous vapour is the active agent, the hydrogen or carbonic anhydride simply preventing access of air and consequent formation of hausmannite. The rose-coloured crystals have the composition SiO_2,MnO, and correspond in crystalline form and other properties with rhodonite; the grey crystals have the composition $SiO_2,2MnO$, and correspond with tephroïte. The presence of alkaline chlorides has no effect on the production of these compounds. In presence of the chlorides of iron, magnesium, and calcium, small quantities of these metals are taken up, but the oxygen ratio remains the same. The artificial crystals are about a degree softer than the natural crystals. Both compounds are anhydrous, and do not appreciably oxidise in dry or moist air. They melt with difficulty at a bright red heat, forming a brown enamel, and they dissolve in fused manganous chloride, and are deposited in definite crystals on cooling. The rose-coloured silicate when fused with manganous chloride in presence of aqueous vapour, is gradually converted into the neutral silicate, and the latter, when fused with manganous chloride and silica out of contact with air and moisture, is converted into an acid silicate, insoluble in hydrochloric acid. Hydrochloric acid has little action on the rose-coloured silicate, but attacks the neutral salt even when very dilute; sulphurous acid also has no action on the first compound, but dissolves the neutral salt. Chlorine water blackens and partly dissolves the grey crystals, but has little action on the acid salt. Saturated solutions of carbonic anhydride and hydrogen sulphide respectively decompose the neutral salt, but have no action on the other. A 2·8 per cent. solution of sodium hydrogen carbonate has very little action on the rose-coloured salt at 40—60°, but partially converts the grey silicate into carbonate. Natural rhodonite behaves in exactly the same way as the artificial product, and it would appear probable from these reactions that the manganese carbonate, sulphide, and peroxide found in mineral veins have been formed by the alteration of tephroïte rather than by that of the much more stable rhodonite. C. H. B.

Meteoric Dust and Analysis of the Soil of Sahara. By Tacchini (*Gazzetta*, **13**, 327).—An investigation as to the origin of the rains of sand and meteoric dust which fall in Italy, and especially in Sicily, shows that the sand comes from Africa, being raised by cyclones, and carried into Sicily and Italy by the strong south-east and south-west currents. Tacchini and Macagno are comparing these powders with the soil from the Desert of Sahara. C. E. G.

Analysis of the Brine-Spring of Stoke Prior, Worcestershire. By A. B. Griffiths (*Chem. News*, **48**, 207).—This deposit of rock-salt is in the lias; the water is pumped from a depth of over 300 feet. The following are the results of analyses recently made by the author, which are compared with results obtained by Northcote in 1854:—

	Northcote (1854.)	Griffiths (1883.)	
		I.	II.
	Per cent.	Per cent.	Per cent.

Sulphuric acid	0·4888	0·4890	0·4892

It contains 25·49 per cent. sodium chloride, the brine is therefore a saturated solution; the sp. gr. is 1·2049 at 24°. D. A. L.

Organic Chemistry.

Galician Petroleum. By B. LACHOWICZ (*Annalen*, **220**, 188—206).—The volatile portion of the petroleum from Boryslaw, in Galicia, boiling between 30° and 125°, contains the following hydrocarbons:—(1) Isopentane boiling at 30°, which yields a chloride boiling at 100° (sp. gr. 0·8703 at 20°); (2) normal pentane boiling at 37° (sp. gr. 0·6267 at 14°), yielding two chlorides boiling at 106° and 104°; (3) a hexane boiling at 60°; (4) hexane boiling at 70° (sp. gr. 0·6985 at 14°); (5) heptane boiling at 99°; (6) nonane boiling at 148°; and (7) decane boiling at 152°, and a decane boiling at 162—163° (sp. gr. 0·7324 at 20°); also benzene, toluene, xylene, and mesitylene. The petroleum does not contain any olefines. The author is of opinion that olefines do not occur ready formed in petroleums, but that they are produced in the process of distillation.

The relatively high sp. gr. of certain portions of the distillate of the petroleum, from which the hydrocarbons of the benzene series have been removed, leads the author to infer the presence of the hydrides of the aromatic hydrocarbons, *e.g.*, hexahydrotoluene and hexahydro-isoxylene. W. C. W.

Some Paraffins and their Derivatives. By B. LACHOWICZ (*Annalen*, **220**, 168—188).—*Diamyl*, $C_{10}H_{22}$, prepared by the action of sodium on amyl bromide from commercial amyl alcohol, boils at 157·1°, and has the sp. gr. 0·72156 at 22°. It is a tasteless liquid, having a faint odour. It is soluble in 12 parts of acetic acid at the ordinary temperature, and is miscible with alcohol, ether, benzene, and chloroform in all proportions; it is not attacked by sulphuric or nitric acid. The hydrocarbon ignites at 53°. No bromide could be isolated by the action of bromine on diamyl, as the product splits up into decylene and hydrobromic acid on distillation. Decylene (boiling at 161·5°) has an aromatic odour.

Normal decane, obtained by the action of sodium on a mixture of octyl and ethyl bromides diluted with benzene, is tasteless, and almost inodorous. It boils at 169·5°, and ignites at 55°. Its sp. gr. at 18° is 0·73097. Dioctyl (melting at 19—20°) is obtained as a bye-product. Secondary octyl bromide (sp. gr. 1·0989 at 22°), boils at 188°, with slight decomposition. Octylene boils at 122·4°.

When sodium acts on a mixture of ethyl bromide and secondary octyl bromide, dioctyl and butane are formed, but decane is not produced. Dioctyl is a thick colourless liquid, boiling at 263° (sp. gr. 0·80011 at 11°). The paraffins are almost devoid of smell.

W. C. W.

Butylene and its Derivatives. By E. PUCHOT (*Ann. Chim. Phys.* [5], **28**, 507—569).—Butylene is most conveniently prepared by warming a mixture of fermentation butyl alcohol ($2\frac{1}{2}$ parts), sulphuric acid ($2\frac{1}{2}$ parts), plaster of Paris (4 parts), and potassium sulphate

1 part). The gas is passed through two flasks containing milk of lime or soda; it is then dried over quicklime, and condensed by a freezing mixture. At the ordinary temperature, water absorbs one-tenth its volume of the gas, alcohol 36 vols., and glacial acetic acid, 62 vols. Liquid butylene boils at −4°. Its sp. gr. at −14·2° is 0·639. Butyl butyrate and isotributylene are obtained in small quantities as bye-products in the preparation of butylene. They are also formed by the action of phosphorus pentachloride on butyl alcohol, and butyl butyrate is produced on heating butyl alcohol with phosphoric anhydride. Butylene is absorbed by sulphuric acid, yielding isotributylene boiling at 180°, and a mixture of isomeric bodies boiling between 172° and 244°. Butylene unites with bromine to form the dibromide $C_4H_8Br_2$, a colourless liquid boiling at 153° (sp. gr. at 0° = 1·8053); with hydriodic acid it yields an iodide which boils with decomposition at 100·25°. Cold concentrated hydrochloric acid absorbs butylene with formation of the tertiary chloride boiling at 55° (sp. gr. 0·8658 at 0°). In diffused daylight chlorine unites with butylene to form the dichloride $C_4H_8Cl_2$, boiling at 129°. The product of the action of alcoholic potash on this chloride contains oxygen. At the ordinary temperature in direct sunlight, chlorine replaces 4 atoms of hydrogen in the chloride, yielding the compound $C_4H_4Cl_6$. At a higher temperature, chlorine expels two more atoms of hydrogen and $C_4H_2Cl_6$ is formed. The former compound is decomposed by alcoholic potash; 4 mols. of hydrochloric acid being eliminated, and C_4Cl_2 produced: it is an unstable liquid, which appears to boil above 200°. Alcoholic potash decomposes the chloride $C_4H_2Cl_6$, yielding a compound having the composition $(C_4Cl_4)_n$. W. C. W.

Some Reactions of Tertiary Alcoholic Iodides. By K. BAUER (*Annalen*, **220**, 158—168).—Tertiary pentyl iodide is decomposed by water into hydriodic acid and ethyl dimethyl carbinol. It is also decomposed by methyl alcohol at 100°, yielding methyl iodide and tertiary amyl alcohol. Under similar treatment tertiary butyl iodide yields methyl iodide and trimethyl carbinol. On heating a mixture of methyl acetate and tertiary butyl or amyl alcohol for several hours, methyl iodide, acetic acid, and butylene or amylene are produced.

W. C. W.

Menthyl Chloride. By G. ARTH (*Compt. rend.*, **97**, 323—324).—When an ethereal solution of menthene is treated with hydrochloric acid gas, or when menthene and a concentrated solution of hydrochloric acid are heated together in sealed tubes at 120°, menthene hydrochloride, $C_{10}H_{18},HCl$, is obtained. It is an oily liquid, which burns with a green-edged flame, and cannot be distilled without decomposition. When boiled with water, it yields hydrochloric acid and menthene, and when heated with silver acetate in a closed vessel, it yields acetic acid, silver chloride, and menthene, but no menthyl acetate. This compound therefore agrees in its properties with the menthyl chloride obtained by Oppenheim by the action of concentrated hydrochloric acid on menthol in a closed vessel, and the author considers that the two compounds are identical, just as camphene hydrochloride and the chloride obtained from borneol are identical. These last two compounds, however, appear to be true hydrochloric ethers, whilst the derivatives of menthol have no analogy to the hydrochlorides of terebenthene.

The menthene used by the author was dextrogyrate, unlike that of Walter, Oppenheim, and Moriya, which was inactive. C. H. B.

Silver Nitrocyanide. By C. L. Bloxam (*Chem. News*, 48, 154).—The author has examined the crystalline compound obtained by dissolving pure silver cyanide in a nearly saturated boiling solution of silver nitrate. It is anhydrous, and is decomposed by water into silver cyanide and nitrate. Analysis gives 68·09 per cent. total silver, determined in nitric acid solution of the compound; 22 97 per cent. silver as cyanide, determined in residue from decomposition with water; 45·64 per cent. silver as nitrate, determined in aqueous extract. Its constitution is therefore $AgCy,2AgNO_3$, and not $AgNO_3,2AgCy$, as is generally supposed. D. A. L.

Reaction between Mercuric Cyanide and Silver Nitrate in Presence of Ammonia. By C. L. Bloxam (*Chem. News*, 48, 161).—Wöhler obtained a salt having the formula $AgNO_3,HgCy_2 + 2Aq$, from which, according to *Gmelin's Handbook*, alkalis throw down silver cyanide, a reaction incompatible with the above formula. The author has investigated the subject, and his results form the substance of this paper.

When neutral solutions of mercuric cyanide and silver nitrate are mixed together, the mixture becomes acid, indicating the formation of mercuric nitrate, whilst it deposits a crystalline double salt. The same salt is formed when precipitated silver cyanide is dissolved in a solution of mercuric nitrate. The aqueous solution of the salt is precipitated by ammonia and by hydrocyanic acid, which causes the separation of silver cyanide, indicating the presence of silver nitrate in the salt.

If mercuric cyanide in solution is added by degrees to an ammoniacal solution of silver nitrate, a white, opaque and silky crystalline precipitate separates. The two precipitates have the same composition, and the numbers from analysis, after corrections have been made for impurities, agree with those required by the formula $2HgO,HgCy_2,7AgCy$:—

	Ag.	Hg.	Cy.
Calculated (for formula) ..	46·60	36·99	14 42
Found	46·43	37 03	14 29

The impurities found were 0·32 per cent. of ammonia and 2·11 per cent. nitric acid. The silver was determined as chloride, the mercury as sulphide, and the cyanogen by converting it into ammonium thiocyanate, and subsequent precipitation with silver nitrate. Both precipitates are anhydrous, and explode when heated, the opaque one more violently than the crystalline. The filtrate from these precipitates deposits silver cyanide, and the filtrate from this contains a small quantity of silver and much mercury and cyanogen.

The author is therefore of opinion that in the above experiments the mercuric cyanide and silver nitrate are converted, at least partially, into silver cyanide and mercuric nitrate, and the precipitate formed in the presence of ammonia is composed of silver cyanide and mercuric oxycyanide.

D. A. L.

Influence of Asymmetrical Carbon-atoms on the Ethanes Derived from Active Amyl Alcohol. By F. Just (*Annalen*, **220**, 146—157).—In order to observe the influence of asymmetrical carbon-atoms on the optical activity of organic compounds, and to test the accuracy of Le Bel's hypothesis (*Bull. Soc. Chim.* [2], **22**, 337) the author has examined a series of the derivatives of active amyl alcohol. The amyl alcohol was prepared from fusel oil by Le Bel's process. Repeated attempts to obtain the methylamyl described by Le Bel (*ibid.* [2], **25**, 545) proved unsuccessful, but the following compounds were investigated. *Isopentane*, boiling at 30°, prepared by the action of zinc and hydrochloric acid on an alcoholic solution of active amyl iodide; *methylethylpropylmethane*, boiling at 91°, from amyl and ethyl iodides, and *diamyl* which yielded the following results:—

	Sp. gr.	$[\alpha]$.
Amyl alcohol, $C_2H_5.CHMe.CH_2.OH$	—	−2·82
Amyl iodide, $C_2H_5.CHMe.CH_2I$	1·5425 at 16°	+2·43
Ethyldimethylmethane, $C_2H_5.CHMe_2$..........	0·6375 at 13	0
Methylethylpropylmethane ...... $C_2H_5.CHMe.CH_2.CH_2Me$..	0·6895 at 20	+3·93
Active diamyl, $C_2H_5.CHMe.CH_2.CH_2.CHMe.C_2H_5$	0·7463 at 22	+8·69

These results confirm the accuracy of Le Bel's hypothesis.

W. C. W.

β-Butyl Glycol. By A. Wurtz (*Compt. rend.*, **97**, 473—475).—The action of sodium-amalgam on a cold dilute slightly acid solution of aldol yields butyl glycol, which forms a thick perfectly colourless liquid boiling at 207—208° under a pressure of 769 mm., and soluble in all proportions in water, alcohol, and ether; sp. gr. at 0° = 1·0259. It is violently attacked by phosphorus pentachloride, with formation of a small quantity of a chloride boiling at 130—135°, and another product which cannot be distilled, but which contains both chlorine and phosphorus. Acetic chloride also reacts violently with butyl glycol, forming hydrochloric acid and an acetin which cannot be purified from chlorine even by distillation with silver acetate. The same acetin is easily obtained by heating the glycol at 100° in sealed tubes for several days with 6 or 8 times its weight of acetic anhydride. It forms a colourless neutral liquid, insoluble in water, with a feeble acetic odour; sp. gr. at 0° = 1·055. It has the composition $C_4H_8(\overline{Ac}O)_2$. When the butyl glycol is heated for some time with a large excess of highly concentrated hydriodic acid it yields butylene di-iodide, $C_4H_8I_2$, probably $CHMeI.CH_2CH_2I$; sp. gr, at 0° = 2·291.

That fraction of the crude butyl glycol which boils at 220—250° under ordinary pressure, contains a substance which boils at 160—165° under a pressure of 15 mm. It has the same composition as dialdanic alcohol, $C_{14}H_{16}O_3$, and is probably an isomeride of that body. It yields an acetin.

C. H. B.

Fermentation of Glycerol with the Bacteria from Ammonium Tartrate. By A. VIGNA (*Gazzetta*, **13**, 293—296; *Ber.*, **16**, 1438).—The glycerol (2,200 grams) mixed with a solution of potassium phosphate (22 grams) and ammonium tartrate (44 grams), is diluted with water (40 litres), and a small portion of liquid containing the bacteria of ammonium tartrate added; this is easily obtained by adding to a solution of ammonium tartrate a small quantity of the salts necessary to nourish the bacteria, and exposing it to the air until they have developed. The glycerol mixture is allowed to ferment for two months at a temperature of 20—25°, adding calcium carbonate from time to time to neutralise the paraffin acids as they are formed: hydrogen and carbonic anhydride are evolved during the whole time that the fermentation is going on; when gas is no longer given off the liquid is distilled with excess of calcium carbonate; ethylic alcohol (72 grams), normal butylic alcohol (196 grams), and an insignificant quantity of the higher alcohols pass over with the aqueous vapour. The author has not as yet examined the residuum containing the calcium salts. As the yield of normal butyl alcohol is 9 per cent. of the glycerol employed, it seems to be the most convenient process for preparing that compound. C. E. G.

Electrolysis of Glycerol with Electrodes of Carbon and Platinum. By A. BARTOLI and G. PAPASOGLI (*Gazzetta*, **13**, 287—293).—The authors have already published on this subject (Abstr., 1882, 406).

Electrolysis with Gas-carbon Electrodes.—The glycerol diluted with an equal bulk of dilute sulphuric acid (1 : 5), was electrolysed, using six Bunsen's elements which were renewed every five days; the negative electrode was of platinum, and the positive of gas-carbon; hydrogen in abundance was evolved at the negative pole, and but very little gas at the positive pole, which was rapidly disintegrated, being reduced to one-third of its weight after the action had continued for a month. An abundant black deposit of carbon mixed with mellogen formed at the bottom of the voltameter; the liquid became dark, and there was an intense, suffocating odour of acraldehyde.

The liquid, filtered from the black deposit and neutralised with barium carbonate, yielded a nearly colourless solution; on distilling this, water passed over, together with trioxymethylene which is left in the crystalline state on evaporating the distillate over sulphuric acid (Rénard, Abstr., 1880, 25). It melts at 155°, is but sparingly soluble in water, insoluble in alcohol, and reduces Fehling's solution and nitrate of silver. When hydrogen sulphide is passed into its solution at 60°, a white precipitate of methylene oxysulphide, $(C_3H_6S_2O)_2,H_2O$, is obtained: this has a marked alliaceous odour, and melts at 80°. If the aqueous solution of trioxymethylene is evaporated on the water-bath, taking care always to keep it strongly alkaline with ammonia, a substance is obtained melting at 120—125°, and having all the properties of Butlerow's hexamethylenamine, $C_6H_{12}N_4$.

The solution of barium salts remaining in the retort was carefully examined and found to contain glyceric acid and a small quantity of a saccharine substance, but no benzenecarboxylic acids; much undecomposed glycerol was also present.

Electrolysis with Graphite Electrodes.—The electrolysis took place in much the same way as with the carbon electrodes, only that the solution remained colourless, and the graphite (positive) electrode was but very little disintegrated, the small quantity of black deposit formed consisting of a mixture of unaltered graphite with graphitic oxide.

The solution, when neutralised with barium carbonate and distilled, yielded trioxymethylene, and the residue in the retort was found to contain, besides glycerol, formic acid and a substance having many of the characters of a glucose, but incapable of undergoing fermentation; with ammoniacal lead acetate this new compound yields a white precipitate insoluble in water. The glucose solidifies over sulphuric acid, but is not crystallisable; it is soluble in alcohol, and easily reduces Fehling's solution and ammoniacal silver nitrate.

Electrolysis with Platinum Electrodes.—When both the electrodes are of platinum, gas is evolved in abundance at both poles; there is a powerful odour of acraldehyde, and the liquid remains colourless. The solution when treated in the way previously described was found to contain formic and glyceric acids and a minute quantity of a substance resembling a glucose. C. E. G.

Maltose. By A. Herzfeld (*Annalen*, **220**, 206—224).—The rotatory power of a 5 per cent. solution of pure maltose was found to be $[\alpha]_D = 139°$, which agrees closely with Soxhlet's results $[\alpha]_D = 139.3°$, and differs considerably from that found by O'Sullivan, $[\alpha]_D = 149.5°$. Maltose forms the following compounds with sodium and calcium, $C_{12}H_{21}NaO_{11}$ and $C_{12}H_{20}CaO_{11} + H_2O$, and analogous compounds with barium and strontium.

The *octacetic derivative*, $C_{12}H_{14}O_{11}\overline{Ac}_8$, crystallises in thin prisms which belong to the mono- or tri-clinic system. The crystals melt with decomposition at 150—155°. They are soluble in ether, warm alcohol, benzene, and acetic acid. For the solution in benzene $[\alpha]_D = 81.18°$.

The reducing action of maltose on Fehling's solution is equal to about two-thirds of that of glucose, but if the filtrate from the cuprous oxide is acidified with hydrochloric acid the solution slowly acquires the power of reducing a further quantity of Fehling's solutions equal to about half the volume originally reduced. In this respect maltose resembles lactose. A second point of analogy is that neither of these sugars form double salts with borax, or with potassium or sodium chlorides or bromides.

Maltose is not a simple anhydride of glucose; its molecular weight must be at least 3 times as great as that of diglucose.

W. C. W.

Saccharin. By C. Scheibler (*Ber.*, **16**, 24—34).—In the preparation of saccharin by the action of the alkaline-earths on the glucoses, the author has observed that a vigorous absorption of oxygen from the air always occurs. He is working at this subject and also at the action of aqueous ammonia on the glucoses. A. J. G.

Diethyl Methylene Ether. By L. Pratesi (*Gazzetta*, **13**, 313—315).—On distilling a mixture of paraformaldehyde (trioxymethylene) with ethyl alcohol and sulphuric acid—continuing the distillation until it becomes turbid on the addition of water,—a product is obtained which, when treated with water and calcium chloride, yields impure diethyl methylene ether, $CH_2(OEt)_2$. It may be purified by digesting it with potash, first in a flask furnished with a reflux condenser, and then with fresh potash in a sealed tube heated at 100°. It boils at 87—88°, has a sp. gr. of 0·8504 at 0°, and a vapour-density of 102 referred to hydrogen, $C_5H_{12}O_2$ requiring 104. It is less soluble in warm water than in cold, requiring 11 vols. of water at 18° for that purpose, and 15 vols. at 30°.

The boiling point and solubility of the substance show that it is isomeric with Wurtz's methylacetyl, so that there can be no doubt the formula $C_2H_4(OEt).OMe$, assigned by Wurtz to the compound obtained by the action of sulphuric acid and manganese dioxide on a mixture of ethyl and methyl alcohols, is correct. C. E. G.

Action of Ammonia on Propaldehyde. By A. WAAGE (*Monatsh. Chem.*, 4, 708—732).—This paper gives a detailed account of experiments, a preliminary notice of which has already been published (Abstr., 1883, p. 39). These experiments confirm the formation of parvoline, $C_9H_{13}N$, from the crystalline compound $C_{15}H_{29}N_3$ produced by the action of carbonic acid on propaldehyde-ammonia, C_3H_6O,NH_3 or $CH_2Me.CH(NH_2)(OH)$, or from its mother-liquor or the crude product containing the two. When this crystalline product is heated with dilute hydrochloric acid, propaldehyde and methylethylacraldehyde, $C_6H_{10}O$, distil over, and the residue distilled with potash yields parvoline, together with a dark resinous residue:

$$2C_{15}H_{29}N_3 + 6H_2O = C_9H_{13}N + C_6H_{10}O + 5C_3H_6O + 5NH_3 + H_2.$$

Parvoline thus obtained is a mobile, colourless, strongly refracting liquid, boiling at 198—200°, lighter than water, having a very strong aromatic odour like that of the other pyridine-bases, and an extremely bitter taste. It is not very soluble in water, but dissolves readily in alcohol and ether; forms white fumes with hydrochloric acid, and colours pine-wood yellow. With *picric acid*, it forms a compound containing molecular proportions of its two constituents. This compound forms crystalline laminæ having the colour of picric acid, more soluble in alcohol than in water, melting at 149°. With *tannin solution*, parvoline forms a white flocculent precipitate, easily soluble in alcohol; with phosphotungstic acid it forms a faint bluish-white body, which increases on addition of hydrochloric acid and is insoluble in alcohol; with *potassio-mercuric* iodide, a yellowish-white precipitate, easily soluble in alcohol and in hydrochloric acid. Iodised solution of potassium iodide forms with it a brown flocculent precipitate soluble with violet colour in carbon sulphide. Potassio-bismuthous iodide forms a dark brown precipitate soluble in hydrochloric acid, and coloured yellow by alcohol. Parvoline aurochloride crystallises in deliquescent yellow needles.

The parvoline formed as above agrees with that which is obtained from bituminous shale in all its properties except the boiling point, which the author finds to be 198—200°, whereas shale parvoline boils at 188°. The lower boiling point of the latter is probably due to the admixture of lower homologues.

The decomposition of the compound $C_{15}H_{29}N_3$ by hydrochloric acid yields also a small quantity of a lower base of the series, viz., C_6H_7N (composition determined by analysis of platinochloride), which distils for the most part at 160°, has a more pungent odour than parvoline, and appears to be identical with picoline.

Oxidation of Parvoline.—This base oxidised with potassium permanganate is converted into a pyridine-dicarboxylic acid, $C_7H_5NO_4 = C_5H_3N(COOH)_2$, which crystallises in crusts of chalky microscopic needles melting at 219°. It gives a red coloration with ferrous sulphate; with lead acetate after a while a white precipitate insoluble in excess; with silver nitrate a white flocculent precipitate, easily soluble in ammonia and in nitric acid; blue-green with cupric acetate. Its *cadmium salt* is obtained by precipitation, as a white crystalline body, $C_7H_3NO_4Cd,4H_2O$, which gives off half its water on prolonged standing over sulphuric acid, or when heated to 140°. In most of these characters the acid in question agrees with lutidic acid (*Monatsh. Chem.*, 1, 20); the latter however and its copper salt are described as containing crystal-water, whereas the pyridine-dicarboxylic acid described above and its copper salt are anhydrous; lutidic acid is also described as more soluble in water than Waage's acid. The calcium salt of the acid heated in a tube with excess of quicklime yielded a distillate of pyridine. H. W.

Tobacco Fat. By R. KISSLING (*Ber.*, 16, 2432—2434).—The vegetable wax occurring in tobacco, and usually termed "tobacco fat," has not previously been obtained in a state of purity. To prepare it, tobacco is extracted with ether, the extract, after the removal of the greater part of the ether, mixed with alcohol and the precipitated wax purified by repeated crystallisation from hot alcohol. The wax then forms a snow-white mass of satiny lustre, melts at 63°, and on analysis gave numbers agreeing with the formula $C_{70}H_{140}O_2$, but after removal of a small quantity of a substance insoluble in cold ether, the results agreed better with $C_{60}H_{120}O_3$ (mellissyl-mellisate).

Kentucky tobacco yielded 0·18 per cent. of wax.

In the course of some investigations on the constituents of tobacco-smoke, a wax-like body was obtained, similar in appearance to tobacco-wax, melting at 64·5°, but appearing, from its analysis, to be a hydrocarbon containing C 84·7—85·5 per cent., and H 14·63—15·16 per cent. A. J. G.

An Isomeride of Laurene. By A. RENARD (*Compt. rend.*, 97, 328—330).—When that portion of crude rosin-oil which boils between 180° and 200° is treated repeatedly with sulphuric acid and carefully distilled, it yields a light oil which boils at 193—195°, and is not attacked by ordinary sulphuric acid. This liquid has the composition $C_{11}H_{16}$; vapour-density, 5·37; sp. gr. at 19° = 0·8588. It is an isomeride of laurene. It dissolves in fuming nitric acid with development of heat and evolution of nitrogen oxides, forming a heavy oily orange-coloured mononitro-derivative, $C_{11}H_{15}NO_2$. The hydrocarbon is only slightly attacked by ordinary nitric acid in the cold, but yields isophthalic acid when boiled with it. It is, therefore, metaethylpropylbenzene, C_6H_4EtPr [1 : 3]. On treating it with fuming sulphuric acid, a sulphonic acid is formed. The barium salt is somewhat soluble in boiling water, but only very slightly soluble in cold water. It forms brilliant white crystalline plates which, when dried at 100°, have the composition $(C_{11}H_{15}SO_3)_2Ba + H_2O$, but become anhydrous at 175°.

The metaethylpropylbenzene contains a small quantity of a hydrocarbon which is not attacked by fuming sulphuric acid or by ordinary nitric acid. It is in all probability one of the higher members of the $C_nH_{2n-6}H_6$ series. C. H. B.

Chemical Nature of Phlorol. By V. OLIVERI (*Gazzetta*, **13**, 263—269).—When barium phloretate is distilled over an open fire with lime and powdered glass, part of it is resolved into phlorol, $C_8H_{10}O$, and carbonic acid: $(C_9H_9O_3)_2Ba + CaH_2O_2 = 2C_8H_{10}O + CO_3Ba + CO_3Ca$, while a portion of the phlorol undergoes further decomposition into ethylene and ordinary phenol: $C_8H_{10}O = C_2H_4 + C_6H_6O$. The phlorol thus obtained is a colourless strongly refractive liquid, having the characteristic odour of the phenols, boiling at 210—212°, soluble in alcohol and ether, slightly soluble in water. Its aqueous solution gives a faint green coloration with ferric salts. Its potassium salt is easily decomposed by carbonic acid. The *methylic ether*, $C_9H_{12}O = C_6H_4Et.MeO$, prepared by digesting molecular proportions of phlorol and potassium hydroxide dissolved in anhydrous methyl alcohol, is a heavy strongly refracting oil having a pleasant etheric odour, boiling at 185°, not oxidised by potassium permanganate.

Phlorolcarboxylic acid, $C_9H_{10}O_3 = HO.C_6H_3Et.COOH$, prepared by heating phlorol with sodium and carbonic anhydride, crystallises in slender silky colourless needles, slightly soluble in cold water, very soluble in alcohol and in ether, melting at 112°. Its aqueous solution is coloured violet by ferric chloride. Its *barium salt*,

$$(HO.C_6H_3Et.COO)_2Ba,H_2O,$$

crystallises in small scales. By fusing phlorol with potassium hydroxide, two acids are obtained, viz., salicylic acid melting at 156—158°, and a small quantity of metahydroxybenzoic acid, at 190—195°.

The phlorol prepared as above is identical with the *ortho*-ethylphenol, $C_6H_4Et.OH$, which Suida and Plhon obtained by the action of nitrous acid on amidethylbenzene (Abstr., 1881, 268), and Beilstein and Kuhlberg by fusing potassium ethylbenzenesulphonate with potassium hydroxide (*Annalen*, **156**, 211), the products formed in these several processes agreeing in boiling point, in their behaviour with fused potash, and with bromine-water, and in yielding carboxylic acids exhibiting similar properties. H. W.

Nitroresorcinols. By G. SCHIAPARELLI and M. ABELLI (*Gazzetta*, **13**, 257).—*Mononitrodibenzoresorcinol*, $C_6H_3(NO_2)(O\overline{Bz})_2$, obtained by heating dibenzoresorcinol (m. p. 117°) with a mixture of sulphuric and nitric acids, crystallises in stellate groups of needles melting at 107°, and is resolved by saponification into benzoic acid and mononitroresorcinol melting at 115°.

Trinitrodibenzoresorcinol, $C_6H(NO_2)_3(O\overline{Bz})$, is formed on dissolving dibenzoresorcinol in cold strong nitric acid (sp. gr. 1·5), and separates on addition of water, as a faintly yellowish solid substance which, after crystallisation from methyl alcohol, melts at 123°. By saponification with alcoholic potash, it is resolved into metanitrobenzoic acid and nitroresorcinol melting at 115°, ethyl metanitrobenzoate melting at 43° being formed at the same time. The separation of the *m*-nitrobenzoic acid and nitroresorcinol was effected by the different solubilities of their copper-salts.

On dissolving diacetylresorcinol in well cooled nitric acid of sp. gr. 1·45 and adding water, a white or slightly yellowish substance separates, consisting of a mixture of dinitroresorcinol and styphnic acid, melting at 175°. The dinitroresorcinol separated from this mixture by fractional crystallisation, melts at 214·5°. H. W.

Arbutin. By J. HABERMANN (*Monatsh. Chem.*, **4**, 753—786).—This paper gives a detailed description of a large number of experiments on the composition of arbutin and its behaviour at high temperatures, tending to establish the correctness of the formula $C_{25}H_{34}O_{14}$, deduced by Hlasiwetz and Habermann for arbutin, from the occurrence of methylquinol, $C_7H_8O_2$, as a product of its decomposition (*Ber.*, **14**, 302), in opposition to the view put forward by H. Schiff (*Gazzetta*, **11**, 99; and Abstr., 1881, 610) and Michael (*Ber.*, **14**, 2097; and Abstr., 1882, 174) that two different arbutins occur in nature, viz., arbutin, $C_{12}H_{16}O_7$, and methylarbutin, $C_{13}H_{18}O_7$. H. W.

Hydroxybromotoluquinone. By G. SPICA and O. MAGNANIMI (*Gazzetta*, **13**, 312—313).—A paper by Spica and Canzoneri on some brominated derivatives of toluquinone has been already published (Abstr., 1883, 330), in which it is stated that the action of potassium hydroxide on tribromotoluquinone gave rise to resinous products from which nothing could be obtained in a state fit for analysis. The authors now find that on treating the tribromoquinone with a 5 per cent. solution of potassium hydroxide in the cold, it dissolves, and on acidifying with hydrochloric acid a reddish flocculent precipitate is obtained. This is somewhat difficult to purify, but by repeated treatment with cold benzene the impurities are dissolved, and a reddish-white substance is left; this may be purified by recrystallisation, first from dilute alcohol, and then by dissolving it in absolute alcohol and allowing it to crystallise by spontaneous evaporation. It forms pale rose-coloured crystals of the composition $C_6HMeBr_2(OH)\colon O_2''$, melting at 196—197°. The yield is very small, being only about 5 per cent. of the tribromotoluquinone employed. When submitted to the reducing action of sodium amalgam it does not yield a hydroxytoluquinol, but the action goes further, and cresol is formed. From want of material the authors have not as yet been able to ascertain which cresol this is. C. E. G.

Electrolysis of Pyrogallol. By E. ROTONDI (*Gazzetta*, **13**, 279).—By electrolysing solutions of pyrogallol acidulated with sulphuric acid, the author has obtained, at the positive pole, mixed with other products, a crystalline substance, which after recrystallisation exhibits all the properties of purpurogallin. From his electrolytic researches he is inclined to think that purpurogallin is not a direct product of the oxidation of pyrogallol, but is derived from an intermediate compound.

H. W.

Pyrocoll. By G. L. CIAMICIAN and P. SILBER (*Gazzetta*, **13**, 320—322).—In a paper by Ciamician and Danesi (Abstr., 1882, 875), they described a compound of the formula C_5Cl_7NO, obtained by the action of phosphorus pentachloride at 250° on perchloropyrocoll, which evolved ammonia in abundance when boiled with potassium hydroxide solution. This compound is decomposed when heated with water at 130° into ammonia, carbonic and hydrochloric acids, and an acid free from nitrogen, which may be extracted from the solution by means of ether. It melts at 85—86°, and has all the properties of the α-dichloracrylic acid obtained from mucochloric acid by Bennet and Hill (Abstr., 1879, 616). The barium and silver salts also correspond with those described by these chemists.

It would seem, therefore, that the decomposition of the compound C_5H_7NO takes place in the manner represented by the equation $C_5H_7NO + 5H_2O = C_3Cl_2H_2O + 5HCl + NH_3 + 2CO_2$.

Synthesis of Acetylphenylparacoumaric and Phenylparacoumaric Acids. By A. OGLIALORO (*Gazzetta*, **13**, 173).—The first of these acids is formed on heating parahydroxybenzoic acid aldehyde with acetic anhydride and sodium alphatoluate; the second by boiling the first with baryta-water. Acetylphenylparacoumaric acid melts at 170°, phenylparacoumaric acid at 219°.

H. W.

Synthesis of Phenylmelilotic Acid. By S. SARDO (*Gazzetta*, **13**, 273).—This acid, discovered by Oglialoro (*Gazzetta*, **9**, 428; and Abstr., 1880, 164), is formed by the action of sodium amalgam on phenylcoumarin dissolved in dilute alcohol. On decanting the resulting alkaline solution, filtering, and acidifying with hydrochloric acid, a viscid substance separates, from which, by fractional extraction with ether, evaporation, treatment of the residue with water containing a little alcohol, and fractional crystallisation, *phenylmelilotic acid*, $C_{15}H_{11}O_3 = C_9H_9PhO_3$, is obtained in small prisms, melting at 120°, slightly soluble in cold, more readily in boiling water, also in ether, alcohol, benzene, and chloroform. Its *silver salt*, $C_{15}H_{13}O_3Ag$, obtained by precipitation, is white, alterable by light, slightly soluble in cold, somewhat more freely in boiling water, and crystallisable.

Electrolysis of Solutions of Ammonia and Ammoniacal Salts with Carbon Electrodes. By A. BARTOLI and G. PAPASOGLI (*Guzzetta*, **13**, 281—286).

Electrolysis of Solutions of Ammonia with Electrodes of Gas-carbon or Wood-charcoal.—Pure ammonia solution is electrolysed with difficulty, requiring a powerful pile, but if it is mixed with an alkaline salt the liquid conducts the current and is decomposed. The authors employed a saturated aqueous solution of ammonia mixed with half its volume of a solution of pure sodium chloride and a pile of four to six Bunsens, which was allowed to act for periods varying from a week to two months, the battery charges being renewed every three or four days. The carbon used for the electrodes was purified by heating it to a very high temperature in a current of chlorine. The evolution of gas from the negative electrode was considerable, although but little was given off from the positive: the latter was strongly acted on, and a black powder was deposited at the bottom of the voltameter, whilst the supernatant liquid was almost colourless. The solution evolved abundance of carbonic anhydride when neutralised with hydrochloric acid, and the addition of barium chloride then produced a precipitate from which mellic, pyromellic, and hydromellic acids were isolated and recognised; the filtrate from the mixed barium salts contained hydropyromellic acid.

The black precipitate at the bottom of the voltameter, after being washed free from ammonia, was boiled for a long time with soda solution, filtered, and the black filtrate precipitated with hydrochloric acid in excess: this precipitate is insoluble in water or acids. It is black, uncrystallisable, neither melts nor volatilises, and contains carbon, hydrogen, oxygen, and nitrogen. Like mellogen, it yields benzenecarboxylic acids when treated with oxidising agents, but differs from it in containing nitrogen.

Electrolysis of Ammoniacal Salts with Carbon Electrodes.—Solutions of ammoniacal salts when electrolysed in the manner above described yield a precipitate containing mellogen free from nitrogen, but no appreciable quantity of benzenecarboxylic acids could be found in the clear solution.

Electrolysis of Ammonia with Electrodes of Graphite.—The experiments were conducted in precisely the same manner as those first described, using, however, electrodes of purified graphite. Gas was given off from both electrodes, but only in small quantity from the positive. which became gradually disintegrated and formed a black precipitate. Mellic acid was detected in the clear supernatant liquid, which also appeared to contain pyromellic, hydromellic, and hydropyromellic acids. The black precipitate was nothing but disintegrated graphite.

Electrolysis of Ammoniacal Salts with Electrodes of Graphite.—After passing a strong current for 15 days, the clear liquid was examined, but no trace of benzenecarboxylic acids or any other carbon compound could be detected. The black precipitate was a mixture of unaltered graphite with graphitic acid, and another substance analogous to graphitic oxide, sparingly soluble in alkaline and ammoniacal solutions; the yellow liquid thus obtained deposited dark red flocks when acidified.

It will be seen from the above that when ammonia solution is electrolysed, using electrodes of gas-carbon or wood-charcoal, it yields benzenecarboxylic acids, as is the case with solutions of the fixed alkalis under similar conditions, but that the black powder formed by the disintegration of the electrodes differs from mellogen in that it contains nitrogen; moreover, the authors have shown that this black substance is essentially distinct from ulmic compounds, since it yields mellic acid when treated with oxidising agents, whilst ulmic compounds do not. C. E. G.

Ethylic Dinitrophenylacetoacetate. By J. HECKMANN (*Annalen*, **220**, 128—146).—*Ethylic orthoparadinitrophenylacetacetate*,

$$CH_3CO.CH(COOEt).C_6H_3(NO_2)_2,$$

is prepared by adding a slight excess of dinitrobromobenzene in alcoholic solution to a mixture of sodium ethylate and ethyl acetoacetate in their molecular proportions. The liquid is kept at a temperature of 20—25° for a week; at the end of this time it will have lost its alkaline reaction, and on the addition of water ethylic dinitrophenylacetacetate will be precipitated. If a higher temperature is employed, a portion of the ethylic dinitrophenylacetoacetate is decomposed. The crude product is purified by recrystallisation from warm alcohol. Unaltered dinitrobromobenzene is removed by dissolving the crystals in cold dilute potash, and rapidly reprecipitating with dilute hydrochloric acid. The pure ethylic salt crystallises in amber-coloured prisms or plates, which appear to belong to the triclinic system. The crystals are soluble in warm alcohol, ether, benzene, and chloroform. They melt at 94°, and decompose at a higher temperature with slight detonation. On boiling with water containing 10 per cent. of sulphuric acid, *orthoparadinitrophenylacetic*, carbonic, and acetic acids, and dinitrotoluene melting at 70° are formed. *Dinitrophenylacetic acid*, $C_6H_3(NO_2)_2.CH_2.COOH$ [$CH_2.COOH : NO_2 : NO_2 = 1 : 2 : 4$], crystallises in pale yellow needles melting at 160°. Ethylic dinitrophenylacetoacetate dissolves without decomposition in cold dilute alkalis, but on boiling with alcoholic potash the solution blackens and decomposition ensues, a black amorphous acid being produced, together with a white crystalline compound of the composition $C_{24}H_{18}N_6O_{15}$, melting at 105·5°, which is sparingly soluble in boiling alcohol. The crystalline substance dissolves in dilute potash or soda, forming a blue solution, and is reprecipitated by carbonic acid. On shaking a solution of the substance in benzene with alcoholic potash, the compound $C_{24}H_{16}K_2N_6O_{15}$ is obtained in golden plates, which explode when heated. The crystals are soluble in water, yielding a blue solution.

The black compound mentioned above is also formed by the action of alcoholic potash on the preceding substance or on dinitrophenylacetic acid. It appears to have the composition $C_{48}H_{32}N_6O_{19}$, and to yield a silver salt, $C_{48}H_{29}Ag_3N_6O_{19}$, containing 3 mols. H_2O.

W. C. W.

Azylines. By E. LIPPMANN and F. FLEISSNER. Third Memoir. (*Monatsh. Chem.*, **4**, 788—799).—The action of methyl iodide on diethylanilinazyline is very different from that of ethyl iodide (Abstr., 1883, 868). On heating the azyline with 4 mols. methyl iodide in a sealed tube at 100°, dissolving the resulting crystalline mass in water, evaporating to a syrup, repeatedly boiling with water the resinous substance which separates out, evaporating the solutions thereby obtained to the crystallising point, and repeatedly precipitating with alcohol, white shining four-sided needles are obtained, melting at 218°, and consisting of the *di-iodomethylate of dimethyldiethyl-paraphenylenediamine*, $C_{14}H_{26}N_2I_2 = C_6H_4(NMe_2)(NEt_2),2MeI$, or rather perhaps *tetramethyldiethyl-paraphenylammonium iodide*, $NMe_3I.C_6H_4.NEt_2MeI$. This iodide dissolves very easily in water, sparingly in alcohol, and not at all in ether. It is not attacked by strong potash-lye, but silver oxide decomposes it immediately, forming the corresponding hydroxide $C_{14}H_{26}N_2(OH)_2$.

When diethyl-*p*-phenylenediamine is treated with methyl alcohol and hydrochloric acid at 200°, the contents of the tube precipitated with potash, and the separated oil dried and fractionated, diethyldimethyl-*p*-phenylenediamine, $NEt_2.C_6H_4.NMe_2$, is obtained, as a faintly yellow oil, which turns brown in the air, and exhibits a deep blue colour with oxidising agents, *e.g.*, copper sulphate, potassium dichromate, iodine, bleaching powder, &c. This base, heated with methyl iodide, is converted into the compound $C_{14}H_{26}N_2I_2$ above described.

Oxidation.—Azylines are but slightly attacked by weak oxidising agents, undergoing no alteration on exposure to the air at ordinary temperatures, and very little when heated above their melting points. Potassium permanganate acts on them but slowly in alkaline, very quickly in acid solution. Chromic acid, manganese dioxide, and sulphuric acid, as well as lead dioxide, act on them with violence. With potassium permangante, the chief products formed are acetic, carbonic, and oxalic acids. With chromic acid or a mixture of potassium dichromate and sulphuric acid, the liquid froths, emits a peculiar odour like that of chlorine, and deposits a small quantity of yellow needles, easily volatile with water-vapour, very soluble in ether: probably quinone.

When diethylanilinazyline is slowly added to well-cooled red nitric acid of sp. gr. 1·5, it dissolves, and the solution diluted with water deposits shining red needles of *dinitrodiethylaniline*, $C_6H_3(NO_2)_2Et_2N$, contaminated with brown products. The same compound is, however, more easily and abundantly obtained by adding ordinary strong nitric acid to a well-cooled solution of the azyline in glacial acetic acid, then precipitating with water, and crystallising from alcohol. The compound thus obtained forms orange-red needles melting at 180°, easily soluble in hot alcohol, also in benzene and in ether, sparingly in light petroleum. In these and all its other characters it agrees with the dinitrodiethylaniline which von Romburgh obtained (*Rec. Trav. Chim.*, **2**, 35; *Ber.*, **16**, 1496) by the action of red nitric acid (sp. gr. 1·48) on diethylaniline dissolved in strong sulphuric acid. By boiling with potash, it is resolved into diethylamine and dinitrophenol: $C_6H_3(NO_2)_2.NEt_2 + KHO = NHEt_2 + C_6H_3(NO_2)_2.OK$. The authors found that this decomposition is effected only by very strong potash-lye, and that it is accompanied by the evolution of ammonia and diethylamine. According to Romburgh, the dinitrophenol produced in this reaction is the ordinary modification $OH : NO_2 : NO = 1 : 2 : 4$; consequently the two nitro-groups in the corresponding aniline derivatives must be similarly situated $[NH_2 : NH_2 : NO_2 = 1 : 2 : 4]$.

AZYLINES OF TERTIARY DIPHENYLAMINES. — These compounds are formed by passing nitrogen dioxide through an alcoholic solution of a tertiary diphenylamine, the liquid then turning red, and yielding after some time a crystalline deposit of the azyline, mixed with coloured secondary products, which greatly diminish the yield of the azyline. They are weak bases, forming neither salts nor double compounds. With hydrochloric acid they give a blue-violet, with acetic acid, a green coloration, both these reactions being very delicate.

Methyldiphenylaminazyline,

$$C_{26}H_{24}N_4 = PhMeN.C_6H_4.N : N.C_6H_4.NPhMe,$$

forms yellow crystals, melting at 150°, very slightly soluble in cold alcohol, freely in chloroform and benzene.

Ethyldiphenylaminazyline,

$$C_{28}H_{28}N_4 = PhEtN.C_6H_4.N : N.C_6H_4.NPhEt,$$

separates from alcoholic solution in large red monoclinic crystals, exhibiting the combination $0P.P.\infty P$ and the opposite faces. Axial ratio $a : b : c = 0·206106 : 1 : 1·1826$. Angle $ac = 92° 29' 30''$. Double refraction very strong. H. W.

An Aromatic Glycol. By G. Rousseau (*Ann. Chim. Phys.* [5], **28**, 145—198).—Of the α- and β-naphthols, the latter alone yields a hydroxyaldehyde when heated with chloroform and alcoholic potash (Reimer and Tiemann's reaction); but only one such compound is obtained, and not a mixture of two isomerides (comp. Abstr., 1882, 735, 1211, 1299). During the course of the reaction, large quantities of resinous substances are formed, from which the aldehyde may be separated by steam distillation. The aldehyde crystallises in slender refractive needles, which melt at 77°. Its ethereal solution gives a crystalline magma with sodium hydrogen sulphite; it combines also with aniline, yielding a yellow crystalline compound melting at 90°. The principal product of the reaction is, however, an *aromatic glycol*, $C_{22}H_{12}(OH)_2$, formed probably by the partial hydrogenation of the hydroxyaldehyde, two molecules of which combine together with elimination of two molecules of water. This glycol forms small white crystals, which are with difficulty separated from the adhering resins; it is insoluble in alkalis, soluble in concentrated sulphuric acid, with production of a blood-red solution, from which red crystals of an ethereal sulphate separate out. This glycol and its immediate derivatives are characterised by the readiness with which they are transformed into the corresponding ether, $C_{22}H_{12}O$; in this respect the glycol is analogous to the pinacones. The *bromhydrin* has been already described (*loc. cit.*, 1299); it takes up a molecule of bromine, yielding the compound $C_{22}H_{12}Br(OH),Br_2$, which crystallises in yellow leaflets resembling lead iodide, and decomposes at 280° without melting. The chlorhydrin, $C_{22}H_{11}Cl(OH).HCl,3OH_2$, crystallises in red needles. Both the brom- and chlor-hydrin, when dissolved in acetic acid, yield on evaporation of the solution a crystalline substance, consisting of a molecule of the haloïd ether and a molecule of acetic acid.

The *ether*, $C_{22}H_{12}O$, can be obtained by the action of dehydrating or reducing agents on the glycol, or by boiling the ethereal derivatives with alcohol; it crystallises in pale yellow needles which melt at 198°, insoluble in cold alcohol, readily soluble in acetic acid. By the action of hydrogen, it is converted into the *monohydroxyl alcohol*, $C_{22}H_{13},OH$. The *monethyl* derivative of the glycol, $C_{22}H_{12}(OH).OEt$, prepared by decomposing the chlor-, brom-, or iod-hydrin with alcoholic potash, forms small feathery crystals, which by solution in benzene and subsequent evaporation is separable into two substances, the one melting at 250°, and probably identical with the monhydroxyl alcohol, the other crystallising in brilliant leaflets, melting at 144°, or the ethyl derivative.

The amido-derivative, $C_{22}H_{12}(OH).NH_2$, obtained by the action of ammonia on the bromhydrin, crystallises in slender colourless needles; it acts as a weak base, combining with hydrochloric or hydrobromic acids to form crystalline salts, of which the hydrochloride yields a platinochloride salt, crystallising in golden needles. Both the hydrochloride and hydrobromide are converted into the ether when boiled with alcohol.

The *monoatomic alcohol*, $C_{22}H_{13}O_{11}$, alluded to above, is one of the products of the reaction of chloroform with alcoholic potash on β-naphthol, but is best prepared by the action of reducing agents on the chlor- or brom-hydrin. It crystallises in silky needles, which decompose at 260°. When heated with the haloïd acids, it is probably retransformed into the halogen derivatives of the glycol.

The glycol, when heated to a red heat with soda-lime, is decomposed into carbonic anhydride and a dinaphthyl, probably identical with the compound obtained by Watson Smith by passing naphthalene vapour through a red-hot tube (comp. Trans., 1879, 224—232).

V. H. V.

Colocynthin. By G. HENKE (*Arch. Pharm.* [3], 21, 200—205).—The bitter principle of colocynth, or *Citrullus colocynthus*, was obtained by Walz in the following manner:—The colocynth was exhausted with alcohol (sp. gr. 0·40) and the residue from the evaporation of the alcoholic solution dissolved in cold water, and precipitated with lead acetate. The lead was removed from the filtrate by sulphuric acid, and the liquid precipitated with tannic acid. This precipitate, after being dried, was dissolved in alcohol, and the tannic acid precipitated by lead acetate; the lead was then removed from the filtrate, and the solution digested for some time with animal charcoal. The filtrate from this solution evaporated to dryness and extracted with ether, left a residue of colocynthin. This was subsequently slowly deposited from a solution in alcohol in yellowish-white tufts of crystals. Its formula was found to be $C_{56}H_{42}O_{23}$. It was soluble in 8 parts of cold and 6 parts of hot water. By treatment with acids, colocynthin was said to yield a sugar having the formula $C_{12}H_{10}O_{10}$, and colocyntheïn, $C_{44}H_{32}O_{13}$, which is soluble in ether. The author attempted to extract colocynthin by a similar process, with the difference that the tannate of colocynthin was decomposed by evaporation with freshly precipitated lead carbonate, and the colocynthin extracted from the dry residue with absolute alcohol. The colocynthin obtained by this method is in the form of a light yellow powder, which could not be crystallised. It is without action on litmus, insoluble in chloroform, ether, benzene, carbon bisulphide, and light petroleum, but soluble in 20 parts of cold and 16 parts of hot water. It is also soluble in alcohol, and is reprecipitated in white flocks on adding ether. Concentrated sulphuric acid dissolves it in the cold, producing a deep red solution; the colocynthin is carbonised by heating this solution. Dilute sulphuric acid has no action. The aqueous solution of colocynthin easily reduces Fehling's solution. Concentrated hydrochloric and nitric acids both dissolve colocynthin, forming coloured solutions, and on boiling the hydrochloric acid solution a dark green greasy substance is precipitated, which after being dried over sulphuric acid, is only partly dissolved by ether. The hydrochloric acid solution from which this substance was obtained reduces Fehling's solution. The author considers that these experiments, as far as they go, fail to confirm the results previously obtained by Walz. W. R. D.

Laserpitin. By R. Külz (*Arch. Pharm.* [3], 21, 161—175).—The author has made an investigation to determine the nature of the bitter principle *laserpitin*, which is contained in the root of *Laserpitium latifolium*, or white gentian root, and to discover the connection (if any) which obtains between this substance and the bitter principles contained in other umbelliferous plants.

Laserpitin.—The finely sliced root was extracted by boiling with light petroleum, and on evaporating the solution *laserpitin* was deposited in crystals belonging to the monoclinic system. These were purified by recrystallisation from light petroleum, and were found to contain no water of crystallisation. *Laserpitin* melts at 118°, is insoluble in dilute acids or alkalis, but is easily soluble in chloroform, ether, benzene, and carbon bisulphide. Concentrated acids decompose it, sulphuric acid dissolving it with the production of a deep red colour. This same colour is observed when *laserpitin* is boiled with concentrated hydrochloric acid, or with alcoholic potash.

A series of combustions of the pure laserpitin gave numbers pointing to the formula $C_{15}H_{22}O_4$. No chloride or bromide of laserpitin could be obtained, but an acetate, $C_{15}H_{22}O_4,\overline{Ac}OH$, crystallised in silky needles from a solution in acetic acid; even this salt was unstable. Several derivatives of laserpitin were obtained. An attempt to produce an acetyl derivative by the direct action of acetic chloride or acetic anhydride gave negative results.

When laserpitin is distilled with zinc-dust or soda-lime, no benzene or other aromatic hydrocarbon is obtained, from which the author concludes that the molecule of laserpitin contains no compound constituted on the type of the closed carbon-ring.

The action of concentrated hydrochloric acid on an alcoholic solution of laserpitin gives rise to methylcrotonic acid, and the action of concentrated sulphuric acid yields angelic acid.* When laserpitin is heated with dilute nitric acid, oxalic acid is one of the products. Ebullition with alcoholic potash yields angelic acid, and fusion with potassium hydroxide, methylcrotonic acid.

Monacetyllaserpitin, $C_{15}H_{21}\overline{Ac}O_4$, may be obtained by the action of acetic anhydride on laserpitin in presence of anhydrous sodium acetate. It crystallises in colourless needles melting at 113°, and soluble in glacial acetic acid, alcohol, ether, and chloroform, but insoluble in water.

---

* In another place the author mentions the production of angelic acid by the action of hydrochloric acid, and of methylcrotonic acid by the action of sulphuric acid on laserpitin, but from internal evidence this is probably a mis-statement.—W. R. D.

Dinitrolaserpitin, $C_{15}H_{20}(NO_2)_2O_4,H_2O$, is obtained as an amorphous mass by the action of nitric acid on *laserpitin*. It melts at 115°, and is insoluble in water, but soluble in alcohol, ether, chloroform, and glacial acetic acid.

Bromolaserpitin, $C_{30}H_{39}Br_5O_8$, obtained by the action of bromine on a solution of laserpitin in chloroform, crystallises in rosettes, which are soluble in ether, alcohol, chloroform, and glacial acetic acid; they melt at 90°.

Lazerin, $C_{20}H_{30}O_5$, is a resinous substance (called by the author *lazerol*) which is produced when concentrated acids or alkalis act on laserpitin. It is insoluble in acids, but is dissolved by ether, alcohol, chloroform, and glacial acetic acid. Its production, together with angelic acid or methylcrotonic acid, by the action of sulphuric or hydrochloric acids on laserpitin, is symbolised by the equation

$$2C_{15}H_{22}O_4 + H_2O = C_{20}H_{30}O_5 + 2C_5H_8O_2.$$

Attempts to produce derivatives of this body were unsuccessful. From these results, the author infers that laserpitin is chemically different from peucedanin, ostruthin, and athamantin, bitter principles which have been found in other umbelliferous plants. W. R. D.

Quinaldine Bases. By O. DOEBNER and W. v. MILLER (*Ber.*, **16**, 2464—2472).—Several methods for the preparation of quinaldine have been already described (Abstr., 1882, 868; 1883. 602; and *Ber.*, **16**, 165, and 1835), but it is most simply effected by heating on the water-bath a mixture of 1½ parts paraldehyde, 1 part aniline, and 2 parts hydrochloric acid; in all probability the aldehyde is first converted into aldol by the hydrochloric acid, but whether this reacts directly on the aniline, or is first converted into crotonaldehyde, remains an open question. The hydrochloric acid may be replaced by other concentrated acids, but the yield is not so good.

Tetrahydroquinaldine, $C_{10}H_{13}N$, is readily obtained by the action of tin and hydrochloric acid on quinaldine; it forms a colourless liquid of agreeable odour, boils at 246—248°, at 709 mm. pressure, is sparingly soluble in water, readily soluble in alcohol, ether, and benzene. Its salts crystallise well, are generally readily soluble in water, and are characterised by the blood-red coloration produced in their aqueous solution by oxidising agents. The *platinochloride* forms clear yellow needles. Nitrous acid gives a yellow nitroso-compound; from this, hydroquinaldine must be a secondary base, standing to quinaldine in the same relation as piperidine does to pyridine, and having the constitution  $C_6H_4\left\langle\begin{array}{l}NH.CH.CH_3\\ \quad\;\;|\\ CH_2.CH_2\end{array}\right.$. A base of this formula has been obtained by Jackson (Abstr., 1881, 742) from methylphenyl ethyl ketone, which from its properties appears to be identical with tetrahydroquinoline.

Methyl hydroquinaldine, $C_{10}H_{12}NMe$, obtained by the action of methyl iodide on hydroquinaldine, is a colourless liquid boiling at 245—248° at 708 mm. pressure. The platinochloride,

$$(C_{11}H_{15}N)_2,H_2PtCl_6,$$

is sparingly soluble in water. Other alkyl derivatives have been obtained; they are all characterised by yielding green colouring matters when heated with benzotrichloride and zinc chloride.

Quinaldine methiodide, $C_{10}H_9N,MeI$, is obtained by the direct union of methyl iodide and quinaldine; it crystallises in long citron-yellow needles, melts at 195°, is readily soluble in water and hot alcohol, insoluble in ether. When heated with concentrated potash, it yields a very small quantity of a carmine colouring matter.

Methylquinaldines.—On treating the isomeric toluidine in a manner similar to that already described in the case of aniline, three methylquinaldines are obtained.

Orthomethylquinaldine, $C_{10}H_8MeN$ [1 : 2], is a colourless liquid, which soon turns brown on exposure to air, boils at 252°, is sparingly soluble in water, readily soluble in alcohol and ether; its odour closely resembles that of quinaldine. The *dichromate*, $(C_{11}H_{11}N)_2,Cr_2O_7H_2$, crystallises in orange-yellow needles, readily soluble in water. The *platinochloride*, $(C_{11}H_{11}N)_2,H_2PtCl_6$, forms bright yellow needles, sparingly soluble in water. *Hydro-orthomethylquinaldine*, $C_{10}H_{12}MeN$, is a colourless liquid of agreeable odour; it boils at 260—262°, and is characterised by the sparing solubility of its hydrochloride in hydrochloric acid. The platinochloride forms round nodules of concentrically grouped brownish-red needles. The hydro-base gives a blood-red coloration with ferric chloride, and on treatment with methyl iodide, yields a liquid methyl derivative, $C_{11}H_{14}NMe$.

Paramethylquinaldine, $C_{10}H_8MeN$ [1 : 4], forms large colourless rhombic prisms, melts at 60°, and boils at 266—267°. It has an odour like that of aniseed, is sparingly soluble in hot water, readily in alcohol, ether, and benzene. The *dichromate*, $(C_{11}H_{11}N)_2,Cr_2O_7H_2$, forms long yellow needles, sparingly soluble in cold water. The *platinochloride*,

$$(C_{11}H_{11}N)_2,H_2PtCl_6,$$

crystallises in nearly colourless slender needles, and is sparingly soluble in hot water. *Hydroparamethylquinaldine*, $C_{10}H_{12}MeN$, forms a colourless, mobile liquid, boils at 267°, is sparingly soluble in water, readily in alcohol and ether. Solutions of its salts give a red coloration with ferric chloride.

Metamethylquinaldine, $C_{10}H_8MeN$ [1 : 3], crystallises in colourless needles, melts at 61°, and boils at 264—265°; is sparingly soluble in water, readily soluble in alcohol, ether, and benzene. It has a faint quinaldine-like odour. The *dichromate*, $(C_{11}H_{11}N)_2,Cr_2O_7H_2$, crystallises in long orange-red needles, nearly insoluble in water. The *platinochloride*, $(C_{11}H_{11}N)_2,H_2PtCl_6$, forms tufts of small yellow needles, sparingly soluble in water.

All primary amines of the aromatic series appear to react with aldehyde to form quinaldine-like bases, several of which are being investigated by the authors. A. J. G.

Quinaldic Acid (α-Quinolinecarboxylic Acid). By O. DOEBNER and W. v. MILLER (*Ber.*, **16**, 2472—2476).—In their earlier experiments on the oxidation of quinaldine (Abstr., 1883, 602), the authors were unable to confine the oxidation to the methyl-group; they have now accomplished this by dissolving 10 grams of the base in sulphuric acid (1 : 5), adding a solution of 28 grams of chromic acid and 40 grams of sulphuric acid in 100 c.c. of water, and heating on the water-bath until the chromic acid is completely reduced. *Quinaldic acid*,  $C_6H_4\left<\begin{matrix}N{=}C.COOH\\ |\\ CH{=}CH\end{matrix}\right.$, so obtained, crystallises with 2 mols. H_2O in colourless asbestos-like needles, sparingly soluble in cold, readily in hot water. The anhydrous acid melts at 156°. Quinaldic acid yields salts with both acids and bases, of which those with acids crystallise the best. The *sulphate* is readily soluble in water; the *nitrate* crystallises in prisms and is sparingly soluble in water containing nitric acid; the *hydrochloride*, $C_{10}H_7NO_2,HCl + H_2O$, forms large tables sparingly soluble in water. The *dichromate*,

$$(C_{10}H_7NO_2)_2,H_2Cr_2O_7,$$

forms red crystals sparingly soluble in cold water. The *picrate* crystallises in tufts of long yellow needles readily soluble in hot water and alcohol. The *platinochloride*, $(C_{10}H_7NO_2),H_2PtCl_6 + 2H_2O$, forms tabular crystals sparingly soluble in cold, readily soluble in hot water.

The *quinaldates* of the alkalis are readily soluble in water. *Calcium quinaldate*, $Ca(C_{10}H_6NO_2)_2$, is obtained as a white precipitate sparingly soluble in water. The *copper salt*, $Cu(C_{10}H_6NO_2)_2 + 2H_2O$, forms a microcrystalline bluish-green precipitate. The *silver salt* is obtained as an amorphous precipitate, not decomposed by light; it dissolves in hot concentrated solution of silver nitrate; on cooling a double compound of the formula $C_{10}H_6NO_2Ag + C_{10}H_7NO_2,NO_3H + H_2O$ separates in silky needles.

On heating quinaldic acid to a little above its melting point, it is quantitatively decomposed into carbonic anhydride and quinolines.

This acid completes the series of quinolinecarboxylic acids in which the carboxyl is considered to be attached to the pyridine nucleus, and from its formation from quinaldine must be the α-acid. β-Quinolinecarboxylic acid was obtained by Riedel from β-ethylquinoline (*Ber.*, **16**, 1613), whilst the quinolinecarboxylic acid obtained by Graebe and Caro (Abstr., 1880, 398) must have the carboxyl-group in the γ-position. A. J. G.

Caffeïne and its Salts. By H. BIEDERMANN (*Arch. Pharm.* [3], **21**, 175—186).—The author has examined caffeïne and its principal salts, as the existence of many of these has recently been denied by several authors. Caffeïne, $C_8H_{10}N_4O_2,H_2O$, melts at 230·5°; the aurochloride of caffeïne has the formula $C_8H_{10}N_4O_2,HCl,AuCl_3 + 2H_2O$, and the platinochloride the formula $(C_8H_{10}N_4O_2)_2,H_2PtCl_6$. Caffeïne hydrochloride, $C_8H_{10}N_4O_2,HCl + 2H_2O$; hydrobromide,

$$C_8H_{10}N_4O_2,HBr + 2H_2O;$$

nitrate, $C_8H_{10}N_4O_2,HNO_3 + H_2O$; sulphate, $C_8H_{10}N_4O_2,H_2SO_4$; formate, $C_8H_{10}N_4O_2,H_2CO_2$; acetate, $C_8H_{10}N_4O_2,(\overline{Ac}HO)_2$; benzoate, $C_8H_{10}N_4O_2,C_4H_8O_2$; and valerate, $C_8H_{10}N_4O_2,C_5H_{10}O_2$, were all obtained in the crystalline state by dissolving caffeine in the appropriate acid, and evaporating the solution over potash. All these salts are unstable, and cannot be crystallised from alcohol or water; at 100° they are either wholly or partially decomposed. Anhydrous chlorides having the formulæ $C_8H_{10}N_4O_2,4HCl$ and $C_8H_{10}N_4O_2,HCl$, were obtained by the action of dry hydrochloric acid gas on caffeïne. A normal sulphate was also obtained which crystallised with 1 mol. H_2O. When caffeine is dissolved in a strong solution of hydriodic acid and the solution evaporated over potash, the normal hydriodide is not alone obtained, but a periodide, $(C_8H_{10}N_4O_2,HI,I_2)_2 + 3H_2O$, and also a mixture of the normal hydriodide, $C_8H_{10}N_4O_2,HI$, and the hydriodide, $C_8H_{10}N_4O_2,2HI$. W. R. D.

Papaverine. By G. GOLDSCHMIEDT (*Monatsh. Chem.*, **4**, 704—707).—The oxidation of papaverine with potassium permanganate yields nothing but uncrystallisable products. On boiling this base with a somewhat dilute solution of potassium permanganate, ammonia is given off, and an uncrystallisable acid is formed which decomposes carbonates and forms amorphous salts.

Papaverine fused with potassium hydroxide yields protocatechuic acid and an alkaline distillate containing papaverine, methylamine, and dimethylhomocatechol, boiling at 218° and convertible by oxidation into protocatechudimethyletheric acid. The same two volatile products, dimethylhomocatechol and methylamine, are formed in the dry distillation of papaverine, and apparently also in the distillation of that base with lime or zinc-dust.

Baryta-water acts very slowly on papaverine, with evolution of ammoniacal vapours, and formation of a very small quantity of a greasy substance smelling like guaiacol. Sodium-amalgam slowly converts papaverine in alcoholic solution into a thick oil which deposits crystals after long standing. With acetic anhydride and sodium acetate, papaverine does not yield an acetyl-derivative, whence it may be inferred that this base does not contain an acetyl-group.

Papaverine, heated with hydrochloric acid in a sealed tube at 130°, yields a gas which burns with a green flame (probably methyl chloride) and a solution, the evaporated residue of which forms a thick brown oil which, in dilute aqueous or alcoholic solution, gives with ferric chloride a deep emerald-green coloration, changed by sodium carbonate to red—a reaction probably due to homocatechol. With potash-lye, the oil forms a dark brown liquid. Sodium carbonate added to the aqueous solution of the oil, throws down a white flocculent precipitate which soon resinises after filtration, and turns green in contact with the air. These reactions point to the presence of apomorphine. H. W

Compound of Quinine with Chloral. By G. MAZZARA (*Gazzetta*, **13**, 269—272).—This compound, *chloral-quinine*, is formed on adding to a solution of quinine in chloroform dried at 120° an equivalent quantity of chloral (5·5 g. anhydrous chloral to 10 g. quinine). On evaporating the liquid in a dry atmosphere, a yellowish transparent gelatinous mass is left, which dissolves in cold ether; and on exposing the solution to a gentle heat, a white mammellary crystalline substance separates which soon pervades the whole liquid, converting it into a pulp. The same result is more quickly obtained on adding the calculated quantity of chloral to a solution of quinine in chloroform diluted with anhydrous ether, and heating the liquid. The precipitate, after washing with ether and drying over sulphuric acid, forms an apparently amorphous, perfectly white and very light mass, having a slightly bitter taste, melting and blackening at 149°, not perceptibly altering in dry air. This body has the composition $C_{20}H_{24}N_2O_2,CCl_3.COH$. It is insoluble in benzene, sparingly soluble in cold, more soluble in hot alcohol, from which it separates on evaporation as a gelatinous mass. The solution, on addition of water, deposits a white precipitate consisting of a mixture of quinine and chloral-quinine.

Chloral-quinine dissolves in water slightly acidulated with sulphuric, acetic acid, &c., forming solutions which exhibit a fluorescence similar to that of quinine salts, and react like the latter with chlorine and potassium ferricyanide. The acetic acid solution yields with sodium bicarbonate a precipitate nearly free from chlorine. These reactions show that chloral-quinine is decomposed partially by water, completely by acids.

Phenols, as is well known, do not form addition-products with chloral, but in presence of dehydrating agents they yield condensation-products with elimination of water—phenol and thymol for example, forming respectively dihydroxyphenyl- and dihydroxythymyl-trichlorethane. The author has also succeeded in obtaining addition-products by the action of chloral on paracresol and thymol, without the aid of sulphuric acid.

Paracresol-chloral, $C_6H_4Me(OH),CCl_3.COH$, crystallises in small needles melting at 52—56°. *Thymol-chloral*,

$$C_6H_4.Me(C_3H_7)(OH),CCl_3.COH,$$

melts at 130—134°. H. W.

Solubility of Strychnine and Preparation of some of its Salts. By P. Crespi (*Gazzetta*, **13**, 175).—The author has determined the solubility of strychnine at ordinary temperatures and at 56°, 78°, and 98·5° in various solvents. He finds that 1 pt. of water at 14·5° dissolves 0·025 pt. of strychnine; that 1 pt. absolute alcohol dissolves from 0·302 to 0·325 at 8·25° and 10·75°; 0·975 at 56° and 1·846 at 78°; that amyl alcohol, one of the best solvents, dissolves 0·525 at 11·75°, and 4·262 at 98·5°; that its solubility in dilute alcohol increases with the proportion of water up to 85° of Gay-Lussac's areometer, and diminishes at greater dilution.

The salts described are the normal succinate, $C_4H_4O_4Str_2,6\frac{1}{2}H_2O$; normal malate, $C_4H_6O_5Str_2,3\frac{1}{2}H_2O$; normal pyrotartrate,

$$C_5H_8O_4Str_2,5\frac{1}{2}H_2O,$$

and the phthalate which has not been analysed. H. W.

Behaviour of Strychnine in the Animal Organism; and a Product of the Action of Potassium Permanganate on Strychnine. By Plugge (*Chem. News*, **48**, 207).—The contention as to whether alkaloïds do or do not undergo decomposition in the animal organism has never been definitely settled. Kerner (*Pfluger's Archiv.*. **2**, 20; **3**, 30) proved that quinine in part reappears unchanged in the urine, whilst another portion becomes oxidised into dihydroxyquinine, a substance which is also obtained by the action of potassium permanganate on quinine. The author has made similar experiments with strychnine. Strychnine was given to animals; and the blood, tissues, and urine were examined. The results obtained indicate that the strychnine is decomposed in the organism, but the investigation is incomplete.

By the action of potassium permanganate on strychnine, a yellowish-brown or light grey amorphous substance is obtained. It is sparingly soluble in cold water, ether, and chloroform, more freely in hot water, from which it is partially deposited on cooling; readily soluble in alcohol, and very readily in dilute aqueous alkaline solutions, from which it is incompletely reprecipitated by adding hydrochloric acid. The substance is neither bitter nor poisonous, and is not precipitated by the usual alkaloid reagents. Treated with chromic mixture, it gives a red-violet coloration without the preliminary blue-violet, as is the case with strychnine. The author regards this strychnine-derivative as strychnic acid, to which he assigns the formula $C_{11}H_{11}NO_3,H_2O$ for the present. D. A. L.

Alkaloïds of Buxus sempervirens. By G. A. Barbaglia (*Gazzetta*, **13**, 249—257).—The author has extracted from the leaves and twigs of the box tree, a substance which he regards as a new alkaloïd, and designates by the name *Buxidine*. He denies the existence of the base called *Buxeine* described by Alessandri (*C. J.*, 1882, Abstr., 745) as existing in the same plant. His results however are not very definite. H. W.

Acid Products of the Bacterial Fermentation of Albuminoïds. By A. Gautier and A. Étard (*Compt. rend.*, **97**, 325—328).—When the products of putrefaction are distilled to dryness in a vacuum, and the residue extracted with ether, the principal constituent of the solution (this vol., p. 89) is palmitic acid. Neither stearic nor oleic acid is present, and all traces of the original fatty bodies, and all the corresponding glycerol, have completely disappeared. Stearic acid is, however, represented by a small quantity of amidostearic acid (*loc. cit.*). The acid products of the putrefaction of albuminoïds are—

(I.) *Fatty series*	Formic acid	Very small quantity.
	Acetic ,,	Doubtful.
	Butyric ,,	Large proportion.
	Valeric ,,	Smaller proportion.
	Palmitic ,,	Abundant.
(II.) *Acrylic series*	Acrylic ,,	Small quantity.
	Crotonic ,,	Considerable proportion.

(III.) *Lactic series*......	Glycollic acid	Moderate quantity.
	Lactic (ord.) „	Small quantity.
	Valerolactic „	Doubtful.
(IV.) *Oxalic series*	Oxalic „	Trace.
	Succinic „	Large quantity.
	Carbonic „	Large quantity.
(V.) *Nitrogenous acids*..	$C_9H_{15}NO_4$.....	Moderate quantity.
	Amidostearic acid	Small quantity.
	Leucines and luceïnes.	Abundant.

Physiological Chemistry.

Chemistry of Perspiration. By St. Capranica (*Gazzetta*, 13, 171).—To establish the analogy between the kidneys and sudorific glands, the author has endeavoured to ascertain whether creatinine, which is known to be a normal constituent of urine, exists also in the perspiration. On evaporating 450 c.c. perspiration in a vacuum to one-fifth of its bulk, precipitating with absolute alcohol, filtering, evaporating, and testing the residue by Will's process, he succeeded in demonstrating the presence of creatinine. On the other hand, he does not think that any such relation exists between uric acid and sudoric acid, $C_{10}H_{16}N_2O_{13}$, but he regards the latter as a product of the oxidation of glutamic acid ($2C_5H_9NO_4 + O_6 = H_2O + C_{10}H_{16}N_2O_{13}$), and as probably identical with the cryptophanic acid which Thudichum found in urine.

H. W.

Substitute Values of the Chief Organic Alimentary Principles in the Animal Body. By M. Rubner (*Zeitschr. Biol.*, 19, 313—496).—Previous investigations on this subject by Pettenkofer and Voit (*Zeitschr. Biol.*, 7, 433; and 9, 1 and 435) formed the starting point of the author's researches. His experiments were carried out similarly on the dog. He employs the term *isodynamic* in connection with those principles which are capable of replacing one another, as being more precise than the expression *equivalent*, which has a wider application.

Alimentary fat is isodynamic in equal weight with the body fat. On feeding with fat, loss of weight in fat is arrested by exactly the same amount as food which would otherwise have been consumed as body fat. Alimentary fat, when of the same composition as that of the animal body, is transformed into the latter with facility. Muscle-flesh as food (circulating albumin) is isodynamic in equal weight with the albuminoïd material of the body, which upon insufficient supply of albumin in food becomes consumed (disintegrated organic albumin).

During starvation, when the fat of the body disappears, the organic albumin becomes disintegrated in amount, corresponding with the calorificient value of the previously consumed fat.

The actual value in respect of capacity for heat-production of unorganised or dead albumin and living or organised albumin, is the same. Hence it is extremely probable that the formation of the latter from the former takes place without any accumulation of potential energy.

Fats and carbohydrates, as regards force-producing value, differ for equal weights, 100 parts of fat corresponding on the average with 240 parts of carbohydrate. The isodynamic values for albumin and carbohydrates may be determined from those of fat and albumin on the one hand, and fat and carbohydrates on the other, from which it appears that 100 parts of dried albumin are isodynamic with 110 parts of cane-sugar or 122 parts of grape-sugar. The limits within which a replacement or substitution of one principle for another may take place are very wide.

Hitherto it has been accepted that the alimentary principles replace one another according to definite chemical proportions. The present investigation places beyond doubt that the isodynamic value of these is the expression of equal intrinsic energy.

In the following table, in which the calorificient values of alimentary substances is given after the statements of Danilewsky and Rechenberg, it will be seen that the individual isodynamic values of these differ to an unimportant extent from the results of direct calorimetric determinations.

100 parts of fat corresponding with:—

	By direct experiment on the animal.	By calorimetric determination.
Albumin	211	201
Starch	232	221
Cane-sugar	234	231
Anhydrous grape-sugar	256	243
Ordinary grape-sugar	282	271

The results of experiments in the animal are somewhat higher than those calculated, the difference being due to several causes, such as, in the case of albumin and starch, putrefactive and fermentative changes in the intestine, whereby a loss of potential energy is occasioned, whilst in the case of carbohydrates, the work done by the muscles of respiration being increased, the excretion of CO_2 is also increased, and proportionately to a greater degree than in the case of fat itself, thereby accounting for the somewhat lower value of each of the carbohydrates in comparison with fat.

Assuming that the substitution of alimentary principles was effected according to the amount of oxygen which these required for their oxidation, it is of interest to consider how the isodynamic values as determined in the animal, compare with the values which would thus be obtained.

This is shown in the following table:—
100 parts of fat correspond with—

	According to oxygen consumed.	According to experiment in the animal.	According to calorimetric determination.
Albumin..........	193	211	201
Starch.............	240	232	221
Cane-sugar........	249	234	231
Grape-sugar.......	263	256	243

Excepting albumin, the alimentary principles exhibit lower values than that obtained by calculating the oxygen required for combustion. As the conditions of direct experiment tend rather to yield higher values than otherwise, it is apparent that the capacity of those principles for equivalent amounts of oxygen is not a measure of their capacity for substituting or replacing each other.

Whilst the experiments show this replacement or substitution of one alimentary principle for another, according to the amount of heat-production which is afforded by their combustion in the body, it is not implied that they replace each other because they yield the same amount of heat. The heat-production is only a measure of the total potential energy of the principle, and the isodynamic values indicate only alimentary principles of equal potential energy. A knowledge of these isodynamic values allows of measurement of any given kind of tissue change, and by adding together the calorifacient values of the disintegrated tissues, a numerical expression for the whole is obtained. This expression may take the form of so much albumin, fat, or a carbohydrate, but more appropriately of heat-units, as best corresponding to the essence of the process itself.

The greatest part of all these processes, included under the definition of tissue-change, is in effect an exchange of energy.

Within a small fraction of the total disintegration, it is quite indifferent as to what alimentary principles we introduce into the body. As regards albumin, only a trifling amount is incapable of being replaced by isodynamic quantities of other principles. To this amount the addition of albumin cannot be dispensed with, for there is a constant loss going on of epidermis and hair from the surface, of blood corpuscles, of epithelium in the intestine, and of nitrogenous secretions from the glands. For the renovation of such, processes of growth and maintenance are necessary, while it is easy to show that these processes participate only to an insignificant extent in the total interchange of energy.

What takes place in the organism as a whole may be regarded as taking place in each of its component cells, and that in the individual cell element, one alimentary principle substitutes another according to the proportion of its potential energy.

Albumin is to be regarded as the most readily decomposible principle, a fact which has already been established by the experiments of

Pettenkofer and Voit, although in apparent contradiction to observations as to its comportment outside the body, which tended to show the more difficult disintegration of albumin in comparison with fats and carbohydrates. In the body, the latter exhibit a different relation, the fats being more difficultly oxidisable than the carbohydrates; of course it may be assumed that there is no essential distinction of this kind, which may be accounted for by the readier solubility of the carbohydrates in the juices, whereby in simultaneous feeding with both principles, these are the first to be subjected to disintegration. D. P.

On the Digestion of Cows' Milk, and on the Substances which increase its Digestibility. By J. UFFELMANN (*Bied. Centr.*, 1883, 315—319).—The points considered were—(1) behaviour of milk with hydrochloric acid, lactic acid, and artificial gastric juice; (2) behaviour in the alimentary canal; (3) digestibility of boiled milk and buttermilk; (4) methods of rendering milk more easily digestible. The precipitate formed by a 2 per cent. solution of hydrochloric acid in milk assumes either a fine or heavy flocculent condition, or also cheesy, according to the conditions of mixing, which are, however, not readily ascertained, as variations in the form of the precipitate occur, the reason for which is not apparent. The action of lactic acid is similar to that of hydrochloric acid. The lumpy condition of the curd which is produced by 4 parts acid (2 per cent.) to 5 milk is not readily digested by pepsin, and if an insufficiency of acid produces no curd in the cold, then the addition of pepsin to the warm liquid causes the production of firm and compact curd. Small quantities of lactic acid have no influence on the digestion, but large quantities retard the action of pepsin. The digestive coefficients of milk in the bodies of adults and infants are as follows:—

	Adults.	Infants.
Dry matter....	90—91·7	90—94
Albumin......	98·4—99·2	98·2—99·4
Fat	93·4—95·6	92·2—94·9
Sugar........	100	100
Salts	44·2—56·6	45·4—57

Of the calcium salts only 25—30 per cent. are digested, whereas in human milk the percentage is 75—80. By boiling milk all the gases are removed, as well as some odorous substance; when the boiling is conducted in an open vessel a skin is formed; this skin is not all casein, but has the following constitution:—

	In 1·506 grams.	In 1·086 grams.
Fat........	0·617	0·283
Albumin ..	0·820	0·751
Sugar......	0·062	0·046
Salts	0·007	0·006

The author does not find boiled to be more digestible than unboiled milk. From buttermilk a curd is formed by hydrochloric acid, which is readily dissolved by gastric juice. Of the additions generally made to milk, such as arrowroot, yolk of eggs, &c., to render it more digestible, barley-water is the best, and experimentally it has been shown that the coefficient for albumin is raised to 99·75 by its use.

E. W. P.

Relative Absorption of Neutral Salts in the Human Stomach. By W. Jaworski (*Zeitschr. Biol.*, 19, 397—445).—These experiments were carried out under normal physiological conditions in a healthy man who drank the solutions (500 c.c.) of chemically pure salts and remained at rest until the residual fluid was recovered from the stomach by means of an aspirating pump specially devised for the purpose. This was then submitted to analysis, and the changes in the percentage of the salts determined.

These investigations showed that in the human stomach the absorption of individual salts is different, and dependent upon their chemical composition.

The acid carbonates (magnesium and sodium) underwent the greatest, the chlorides (magnesium, potassium, sodium, and ferric) the least absorption, and the sulphates (sodium and magnesium) between these extremes.

The difference in the absorption of two salts is the greater the longer the solution is present in the stomach.

The presence of acids in the stomach hastens absorption, and the difference in the absorption of individual salts becomes more pronounced. Carbonic acid especially accelerates absorption, which, on the other hand, is hindered by alkalinity of the contents of the stomach.

The presence of common salt neither accelerates absorption nor increases the gastric secretion; the action is negative in both directions.

The secretion of chlorine is greater in proportion to the alkalinity of the saline solution and the length of time the latter remains in the stomach. Acid sodium carbonate excites the secretion of the gastric mucous membrane less than the neutral carbonate.

When distilled water is introduced into the stomach, secretion of acid contents (hydrochloric acid) ensues, and that in proportion to the lowness of its temperature.

Should a salt undergo dissociation of its acid and base in the stomach, these are not absorbed in the ratio of their combining proportions. Saline solutions may be found on aspiration still present in the stomach an hour after their introduction, whereas the same quantity of distilled water disappears almost entirely within half an hour afterwards. From these results certain practical suggestions of clinical importance may be derived.

In the first place the administration of salts in the form of acid carbonates, as with an excess of carbonic acid, is advantageous, for absorption takes place more quickly, and with a more rapid emptying of the stomach there is less irritation of its mucous membrane. The author observed the action of CO_2 and of the acid carbonates, as also of CaH_2CO_3 in a series of experiments with acidulous mineral waters.

Alkaline fluids, on the other hand, delay absorption and the evacuation of the stomach, and the gastric walls are stimulated to secretion more strongly than by other solutions. Acids favour absorption and rapid evacuation of the gastric contents.

The presence of common salt in the stomach does not appear to offer the advantages in regard to digestion which have heretofore been ascribed to it, neither stimulating to greater excretion of the gastric acid (this remark may perhaps not apply to pepsin) nor to evacuation of its contents. In the moderation of the activity of the gastric walls by alkaline agents may probably be found an explanation of the therapeutic results of certain remedies, such as magnesium carbonate, sodium carbonate, and certain metallic oxides, in relieving the pain of cardialgia.

The introduction of salts in the form of chlorides in neutral solution is, as regards gastric absorption, not advantageous, and still less so in the case of neutral carbonates, which are absorbed only in proportion as their transformation into chlorides takes place.

The difficult absorptivity of ferrous chloride is especially to be noted from a medical point of view, and considering the facility of absorption of acid carbonates, it may be assumed that an acid ferrous carbonate would prove the most absorbable of all iron preparations.

D. P.

Basic Phosphate of Lime as an Addition to Cattle Fodder. By COHN (*Bied. Centr.*, 1883, 428).—The author has reviewed several experiments in this direction, and thinks that the addition of the substance, not only to medicines for cattle but to their ordinary fodder, would be very beneficial. He recommends for lambs and young pigs 8·12 grams, for calves and foals 12·20 grams, for oxen and cows 20 25 grams per head per day. J. F.

Influence of Distillers' Waste on Milk Secretion. By M. SCHMOEGER and O. NEUBERT (*Bied. Centr.*, 1883, 312—314).—The full details of the experiments are given, and the results were that distillers' waste (maize) greatly increased the yield of milk, but hardly affected the percentage of fat present. It is consequently a more remunerative food than brewers' grains. E. W. P.

Colouring-matters of the so-called Bile of Invertebrates, and of the Bile of Vertebrates, and some unusual Urine Pigments, &c. By C. A. MACMUNN (*Proc. Roy. Soc.*, 35, 370—403).—The author's observations lead him to conclude that the liver of Invertebrates discharges other functions besides those of a pancreas, which biologists generally regard it.

The colouring-matter of the bile in vertebrates does not occur in invertebrata, with the single exception of hæmochromogen, which is found in *Astacus fluviatilis* and the pulmoniferous mollusca.

Hoppe-Seyler had failed to detect bile pigments and bile acids in invertebrates. In the present instance, the animals submitted to investigation were taken from the sub-kingdoms, Mollusca, Arthropoda, and Echinodermata. The most striking result of this examination has been the discovery of a chlorophyll pigment in Mollusca and some Arthropoda, and amongst echinoderms in the radial appendages or cœca of starfishes. This pigment, occurring in the appendages of the enteron, has been termed *enterochlorophyll* by the author, in preference to zoochlorophyll, as more precisely defining the location of the chlorophyll which has been found in the mantle or integument of certain invertebrates.

Enterochlorophyll was not discovered in Lumbricus, Hirudo, or Aphrodite, amongst Vermes.

In this inquiry reliance as to the identity of the pigment under consideration with that occurring in plants has been placed on spectroscopic and chemical tests, the author accepting the dictum of Vogel and Kundt, that if colouring-matters dissolved in the same medium yield identical spectra, and present identical changes of spectra when acted on by the same reagent, the colouring-matters are themselves identical.

As a standard of reference for the spectral bands obtained from the pigment of invertebrates, the measurements of the bands of the first half of the spectrum yielded by the chlorophyll of the leaves of Primula are given.

An alcohol-ether extract gave four bands:—

1st band λ 674 —643
2nd „ λ 622·5—602
3rd „ λ 590 5—567
4th „ λ 548 —530

The residue left by this extract on evaporation and dissolved in rectified spirit, gave a series of five bands:—

1st band λ 684 —634
2nd „ λ 618 —598
3rd „ λ 586 —570
4th „ λ 546·5—534
5th „ λ 484 —465

and this solution treated with nitric acid yielded—

1st band λ 661—646
2nd „ λ 608—592
3rd „ λ 576—561
4th „ λ 539—521
5th „ λ 502—484?

With this latter series of five bands the spectrum yielded by the bile-colouring matters of the lamellibranchiate mollusca, examined under similar conditions of solution in alcohol and treatment with nitric acid, was identical. The molluscs included in this part of the investigation were the common oyster, mussel, and cockle, also Anodon and Unio. Hence it is concluded that the chlorophyll of leafgreen and their bile pigments are identical. It was proved that the colouring matter of the molluscan liver was not due to the presence of parasitic algæ. Negative results were obtained on treating the extracts with ammonium sulphide, showing hæmoglobin to be absent.

Of Cephalopoda, the common squid, *Octopus vulgaris*, only was examined. The results were essentially the same, the five-banded spectrum being yielded by the colouring-matter of the liver on treatment with nitric acid. Some slight differences observable appear to the author to be due to the presence of the pigment in a more highly oxidised state than in other cases, perhaps as an acid enterochlorophyll. Among gasteropod mollusca, species of whelk were examined, including *Buccinum undatum*, *Fusus antiquus*, *Purpura Lapillus*, and *Litorina litorea*, with corresponding results. In the case of *Purpura Lapillus*, which possesses the well-known purple-producing glands, it was noted that there was no peculiarity of the colouring-matter obtained from the liver, which yielded enterochlorophyll alone.

The investigation of the pulmoniferous mollusca embraced several species of snail, *Helix aspersa*, *H. pomatia*, and others; also of slugs, *Limax flavus*, and *Planorbis*.

In these, with the exception of Planorbis, which contains abundance of hæmoglobin, hæmochromogen (reduced hæmatin) was invariably present, in addition to chlorophyll, the author thereby confirming the previous observations of Sorby, who did not, however, notice the latter pigment. The spectrum of hæmochromogen was yielded by the bile, both with and without treatment with ammonium sulphide. Its presence may be dependent upon aërial respiration, and this resemblance of molluscan to mammalian bile in respect of the presence of hæmochromogen is of interest. The respective bands of the two colouring-matters extended generally, the reduced hæmatin first band, λ 570—566, second λ 539—526, and the enterochlorophyll λ 678—661. The bands of reduced hæmatin are not always in quite the same position.

Of Arthropoda, some species of crab, and the common lobster, *Homarus vulgaris*, were examined. Enterochlorophyll was less satisfactorily found, although present in most instances, than in the instance of the mollusca. In *Carcinus mænas* its presence was, however, exceptional, while that of a luteïn pigment appeared to be constant.

The common crayfish, *Astacus fluviatilis*, alone yielded evidence of the presence of hæmatin in the bile, and this in considerable amount. No other crustacean showed evidence of its presence. On treatment with ammonium sulphide, the two bands appeared, intensified, as in the case of the pulmonate mollusca, by caustic soda. The first band alone was easily read; it extended from λ 568·5—559·5. The presence of enterochlorophyll, on the other hand, could not be detected.

In the sub-kingdom, Echinodermata, certain starfishes and sea-urchins were examined. These yielded the usual five-banded spectrum of chlorophyll on addition of nitric acid to the alcoholic extract of the intestinal appendages.

The presence of these pigments, luteïn and tetronerythrin, was likewise indicated in the course of the examination of specimens of starfish. The latter pigment was found in the integument, and had also been found in the shells of the crustaceans previously referred to.

The author concludes from these observations that the existence of enterochlorophyll in the liver or other appendages of the intestine of the animals examined is definitely established. The bile of the pulmonate mollusca and of crayfish contains in addition hæmochromogen, which would appear to be a respiratory pigment, enabling intestinal respiration to be carried on, as in certain crabs, and *Cobitis fossilis.* The so-called liver of these invertebrates in addition to the preparation of a digestive ferment, discharges the function of a pigment-storing and pigment-producing organ in connection with surface coloration.

In some additional observations on the absorption-spectra of bile-pigments in vertebrate animals, the author alludes to his previously published observations, which appear to refer certain bands seen in bile to the presence of altered hæmatins (*Proc. Roy. Soc.*, **31**, 26). He has since proved that urobilin is absent in the bile of reptiles during hybernation. It was detected in the liver of *Salamandra maculata* in larger quantity than could be accounted for on the supposition of its presence in the blood-vessels of that organ, hence its probable formation there.

Concerning the origin of the colouring-matter of bile, proof of the transformation of hæmoglobin into biliverdin was afforded by a pathological fluid derived from the *tunica vaginalis testis* in a case of chronic epididymitis, when tapping had been previously resorted to for removal of the effusion. The fluid without any treatment showed the presence of a hæmoglobin derivative, and the pigment was proved by the action of oxidising and reducing agents to be biliverdin.

Experiments made on the colouring-matters of sheep- and ox-bile, although not completed, tend so far to show that chlorophyll as such cannot be present, inasmuch as the position of the band in red is altogether different, and the spectrum of acid chlorophyll was not obtained with nitric acid. Contrary to the statement of Hoppe-Seyler, the author, by direct experiment, finds that the pigments produced from bilirubin by oxidising agents and those of sheep- or ox-bile are not identical.

Referring next to urinary pigments, the author finds that febrile urobilin is not identical with hydrobilirubin or stercobilin, an alcoholic solution of the former, when acted on by caustic soda, yielding no bands at C and D, as in the case of similarly prepared solutions of the two latter. Harley's "urohæmatin" is shown to be a mixture of several decomposition-products of chromogens under the influence of heat and acids. The urohæmatin described by the author has been met with in four cases of acute rheumatism, and in a case of "idiopathic" pericarditis, its presence in the urine indicating insufficient oxidation of bodies with which it is associated, the normal oxidation of hæmoglobin to urobilin not taking place. Its occurrence in rheumatic fever would further seem to point to an acid fermentation, accompanied by destruction of hæmoglobin and production probably of lactic acid. The presence of urohæmatin in urine can be easily detected, without preliminary isolation, by its characteristic spectra, those of acid and neutral urohæmatin, which are distinguishable from those of methæmoglobin or hæmatin, by the use of ammonium sulphide, which does not affect urohæmatin.

Spectroscopic Detection of Indican.—Indican when present in the urine may be detected by its spectrum when Jaffe's test fails.

The urine, mixed with its own bulk of hydrochloric acid, is boiled, and after cooling, shaken, but not violently, with chloroform. The chloroform layer, if indican be present, is more or less violet, and shows a band before D, and generally one after it. It is noted that the reddening of normal urine when boiled with hydrochloric acid, is not due to the oxidation of indican, and only partly to the oxidation of urobilin chromogen. The author agrees with the view that this reddening is due to urobilin, and that this and indigo-red are two different colouring-matters. He has noticed a band half way between D and E, and extending nearly to E, λ 558—534, in most cases in which indican has been detected by the method described; and treatment with reagents pointed to its being due to some other colouring matter, although in some way connected with the presence of indican.

Uroerythrin, obtained in alcoholic extract from pink urates, gives a double absorption-band of hazy outline from about three-fourths the distance between D and E to beyond F. No connection could be established between it and indican or urobilin. It often accompanies urohæmatin.

In conclusion, the author refers to the existence of a red colouring-matter in pale urine, which becomes visible on adding a mineral acid, but which, as its spectrum showed, is neither indigo-red nor urrhodin. It was also not due to the oxidation of the chromogen of urobilin. From lack of material, the study of this pigment had to be left incomplete. D. P.

Albuminoïds of the Vitreous Humour of the Human Eye. By P. GIACOSA (*Gazzetta*, 13, 171).—In this liquid, the author has detected mucin, a globulin, and an albuminous substance analogous to serum albumin. Considering the small proportion of albuminoïds existing in this liquid, the author regards its viscidity as due to an excess of salts over the albuminoïds. H. W.

Chemical Composition of the Egg and its Envelopes in the Common Frog. By P. GIACOSA (*Gazzetta*, 13, 171).—To isolate the envelope, the author placed the eggs for some hours in lime-water, whereupon the envelope dissolved, while the yolk settled down to the bottom. The filtered solution, treated with acetic acid of 10 per cent., yielded a flocculent precipitate, which, after repeated washing with acetic acid and with pure water, gave by analysis 52·71 per cent. C, 7·1 H, 9·33 N, 1·32 S, and 0·62 ash, whence the author infers the presence of a mucin. This substance resists putrefaction, and does not reduce copper salts till after boiling with dilute sulphuric acid. The author intends to study the products of this decomposition, but as he has not been able to detect the presence of any other bodies, he concludes that the enveloping membrane of frogs' eggs consists of pure mucin. From the oviduct of the frog he also succeeded in extracting a mucin, which, though differing from the preceding in centesimal composition, nevertheless agrees with it in all other characters. H. W.

Localisation of Arsenic in a Case of Poisoning. By J. GUARESCHI (*Gazzetta*, **13**, 176).—From the experiments of Scolosuboff, it would result that arsenic accumulates chiefly in the nervous system, whereas, according to Johnson and Chittenden (*Amer. Chem. J.*, **2**, 332; Abstr., 1881, 1082), it is localised chiefly in the kidneys and liver, and according to Ludwig (*Schmidt's Jahrbucher*, 1881, p. 189), it accumulates chiefly in the liver, and is found also in the bones. The author, having carefully examined the viscera of an individual who died of arsenical poisoning, found that, out of 100 parts of arsenic, the stomach contained 0·0165, the liver 0·00105, the large intestine 0·00133, the lungs and heart 0·006, the muscles 0·00011, and the brain only traces, whence it appears that arsenic tends to accumulate chiefly in the liver, and is likewise found in notable quantity in the lungs and kidneys. H. W.

Physiological Action of Paraldehyde and Contribution to the Study of Chloral Hydrate. By V. CERCELLO (*Gazzetta*, **13**, 172).—The action of this substance is hypnotic and similar to that of chloral, excepting that it does not diminish the pressure of the blood, unless administered in large doses. The sleep which it produces is calm, and not accompanied or followed by disturbances; in fact, it is similar to normal sleep. Paraldehyde is absorbed by the stomach, rectum, and subcutaneous tissue. The author supposes that it acts on the cerebral hemispheres, and then on the *medulla oblongata* and spinal marrow. He recommends it for medical use as an excellent substitute for chloral. H. W.

Supposed Toxic Action of Aqueous Solutions obtained from Fresh Animal Organs. By E. DI MATTEI (*Gazzetta*, **13**, 172).—The author shows by numerous experiments that the symptoms of poisoning consequent on injection of the aqueous extracts of fresh organs (under the skin, into the veins, or into the peritoneal cavity) are due, not to any special toxic principle contained in these organs, as might be inferred from the experiments of Pellicani, but to a purely infective process, determined by the action and decomposition of insoluble but decomposed and alterable materials held in suspension by the injected liquids. In fact, when the turbid juice is freed from solid matters, either by filtration or by evaporation, and only the liquid portion is injected, death does not supervene. Another mode of experimenting consists in injecting beneath the skin of an animal the fresh juice of an organ reduced to a pulp, but not filtered, and, after a time more than sufficient to ensure the complete absorption of the liquid portion, making a wide incision in the skin at the point of injection, and washing with water containing phenol, in order to remove the solid matters remaining beneath the skin. Operating in this manner, death does not occur. H. W.

Chemistry of Vegetable Physiology and Agriculture.

Valuation of Seeds. By A. MAYER and others (*Bied. Centr.*, 1883, 324—325).—Mayer employs as a germinator a glass flask 15 cm. high and 6 cm. broad, having an opening close to the bottom, which allows of the free circulation of air, and removal of excess water. The seeds are laid on blotting paper or cotton stuff placed inside the flask. When compared with Nobbe's germinator, it was found that Mayer's was best for clover, whilst Nobbe's was best for most grass seeds. The reports of germinative power of a sample are made thus: (1) Value $= \frac{\text{purity} \times \text{germinative power}}{100}$; (2) percentage of foreign seeds, which are divided into harmful and harmless. As regards the influence of light, the author finds that the germination of *Poa pratensis* and *Dactylis glomerata* is accelerated, whilst the admission of air has no effect on *Pinus silvestris*, *Lolium perenne*, *Festuca ovina*, and *F. duriuscula*. Nobbe considers that germination should be tried in his germinator, on paper, in sand and in mould, before a satisfactory report can be made. A previous soaking for 6—12 hours is recommended for hard seeds, as also to remove the mucilage from the seeds of *Linum*, *Camelina*, *Cydonia*, &c., so as to admit oxygen more readily to the embryo.

E. W. P.

Chemical Changes induced by the Sprouting of Grain. By M. MÄRCKER and KOBUS (*Bied. Centr.*, 1883, 326—328).—The following table shows the changes which occurred when a sample of barley was exposed to bad weather for a fortnight; the rest of the crop had been well harvested. The ordinary analysis showed no difference between the samples: it was only when a more searching examination was made that a change was manifest:—

	Soluble starch.	Dextrin	Dextrose.	Maltose.	Other soluble matter.	Total starch.	Nitrogen in dry matter.
Normal ...	1·76	1·1	0·0	3·12	5·61	64·10	1·90
Sprouted..	1·17	0·0	4·92	7·32	5·23	57·98	2·045

	Nitrogen as nitrates.	Nitrogen as amide.	Nitrogen as ammonia.	Nitrogen as soluble albumin.	Nitrogen as insoluble albumin.
Normal.....	trace	0·028	0·045	0·087	1·740
Sprouted....	trace	0·454	0·044	0·036	1·511

Kobus found that in wheat, under similar circumstances, the nitrogenous matter was most affected, the gluten being reduced by 20—25 per cent. E. W. P.

Function of Silica in the Vegetation of Maize. By V. JODIN (*Compt. rend.*, **97**, 344—346).—A grain of maize cultivated in a suitable solution of inorganic salts will develop and form a plant of normal appearance without assimilating any notable proportion of silica. This deprivation of silica produces no physiological degeneration in the plant, which can be cultivated in a similar manner through several generations. Under somewhat similar conditions a maize plant will develop and attain full maturity, although retaining in its tissues only one-quarter the normal amount of phosphoric acid and one-half the normal amount of potassium. By cultivating in well moistened vegetable soil, a grain from a plant of the fourth generation cultivated in water free from silica, a strong and vigorous plant is obtained which contains only one-sixth the normal amount of potassium.

These facts confirm Déhérain's supposition that the ash of a plant contains an amount of inorganic salts greatly in excess of that actually required for the proper development of the plant. The accumulation of this excess in the tissues of the plant is due to the purely physical forces, diffusion and evaporation. C. H. B.

Constant Production of Oxygen by the Action of Sunlight on "Protococcus pluvialis." By T. L. PHIPSON (*Chem. News*, **48**, 205—206).—In the summer *Zygnema* and *Conferva* may frequently be seen borne to the surface of pools of stagnant water by innumerable minute bubbles of oxygen-gas. Some of the simplest of the unicellular algæ, *e.g.*, *Protococcus pluvialis* and *P. palustris*, exhibit this peculiarity to a remarkable degree. The author has cultivated some of the last-mentioned plants by exposing pump-water to air and light for some weeks, and, as soon as good growth was obtained, small dead branches of poplar were put in the water; the protococcus developed rapidly upon them. The branches can then be put in flasks full of water and the production of oxygen observed; this takes place immediately the flasks are exposed to the sun's rays; the oxygen comes off in the minutest bubbles, but in such great numbers as to form a froth on the surface; in some higher plants, *e.g.*, *Achillea millifolium*, the gas collects at the ends of the leaves and comes to the surface in large bubbles. If the flask is inverted the evolution of gas continues for about three days; the introduction of a minute quantity of caustic soda stops it on the first day by depriving the plant of carbonic anhydride. On renewing the water, after three days, the evolution recommences, and so by keeping up a constant supply of pump-water, the production of oxygen may be kept up to all appearance indefinitely. The author has devised a simple apparatus for this purpose—a wide-mouthed bottle with tubulure near the bottom is fitted with a gas delivery tube and a tube with tap connected with a water supply; the water must neither be boiled nor distilled, nor must it be in the slightest degree alkaline. A tap is put in the tubulure and is used to empty the bottle. Some of the working poplar branches are placed in the bottle, water is run in, and the bottle exposed to sunlight; the oxygen can be collected in a gas-holder. After three days the old water is run out of the bottle and fresh water run in. The author suggests that by employing graduated vessels, &c., the apparatus might be used as an *actinometer*. The gas produced contains about 98 per cent. oxygen. The author remarks incidentally that carbonic anhydride in presence of sunlight is not decomposed by plants, but simply absorbed, water and hydrogen dioxide being equally essential for the production of oxygen, and the gas being evolved from the tissue as a consequence of the absorption.

D. A. L.

Aldehydic Nature of Protoplasm. By A. B. GRIFFITHS (*Chem. News*, **48**, 179—180).—After reference to the work of Loew and Bokorny (Abstr., 1882, 546, 447, and 882), of Reinke (*ibid.*, 243 and 1312), of Mori (*Chem. Centr.* [3], **13**, 565), of Beyer, of Kretzschmar (*Bied. Centr.*, 1882, 830), and to his own communication to this Journal (Trans., 1883, 195), the author proceeds to describe his new experiments. He has examined the protoplasm of living and dead cells of *Spirogyra*, and finds that it reduces alkaline solutions of cupric salts; that crystals are formed in it by treatment with weak sodium chloride, and that the addition of absolute alcohol to the cells of the *Spirogyra* causes the deposition of crystals of anhydrous *dextrose*. It is therefore probable that the reducing properties of protoplasm are due to this glucose, and that the crystals formed with sodium chloride are $C_6H_{12}O_6,NaCl + H_2O$. This view is supported by the following experiments:—Albumin (white of fresh egg) mixed with a small quantity of a very dilute solution of dextrose, when treated as above described, behaves in a manner precisely similar to the spirogyra cells. Moreover, if the living plant is kept in the dark for a couple of days and is then examined, none of these reactions are observed. This is evidently due to the dextrose being used up in the dark to nourish the cell-walls and tissues, for after a short exposure to sunlight the dextrose reappears and the usual phenomena are to be observed in the plant cells. The author concludes with some remarks on the aldehydic nature of dextrose, on the assimilation of carbon by plants, and on the importance of researches on albumin. D. A. L.

Fatty Constituents of Common Chestnuts. By P. MALERBA (*Gazzetta*, **13**, 173).—Dry chestnuts contain at least 3 per cent. of fatty matters, for the most part liquid and of oily aspect, while the smaller portion is solid, the proportion of fatty matter increasing with age, and fatty acids being formed at the same time. H. W.

Cocoa and Chocolate. By BOUSSINGAULT (*Ann. Chim. Phys.* [5], **28**, 433—456).—The cacao plant rarely flowers before it is 30 months old, but the first flowers are generally destroyed, as the planters do not permit the plants to bear fruit before they are four years old; 100 kilos. of fresh fruit yield from 45 to 50 kilos. of dry cocoa. In Venezuela, after a plant is seven years old, it yields 0·75 kilo. annually. In Magdalena a tree yields 2 kilos. of dry cocoa per annum. The kernel of the species *Montaraz* contains: Butter, 53·3; albumin, 12·9; theobromine, 2·4; gum and tartaric acid, 6·7; cellulose, lignose, starch, 9·1; ash, 4·0; water, 11·6 per cent. The ash consists chiefly of phosphate of calcium, magnesium, and potassium; it also contains silica, carbonic and sulphuric acids. The husk has the following percentage composition:—Butter, 3·9; nitrogenous matter, 14·25, containing 2·8 N; gum, 12 12; tartaric acid and tannin, 5·05; ash, 6·89; water, 12·18; lignose, cellulose, and other compounds not estimated, 45·61. The process of decortication is generally accomplished by means of gentle heat. The following table shows the composition of Trinidad cocoa, decorticated A by heat, B without heating:—

	A.	B.
Butter	54 0	49·9
Starch and glucose	2 5	2 4
Theobromine	3·6	3·3
Asparagine	trace	trace
Albumin	11·8	10·9
Gum	2·5	2·4
Tartaric acid	3·7	3·4
Tannin	0·2	0·2
Soluble cellulose	11·5	10·6
Ash	4·4	4·0
Water	—	7·6
Not estimated	5·8	5 3

Cocoa butter is a white solid which melts at 30° and solidifies at 23°. The gum resembles gum arabic in appearance, and also yields mucic acid when treated with nitric acid. It is powerfully dextrogyrate. Chocolate, prepared by grinding together sugar and gently roasted cocoa, contains varying amounts of sugar. Spanish chocolate contains from 40·6 to 54 per cent. of sugar, and French chocolate contains from 56 to 59 per cent.

The relative value of chocolate and milk as food is seen from the following analysis of equal weights of milk and an emulsion containing 20 per cent. of chocolate:—

	Chocolate emulsion.	Milk.
Albumin	3·0	13·6
Fats	14·0	15 0
Sugar	32·0	15·0
Salts	1·0	2·7

The large proportion of sugar in chocolate diminishes its nutritive power.

W. C. W.

Analysis of some Cider Apples. By R. LEZÉ (*Ann. Agronomiques*, 9, 105).—The fruits were exhibited at the Apple Congress of St. Lô, November, 1882, and analysed by the author at the end of December:—

Variety.	Water.	Sugar.	Ash.	Tannin.	Cellulose, albuminoïds, &c.
Haut griset	80·96	7·64	0·52	0·50	10·38
Avoine	83·38	9·19	0·37	0·21	6·85
Doux lozon	80·64	9·22	0·36	0·19	9·59
Aufriche tardive	82·02	8·59	0·46	0·35	8·58
Cartigny gros	81·08	10·41	0·34	0·57	7·60
Fréquin	84·02	6·08	0·28	0·72	8·90
Airu	83·90	8·50	0·36	0·23	7·01
Petit rouget	84·90	7·40	0·32	0·27	7·11

The variety Fréquin is well known as yielding good cider, which will keep well. J. M. H. M.

Poisonous Properties of Edible Fungi. By G. DUPETIT (*Biel. Centr.*, 1883, 356).—The physiological action of the juices of many fungi on animals is detailed in this paper. The poisonous principle is soluble in water, but insoluble in ether, chloroform, carbon bisulphide, and alcohol; it is precipitated from its solutions by alcohol, tannin, lead acetate, and hydroxide; it therefore less resembles the alkaloïds than the soluble ferments, and its action is destroyed at 100°. In *Boletus* two non-poisonous alkaloïds have been found, the one resembling neurine, the other the ptomaïnes. E. W. P.

Report on Experimental Plots at Grignon in 1882. By P. P. DÉHÉRAIN (*Ann. Agronomiques*, **9**, 106—124).—The crops grown in 1882 were wheat, oats, green maize, sugar-beet, and sainfoin. The yield of oats was under average, and that of wheat very poor, 35 hectolitres per hectare against 50 harvested in 1880. The author attributes the difference, not to the rainfall, which was less and more equally distributed in 1882 than in 1880, but to the difference in temperature, the monthly mean from March to September being from 1·3° to 5·6° (July) less in 1882 than in 1880. For the same reason the vintage of 1882 was a bad one, as the grapes never ripened perfectly.

Wheat.—All the plots carried potatoes from 1875—1879, and wheat 1880—1882; since 1879 no nitrogenous manure has been used. The best yield (27—30 hectolitres) was on those plots which had received dressings of farmyard manure from 1875—1879; plots dressed with sodium nitrate during the same period gave no more grain than the plot unmanured since 1875, although the straw was slightly heavier; and plots which received ammonium sulphate, 1875—1877, yielded less of both grain and straw than the plot unmanured since 1875. The entire wheat crop of the neighbourhood suffered much from rust in June; 10 grams of wheat from one of the plots contained 128 well developed grains weighing 6·12 grams, and 132 stunted badly filled grains weighing 3·88 grams. The two lots were analysed and found to be almost identical in composition.

Oats.—The harvest from the experimental plots was worse than the average of the four years 1878—1881, but better than 1881; the deficiency was most marked in the grain, and the author attributes the falling off to the difficulty of cleaning land carrying the same cereal crop so many years in succession. Oats have been grown on all the plots for the last eight years, and in 1882 the yield from most of the manured plots was actually less than that on the two plots receiving no manure, owing to the encouragement afforded by the manures to the growth of weeds.

Green Maize.—The seventh consecutive year of this crop has yielded results similar to those of the preceding years. The yield, favoured by a wet season, has shown no falling off, and farmyard manure in quantities up to 29,000 kilos. per hectare, has proved by far the most efficacious and remunerative dressing; with 40,000 kilos. instead of 20,000, the increased yield is not sufficient to cover the extra cost of the manure. A moderate dressing of farmyard manure each year has given better aggregate results than the same total quantity distributed over the three years 1875—1877. Partial or complete substitution of sodium nitrate for farmyard manure has resulted in diminished crops.

Sugar-beet.—This crop has been grown in 1881 and 1882 on six plots which carried green maize for the six previous years; the previous dressings on half the plots having been farmyard manure, and on the others ammonium sulphate. The results of 1881 were so decidedly worse on the ammonium sulphate plots, that in 1882 an attempt was made to restore their fertility by new dressings of farmyard manure alone or with artificials: 20,000 kilos. farmyard manure, together with 200 kilos. each of sodium nitrate, superphosphate, and potassium chloride, was the only application which raised the produce of the ammonium sulphate plots to a level with the plots which received no manure in 1881 or 1882, but had been dressed with farmyard manure in 1878, '79, '80. The sugar in average samples of roots from each plot was determined by the polariscope, the percentage varying from 12·04 to 13·73 (the variety grown was *Vilmorin's betterave au collet rose*). The results confirm the author's previous conclusions that the richness in sugar is lowered by nitrogenous manures, and is not sensibly raised either by potassium salts or superphosphate. The most remarkable fact in this series of experiments is the decreased crops on the plots which formerly received ammonium sulphate, a result which the author attributes to the injurious action of this salt on the physical properties of the soil.

Sainfoin.—The sainfoin grown in 1879 had become replaced by grasses at the end of 1881; a new sowing was therefore made in 1882, and a satisfactory crop obtained, the best plots being those which were heavily dressed with farmyard manure from 1875—1878. Analyses of the soil and subsoil, made in the four years preceding 1879, during which the plots carried sugar-beet and green maize, showed a slight progressive diminution in the percentage of nitrogen, even in those plots which received large dressings of farmyard manure; since the occupation of the ground by sainfoin, however, the percentage of nitrogen has remained stationary or has slightly increased. No figures are given on this point. J. M. H. M.

Influence of Rainfall on the Wheat Crop. (*Bied. Centr.*, 1883, 291—294.)—A table of the rainfall and temperature in England during July and August, in the years 1846—1876, is given, and this is divided into four groups; comparing this table with the wheat crops, it appears that when the average temperature of July and August is above the mean, the crop is above average: rain during warm seasons does not lower the quantity although the quality may be deteriorated; however good a season may be in June, no good crop is obtained—that is one above the average—if the average temperature in July and August is below the mean; even if the weather in those months be fine, the quality only is good. If during July and August there is both wet and cold, the yield is always low and the quality poor. E. W. P.

Comparative Feeding Value of Barley, Malt, and Peas. By A. VOELCKER (*Jour. Roy. Agri. Soc.*, 1883, 422).—These experiments were conducted at Woburn. The barley and malt were used in the proportion shown in the malting operation, 140 lbs. of barley yielding 117 lbs. of malt and malt-dust. Three pens, each of ten sheep (10 months old), received throughout the same quantity of swedes, with hay and straw chaff. During the first period of eight weeks, each sheep had in addition ¼ lb. of linseed cake per day; pen 1, ¼ lb. of barley meal; pen 2, the equivalent in malt-meal and malt-dust; pen 3, ¼ lb. of pea-meal. In the second period of two weeks the additional foods were increased to ½ lb. per head per day. In the third period of two weeks they were raised to ¾ lb. In the fourth period of two weeks they were raised to 1 lb. The gain in live-weight of the sheep of each pen was as follows:—

	Pen I. Barley.	Pen II. Malt.	Pen III. Peas.
	lbs.	lbs.	lbs.
First eight weeks........	200½	227¾	228¾
Following six weeks	93	73¾	113
Total fourteen weeks....	293½	301½	341¾

The feeding values of the barley, and of its equivalent in malt, were thus practically equal, whilst that of the peas was distinctly greater.

The maximum rations were continued for two weeks longer; during this time the sheep of pen 1 refused a part of their barley, the results therefore ceased to be comparative. R. W.

Composition and Digestibility of Serradella at various Ages. By H. WEISKE, G. KENNEPOHL, and B. SCHULZE (*Bied. Centr.*, 1883, 307—309).—The seed was sown in the middle of April on two plots, from the first of which a crop was taken on July 22, and from the latter on October 2, also an aftermath was taken from the first plot on October 2. The composition of the crops was as follows:—

	Plot 1.		Plot 2.
	July 22.	October 2.	October 2.
Yield—			
Fresh....	110·0 kilos.	4·345 kilos.	85·00 kilos.
Dry	13·83 „	0·577 „	17·15 „
Containing—			
Albumin........	22·62 p.c.	24·75 p.c.	19·13 p.c.
Fat, &c.	5·2 „	5·12 „	3·95 „
Fibre...........	29·65 „	27·11 „	35·71 „
Cellulose, &c.....	30·89 „	34·33 „	32·39 „
Ash	11·64 „	8·69 „	8·82 „

Feeding experiments showed that the younger plant was more easily digested than the older. E. W. P.

Analyses of Heather (Erica vulgaris), Braken (Pteris aquilina), and Broom (Genista pilosa). By A. PETERMANN (*Ann. Agronomiques*, 9, 251—255).—Vast tracts of poor soil in the Ardennes (derived from schists and quartzose schists) are covered with a thick vegetation of heather, broom, and fern, which is useful to the inhabitants in many ways. The dense mass of vegetation assists in the disintegration of the rock, and acts as a sponge in storing up and gradually giving out the rainfall. Sheep and horses readily eat the young shoots of broom and heather, and the ashes of these plants, burnt on the spot, are found to be a good manure for oats. Cut with the scythe, air-dried, and stacked, these plants furnish fuel in the winter and litter for cattle.* Sometimes they are ploughed in as green manure, and frequently broom in flower is made into a compost with soil and refuse. The analyses in the subjoined tables were made on the air-dried plants, including stems, leaves, and flowers:—

	Fern.	Heather.	Broom.
Water..................	14·70	12·70	12·30
†Organic matter	75·75	85·06	84·79
Mineral matter	9·55	2·24	2·91
	100·00	100·00	100·00
†Containing nitrogen	2·38	0·80	2·54

---

* Fern litter is also extensively used in the New Forest.—J. M. H. M.

Composition of the Ash after Deducting Carbon, Sand, and Carbonic Anhydride.

	Fern.	Heather.	Broom.
Potash	38·53	31·74	43·28
Soda	3·31	5·98	4·18
Lime	11·69	19·78	18·57
Magnesia	6·93	13·28	10·05
Oxide of iron	0·91	3·06	1·12
Sulphur trioxide	7·93	8·14	4·61
Phosphorus pentoxide	4·60	2·73	14·05
Silica	17·51	13·47	1·11
Chlorine	11·09	2·35	3·89
Manganese	—	trace	trace
	102·50	100·53	100·88
Deduct oxygen equivalent to chlorine ...	2·50	0·53	0·88
	100·00	100·00	100·00

Fern and broom thus contain six times, and heather twice as much nitrogen as rye-straw, and their ashes are rich in phosphoric acid and potash.

J. M. H. M.

Beet Cultivation. By CRAHÉ and others (*Bied. Centr.*, 1883, 333).—Crahé found on large plots that a mixture of Chili saltpetre and Baker guano was a more productive manure than ammonium sulphate and guano, both as regards yield of root and of sugar. Märcker found that in 1880 Simon le Grand Rose was the best cropper but lowest yielder of sugar, but in 1881 Klein Wanzlebene was the highest cropper and Vilmorin Blanche gave the best yield of sugar.

E. W. P.

Potatoes and Sweet Potatoes. By SACC (*Bied. Centr.*, 1883, 337).—Potatoes which are planted at all seasons of the year, as in Monte Video, are watery and tasteless, and have the composition—albumin 0·71—0·81, dextrin 0·02—0·05, sugar 1·3, starch 10·2—12·81, bitter extract 2·25, fibre 13·18—11·59, calcium bimalate 0·05, water 73·59—72·91, but if they are planted in October then the composition is normal. Sweet potatoes (*Convolvulus batatas*) require more heat, and contain—albumin 0·56—0·64, glucose 4·0—0·3, mucilage 1·15, pectic acid 1·27, starch 15·0—13·01, fibre 10·02—17·83, ash 1, water 67·0—68·19. They require an open soil and but little manuring. The sweet potato is finer than the potato, and is quite as useful, being largely used in the manufacture of spirits.

E. W. P.

Assimilation of the Organic Matter of Arable Soil. Part I. Historical Résumé. By P. P. DÉHÉRAIN (*Ann. Agronomiques*, 9, 258—265).—The idea that plants directly assimilate the organic matter of the soil was supported by de Saussure, Malaguti, and Soubeyran, and opposed by Liebig and Boussingault. The last-named chemist contended that the utility of humus to vegetation consists in the continuous disengagement of large quantities of carbonic anhydride in the soil, and subsequent writers have supposed that this carbonic anhydride is absorbed by the roots, conveyed to the leaves, and there decomposed in presence of chlorophyll and sunlight. No evidence in favour of the absorption of carbonic anhydride by roots could be obtained by Corenwinder from direct experiments on the point; on the contrary, he has shown that roots take part in respiration, absorbing oxygen and emitting a little carbonic anhydride. Grandeau has attributed another function to humus. He found that the ammonium carbonate extract of soil contains, besides the brown humus bodies, considerable quantities of phosphoric acid, oxide of iron, magnesia, lime, and soluble silica. When this solution is dialysed, only the mineral constituents pass through the septum, forming a colourless solution, the brown matter left on the septum containing only 8 per cent. of ash, whereas before dialysis it contains 53 per cent. From these experiments Grandeau concludes—(1) that the minerals combined with humus are directly assimilable by the roots of plants; (2) that the organic matter itself does not enter the roots, but is the vehicle of the mineral aliment; (3) that the combination of minerals with humus is similar to that found in the liquor of a dung-heap; and (4) that the fertility of a soil is proportional to the quantity of minerals associated with humus and soluble in ammonium carbonate. Petermann has recently demonstrated (and his experiments have been repeated by Grandeau) that soil *not* treated with ammonium carbonate does contain dialysable organic matter, and the question remains, does this organic matter serve directly as plant food? The author's observations on the experimental maize plots at Grignon render an affirmative reply probable. The plots dressed each year with 40,000 kilos. farmyard manure have given an average annual yield of 90,000 kilos. green maize, whilst the highest yield obtained by the use of chemical manures is 68,000 kilos. When maize is grown with the aid of farmyard manure, the soil is found to be much more impoverished of carbon than in the case of potatoes or wheat, which do not benefit so much from the same manure. The author finally quotes the opinion of Sachs, who, after noting the direct assimilation of organic matter by fungi, germinating seeds, and certain parasites, considers it probable that green plants also may share in this function. The direct experiments of the author will be given in a future number.

J. M. H. M.

Ammonia, Chlorine, and Sulphuric Acid in Rain collected at Rothamsted. By Sir J. B. Lawes, J. H. Gilbert, and R. Warington (*Jour. Roy. Agri. Soc.*, 1883, 313).—The results of earlier determinations have been given in a previous paper (Abstr., 1882, 889).

1. *Ammonia in Rain.*—The new determinations were made both in daily rainfalls and in monthly mixtures. The rain was distilled, and the distillate Nesslerised. In 152 daily collections of rain, dew, &c., in the large rain-gauge (0·001 acre), extending from June 22, 1881, to January 5, 1882, the nitrogen as ammonia varied from 0·043 per million (in a rainfall of 0·713 inch on Nov. 27) to 5·49 per million (in a deposit of dew of 0·007 inch on September 17). The rainfall during the whole period amounted to 21·645 inches, and contained an average

of 0·254 of nitrogen as ammonia per million. The proportion of ammonia is much greater in small deposits than in large; it is affected to a still greater extent by the amount of previous washing which the atmosphere has undergone. Ammonia was also determined in 50 monthly mixtures of rain-water. In 24 recent months the analysis of the water was made at the end of each month; the earlier monthly samples were in most cases of considerable age when analysed. In the 24 recent samples the nitrogen as ammonia averaged 0·316 per million; in the whole series of 50 months the average was 0·361. Evidence is given showing that the ammonia in the rain-water generally tended to increase by keeping. Nitrification was possibly prevented by the lead present in the water. The rainfall of summer was generally richer in ammonia than that of winter. The nitrogen as ammonia contributed annually by rain to an acre of land amounts to 2·37 lbs. if calculated from the daily determinations during six months, to 2·47 lbs. calculated from two years' determinations in fresh monthly mixtures, and to 2·66 lbs. if calculated from determinations in 50 monthly mixtures, many of them old. From the last series of determinations it appears that to double the quantity of ammonia per acre the rainfall must be increased about six-fold. From Frankland and Way's results, the nitrogen as nitric acid appears to be about 1 lb. per acre, and the nitrogen as organic matter a similar amount. The total combined nitrogen in the annual rainfall at Rothamsted is thus about 4·5 lbs. per acre.

2. *Chlorine in Rain.*—The determinations of chlorine in monthly mixtures of rain extend over six years, 1877—83. The mean proportion found was 1·99 per million of water, or 14·92 lbs. per acre, equal to 24·59 lbs. of sodium chloride. Two-thirds of the chlorides fall in the six winter months, October to March. The minimum quantity falls in July, the maximum in October and November. The supply of chlorides in summer seems to be very limited, as a large increase in the rainfall produces but little increase in the quantity of chlorides per acre. In winter the increase in the quantity of chlorides with a rise in the rainfall is much greater.

3. *Sulphuric Acid in Rain.*—The sulphuric acid was determined gravimetrically in mixtures representing the rainfall of summer (April—September) and winter (October—March); the determinations extended over two years. When the rain was collected in glass vessels only, the average amount of sulphuric anhydride was 2·41 per million of rain or 18·5 lbs. per acre. When the rain was collected in the large rain-gauge the amount of sulphuric anhydride was 3·95 per million, or 30·3 lbs. per acre. There seems little doubt that in this latter case a part of the sulphuric acid was derived from the vulcanised caoutchouc used for the connections. The rain appears to be slightly richer in sulphuric acid in summer than in winter.

R. W.

Influence of Artificial Manures on the Physical Properties of Soil. By E. Wollny (*Ann. Agronomiques*, 9, 129—131; from *Zeits. des Vereins für die Rubenzuckerindustrie*, November, 1882).—The addition of small quantities of ammonia or fixed alkalis, or of alkaline phosphates or carbonates to water holding clay in suspension, causes the immediate precipitation of the clay in a dense form. Mineral acids and their salts, such as sodium nitrate, act in the opposite manner, precipitating the clay in a light and spongy form, which occupies much space. Hence the author argues that the addition of substances of the former class to soils is injurious to their porosity and lightness, and consequently to fertility, and cites as examples the alkali plains of Nevada and California, the soil of which is hard, dense, non-porous, and sterile. On the other hand, salts such as sodium nitrate, saltpetre, and potassium sulphate exercise an immediate beneficial effect on the porosity of arable soil, but as they are quickly washed out the effect is not lasting, and the fertility is then found to be impaired. Of all artificial manures, lime exercises the most favourable influence on the properties of soil, causing it to aggregate into flocculent particles which persist for years, and render it light and fertile. J. M. H. M.

Weeds in Soils. By H. Putensen (*Bied. Centr.*, 1883, 295—297).—In this paper it is shown that repeated ploughings and harrowings diminish the number of weeds in the soil. E. W. P.

Manuring Experiments at Kiel. By A. Emmerling (*Bied. Centr.*, 1883, 297—306).—This is a report of the experiments made in 1881, which are a continuation of those conducted in 1880; the season was bad, yet conclusions may be drawn which are not without interest, as showing the action of artificial manures under unfavourable circumstances. There were 24 sets of plots on various soils, the crops being generally oats, but buckwheat, barley, and beans were also grown. The manures were superphosphate, precipitated phosphate, dissolved and raw Peruvian guano, steamed and dissolved bone-meal, blood, ammonium salts, and Chili saltpetre (86 9 per cent.). The results are given in full detail in a series of tables. A short summary of these is given here. Ammonia acted but feebly on clay loam, and not at all on sand, but well on black humus earth. Saltpetre was satisfactory in all classes. Phosphates with ammonia produced a low yield in that district where the weather was unpropitious. Phosphates and saltpetre gave contradictory results owing to bad weather. Steamed bones raised the yield of grain, and especially at the drier stations; whilst steamed bones are best on dry lands, the dissolved meal best acted at those stations where rain had fallen in June. Blood failed at all the dry places. In spite of the unfavourable conditions, the guano (raw and dissolved) greatly increased the crop; the latter had, however, increased the grain and straw more than the former. E. W. P.

Manurial Value of Nitrogenous Refuse. .IV. Dried Blood. By A. Petermann (*Ann. Agronomiques*, 9, 241—251).—Thirty-two samples of dried blood examined in 1880—81 gave an average of 11·23 per cent. nitrogen; the physical condition also was satisfactory, being dry, friable, pulverulent, and almost without odour. The manurial value was determined by experiments on plants grown in pots, in two soils of very different physical characters, and the results were compared on the one hand with those obtained without manure, and on the other hand with those obtained by using a quantity of sodium nitrate equivalent in nitrogen to the dried blood. The effect of adding phosphoric acid and potash to the dried blood was also studied. The results given in this abstract are in all cases the mean of two or three concordant experiments.

The first series consisted of 15 flower-pots filled with loamy soil from Gembloux mixed with a quarter of its bulk of quartz sand; the second, 15 pots filled with sand from Campine. Ten grains of spring wheat were sown in each pot on March 17th, 1882; on August 20th, 1882, the plants were removed from the pots, and the straw and grain weighed separately; the results are given in the table.

Manure.	Loam. Mean weight of		Sand. Mean weight of	
	Straw.	Grain.	Straw.	Grain.
No manure	18·19	7·94	5·35	2·08
Dried blood = 0·25 gram N	42·51	19·56	10·70	5·05
Sodium nitrate = 0·25 gram N	44·25	20·14	19·51	7·51
Dried blood (= 0·25 gram N) + precipitated phosphate (= 0·30 gram P_2O_5)	42·90	19·51	20·46	8·94
Sodium nitrate (= 0·25 gram N) + precipitated phosphate (= 0·30 gram P_2O_5)	44·96	19·62	21·36	9·76
Dried blood (= 0·25 gram N) + precipitated phosphate (= 0·30 gram P_2O_5) + potassium chloride (= 0·20 gram K_2O)	43·73	19·44	22·59	12·19
Sodium nitrate (= 0·25 gram N) + precipitated phosphate (= 0·30 gram P_2O_5) + potassium chloride (= 0·20 gram K_2O)	45·01	19·80	23·99	12·98

The highest yields are obtained in the loam, but the effect of the manures is greatest in the sand. In the loam, dried blood produces an increase in the crop practically identical with that given by a quantity of sodium nitrate containing the same amount of nitrogen; the addition of phosphoric acid, or potash, or both, has little effect. In the sand, on the contrary, dried blood is decidedly inferior to its equivalent of sodium nitrate, and both phosphoric acid and potash produce considerable effect; the effect of the phosphatic manure, in all the pots in which it was used, was to hasten the period of ripening.

As the result of these and previous experiments, the author arranges the nitrogenous manures which he has tried in the following order of efficiency (such quantities being employed as contain equal weights of nitrogen):—Sodium nitrate, dried blood, dissolved wool, wool refuse, leather refuse. The efficiency is plainly related to the solubility and readiness to decompose in each case.

J. M. H. M.

Preparation of Manure from Furnace Slag. By WINKELHOFER (*Bied. Centr.*, 1883, 354).—The excess of lime in the slag obtained in the "basic process" is to be removed by treatment with molasses and water, which leaves the phosphates undissolved; the lime is then separated from the saccharate by passing the products of combustion from the furnaces through the solution.

E. W. P.

Insoluble Phosphates. By F. J. LLOYD (*Chem. News*, **48**, 164—165).—The "insoluble phosphates" from superphosphates are divided into two classes, the "white" and the "red." The white are obtained only from manures made from bones, and represent approximately the amount of phosphate not dissolved.

The author has analysed the "red" phosphate with the following result:—

CaO.	Fe_2O_3.	P_2O_5.
32·53	31·80	35·77 per cent.

These numbers correspond with 60·01 per cent. calcium phosphate, 17·63 per cent. ferric phosphate, 22·46 per cent. ferric oxide.

Analytical Chemistry.

Volumetric Analysis. By E. REICHARDT (*Arch. Pharm.* [3], **21**, 106—115).—This paper contains instructions for the performance of the ordinary operations in volumetric analysis, including the precautions to be observed in the preparation of standard solutions, &c.

W. R. D.

Determination of the Density of Solids and Liquids by means of the Specific Gravity Bottle. By S. PAGLIANI (*Gazzetta*, **13**, 172).—The author points out, as a source of error in these determinations, the fact that flat-bottomed glass bottles when filled with liquid exhibit very sensible alterations of level, even when only a slight pressure is exerted on the bottom; and in endeavouring to determine the capacity at 0° of one of these vessels, he observed that the level of the liquid contained in it at 0° was higher than at the ordinary temperature. He therefore recommends for liquids the use of the bottles described by Regnault (*Ann. Chim. Phys.* [3], 9, 438); and in cases when it is necessary to use the ordinary bottles, as in determining the densities of solid bodies, he suggests a previous examination, with the view of ascertaining whether they exhibit the defect above mentioned.

H. W.

Apparatus for the Rapid Analysis of Gases. By A. A. BRENEMAN (*Chem. News*, **48**, 156).—The apparatus consists of a eudiometer fitted with a soft india-rubber stopper bored with two holes, through which pass two tubes closed by valves; one is connected with an exhausted receiver, whilst the other has simply a pointed glass tube attached to it. When in use the gas is introduced into the endiometer over a pneumatic trough, and the volume read off in a convenient cylinder sufficiently full of water. The eudiometer is retransferred to the trough of water, the stopper inserted, and most of the water drawn from the interior of the eudiometer by opening the valve in connection with the exhaust chamber; the absorbent is introduced by applying the point of the pipette to the pointed tube and opening the valve connected with it, when the liquid rushes in to replace the water which has been withdrawn. The absorption being complete, the liquid is removed by opening the exhaust valve (by which means all subsequent absorbents and washings are removed), the eudiometer well rinsed with water, and the volume again read off in the cylinder of water. The mouth of the burette is kept below the surface of water as much as possible. A special form of cup, with a long bent-up handle, is used for transferring the eudiometer from the trough to the cylinder, and *vice versâ*. D. A. L.

Apparatus for the Rapid Analysis of Gas. By A. H. ELLIOT (*Chem. News*, **48**, 189—191).—This apparatus consists of two glass tubes of the same length; one graduated from the top to within a short distance from the bottom, in tenths c.c. to 100 c.c.; the other plain. Both are connected at the lower end with two distinct reservoirs of water by means of flexible tubing; there is a three-way cock at the bottom of the plain tube, with one delivery through the stem. The top of the graduated tube terminates in a capillary tube, bent at a right angle, and fitted with a stopcock. At the top of the plain tube there is a straight capillary tube fitted with a stopcock, below which a lateral capillary tube is fused, which is joined to the capillary of the graduated tube by a rubber connection. Above the stopcock the operator can attach either a movable cylindrical funnel which is ground to fit over the tube, or the tube for the admission of the gas to be analysed. In use, the tubes are filled with water by opening the stopcocks in a suitable manner, and the plain tube is charged with gas, lowering or raising the water reservoirs; the gas is then transferred to and adjusted in the graduated tube, the volume is read off, and the absorbent having been run in to the plain tube through the funnel, the gas is retransferred to the last-mentioned tube, &c. In washing out the plain tube, use is made of the three-way cock; by bringing it into connection with the inside of the tube, and allowing the washings to run out. Absorbents are used in the following order—potash, bromine, potassium pyrogallate, and cuprous chloride. A special arrangement is employed for explosions: a stout glass tube is graduated in tenths c.c. and of 100 c.c. capacity to within a few inches from the bottom; the lower end is connected with a water reservoir, and has a lateral tube fused in the side and fitted with a stopcock; the upper end is closed by a capillary tube and stopcock (to which either a funnel or a piece of bent capillary tubing can be attached), and has platinum wires fused in through the glass. To use this, the tube is filled with water, and by means of the bent tube and india-rubber connections and the water reservoirs and stopcocks, a sufficient amount of gas is admitted from the absorption-tube, the level adjusted, the volume read, and the oxygen allowed to enter by the lateral tube at the bottom, the explosion is proceeded with as soon as the gases have been mixed by slight agitation: the analysis is then finished in the usual manner, absorbents being run in through the funnel. After some practice, a complete gas analysis, using both absorption and explosion tubes, can be made in less than an hour, and results are obtained within a few tenths of a per cent. of the truth.

D. A. L.

Estimation of Bromine in Presence of Large Quantities of Chlorides. By A. Cavazzi (*Gazzetta*, 13, 174).—The author's method consists in the use of oxygenated water (BaO_2 and dilute sulphuric acid), which at 100° liberates all the bromine without decomposing the chlorides. The bromine-vapour is passed into a solution of arsenious acid in hydrochloric acid (0·10 g. As_2O_3 in 20 c.c. of liquid) which absorbs it rapidly. To determine the quantity of bromine thus absorbed, a solution of potassium permanganate is prepared containing 3·55 g. $KMnO_4$ in a litre of distilled water. Now the author finds that 18·30 c.c. of such a solution is just sufficient to impart a permanent red or yellow tint to 20 c.c. of the arsenical solution; and hence by a simple calculation, it is found that 1 c.c. of the same permanganate solution is equivalent to 0·00888 gram of bromine.

If iodides are also present, the iodine must first be separated by means of an acetic solution of barium dioxide and carbon bisulphide (as described by the author in another place), after which the solution containing the bromides and chlorides is mixed with pure lime to alkaline reaction, then evaporated to dryness, and the residue is calcined to convert the acetates of barium and calcium into carbonates. Lastly, the residue is treated with boiling water, and the bromine is determined by the method above described.

H. W.

Purification of Hydrogen Sulphide. By W. Lenz (*Chem. News*, 48, 147).—It is very important that all arsenic should be removed from the hydrogen sulphide employed in chemico-judicial investigations, and the author suggests the following process with this object. Four consecutive wash-bottles kept at a temperature of 60—70° are used to purify the gas. The first bottle contains a mixture of 1 part strong hydrochloric acid with 2 of water; the second, a solution of 1 part of this mixture to 4 of water; the third a similar solution containing 1 to 8; in the fourth, pure water. Neither caoutchouc stoppers nor vulcanised india-rubber connections are permissible. This washing system is very efficient.

D. A. L.

Testing for Free Sulphuric Acid in Wines and Vinegar. By E. Pollacci (*Gazzetta*, 13, 315—316).—The author states that neither Nessler's method nor Lessaigne's gives satisfactory results, and proposes the following:—Strips of filtering-paper, purified by treatment with hydrochloric acid and washing, are immersed in a beaker containing the wine, so that they adhere to the sides, one end touching the bottom and the other projecting about a centimeter above the top, a sufficient number of strips being used to line the interior of the vessel. After 24 to 36 hours, by the spontaneous evaporation of the liquid, a sufficient quantity of the acid will have accumulated in the upper extremities of the strips of paper; these are now cut off and repeatedly triturated with ether in a glass mortar. The ether is evaporated, the residue taken up by water and tested for sulphuric acid in the usual way. This method has the advantage that the free acid alone is separated and detected. C. E. G.

Direct Estimation of Carbonic Anhydride in Presence of Sulphides, Sulphites, and Thiosulphates of the Alkali-metals. By M. König and E. Zatzek (*Monatsh. Chem.*, 4, 733—737).—For the simultaneous estimation of carbonic anhydride and hydrogen sulphide, Fresenius has given a method depending on the retention of hydrogen sulphide by copper sulphate (this Journal, 1871, p. 582); but for the direct estimation of carbonic anhydride under conditions which involve the simultaneous formation of SO_2 and SH_2, as in the examination of crude soda, soda-lyes, &c., no accurate method has hitherto been published. This object may however be attained by the following method, depending on the principle that potassium permanganate, under conditions already described (p. 151 of this volume), converts the sulphides, sulphites, and thiosulphates of the alkali-metals almost entirely into sulphates, so that when a mixture of these salts with carbonates has been thus treated, its subsequent decomposition by an acid gives rise to the evolution of nothing but carbonic anhydride.

The method is applied as follows:—The substance is introduced into a 300 c.c. flask closed by a perforated caoutchouc stopper, through one of the holes of which is inserted a stoppered funnel-tube reaching nearly to the bottom of the flask, and through the other a tube connecting the flask (1) with a Liebig's bulb-apparatus containing an acidulated solution of permanganate; (2) with a $CaCl_2$-tube; (3) with a bulb-apparatus containing caustic potash; (4) with a $CaCl_2$-tube. The apparatus having been made air-tight, a concentrated solution of permanganate is poured in slight excess into the flask, and the carbonate is then decomposed with dilute nitric, sulphuric, or acetic acid (not by hydrochloric acid); the stopcock of the funnel-tube is then closed, and the decomposition of the carbonate is completed by heating the liquid gently at first, and ultimately to the boiling point. The heating is then discontinued; the cock of the funnel-tube is opened; this tube is connected either with a U-tube filled with lumps of solid potash, or with a wash-bottle containing potash-lye; and a slow stream of air is drawn through the apparatus for half to three-quarters of an hour, after which the apparatus may be disconnected. The insertion of the bulb-tube containing the permanganate solution is for the purpose of retaining any portion of SO_2 or SH_2 that may have escaped oxidation in the flask.

The accuracy of the method may be judged of by the following examples, in the first and second of which pure sodium carbonate, Na_2CO_3, was mixed with sulphite; in the second with thiosulphate; in the third with sulphide, sulphite, and thiosulphate together; in the fourth with potassium sulphide, sodium sulphite, and sodium thiosulphate; and in the fifth a mixture of Iceland spar, barium sulphite, and barium thiosulphate was decomposed by dilute nitric acid.

	CO_2 found.	CO_2 calculated.
1..........	41·54 per cent.	41·51 per cent.
2..........	41·34 „	
3..........	41·35 „	
4..........	41·33 „	
5..........	43·75 „	44·00 „

In one case in which the absorption-apparatus containing permanganate was not introduced, a mixture of sodium carbonate and sulphite gave 47·01 per cent. CO_2, whereas the amount according to calculation should have been only 41·51.

This method also gives the means of determining the amount of sulphur contained in the sulphur-compounds mixed with the carbonate. For this purpose, after the carbonic anhydride has been determined as above, the contents of the reaction flask and of the absorption-tube containing permanganate are poured into a beaker, the excess of permanganate and the precipitate of manganite formed in the reaction are decomposed by heating with hydrochloric acid, and after the chlorine has been expelled by boiling, the sulphuric acid is precipitated by barium chloride, &c. H. W.

Estimation of Phosphoric Acid in Manures. By GASSEND and CAMPREDON (*Ann. Agronomiques*, 9, 266—270).—After having obtained the precipitate of ammonio-magnesian phosphate, there are two ways of dealing with it in common use: it is either calcined and weighed as magnesium pyrophosphate, or it is dissolved in acetic acid and titrated with standard uranium acetate. The authors state that, when applied to commercial fertilisers, the first method invariably gives results which are too high, unless solution of the precipitate in hydrochloric acid and reprecipitation are resorted to, necessitating a further delay of over twelve hours. Titration with uranium acetate they believe to be quite accurate and more expeditious than the gravimetric method, even when only one precipitation is employed. A sample of mixed bone superphosphate and precipitated phosphate gave the following percentages of P_2O_5:—

	Uranium method.	Gravimetric method.
P_2O_5 soluble in water............	14·08	15·35
„ „ ammonium citrate	14·99	16·18
„ total.....................	16·11	17·14

The excess by the gravimetric method was proved to be due to impurities retained by the magnesium precipitate, consisting of iron and alumina (traces), lime, sulphuric acid, and silica. The mean quantity of silica in the three precipitates was 0·008 gram, and the authors find that the ammonio-magnesium phosphate retains silica, even after a day's washing with dilute ammonia. J. M. H. M.

Testing of Potassium Bromate. By G. Vulpius (*Arch. Pharm.* [3], 21, 186—190, and *Dingl. polyt. J.*, **249**, 47).—For the determination of phenol, according to the equation—

$$C_6H_6O + 5KBr + KBrO_3 + 3H_2SO_4 = C_6H_3Br_3O + 3K_2SO_4 + 3H_2O + 3HBr,$$

the new German Pharmacopeia stipulates the use of normal solutions of potassium bromide and bromate. The latter, according to Vulpius, often contains a large proportion of potassium bromide, which may be estimated in the following manner:—0·1 gram of the bromate is mixed in a tared beaker with 2 grams of potassium iodide, and the mixture dissolved in 5 c.c. of hot water; 10 c.c. of cold water, and 15 grams of a 25 per cent. solution of hydrochloric acid are then added, and the solution is titrated with decinormal sodium thiosulphate. 1 c.c. of this solution corresponds with 2·785 mgrms. of potassium bromate, taking the equivalent for potassium bromate at 167·1. D. B.

Action of Ammonium Sulphide on Metallic Pyrophosphates. By G. Buchner (*Arch. Pharm.* [3], 21, 115—120).—The author has investigated the action of ammonium sulphide on the solution obtained by adding excess of sodium pyrophosphate to solutions of the salts of those metals which, in the ordinary course of analysis, are precipitated by ammonium sulphide. If sodium pyrophosphate (5 per cent. solution) is added to solutions of the salts of these metals, a precipitate is obtained which is soluble in excess of the reagent. The addition of ammonium sulphide to this solution precipitates the metals as sulphides in the case of zinc, cobalt, nickel, and iron (ferrous and ferric), but produces no precipitate with manganese (manganous and manganic), uranium, chromium, or aluminium. When these last-mentioned solutions are heated, or allowed to stand for some time, the manganese is precipitated as pyrophosphate of manganese, ammonium, and sodium ($MnNH_4NaP_2O_7$). The solutions containing aluminium and chromium become turbid, if boiled and subsequently cooled; but in the case of uranium the solution remains clear even after boiling. If a solution of an iron salt is precipitated by ammonium sulphide, and a solution of sodium pyrophosphate subsequently added, the ferrous sulphide dissolves when the liquid is boiled, forming a colourless solution, which becomes dark green on cooling, and finally deposits nearly all the iron as sulphide. When a solution of manganese salt is treated in a similar way, the liquid deposits crystals of manganese sodium ammonium pyrophosphate. W. R. D.

Specific Gravity of Commercial Copper. By D. Watson (*Dingl. polyt. J.*, **249**, 48).—The author found that copper, when precipitated electrolytically from a solution of the sulphate, has a sp. gr. of 8·955. The sp. gr. of copper is materially affected by different impurities contained in the metal, cuprous oxide having the greatest effect: the following table illustrates this circumstance:—

	Sp. gr.	With $\frac{1}{4}$ p.c Pb.	With $\frac{1}{2}$ p c. As.	With $\frac{1}{4}$ p.c. Pb and $\frac{1}{2}$ p.c. As.
Copper free from Cu_2O..........	8·955	8·961	8·939	8·945
Copper containing 1 p.c. Cu_2O ...	8·925	8·931	8·909	8·915
Copper containing 2·5 p.c Cu_2O..	8·881	8·887	8 865	8·871

The author is of opinion that the sp. gr., in conjunction with the estimation of lead and arsenic, suffices to approximately determine the amount of cuprous oxide in a sample of commercial copper.

D. B.

Estimation of Carbon in Cast Iron. By A. A. Breneman (*Chem. News*, **48**, 168).—In the process recommended, the carbonaceous residue obtained when cast iron is dissolved, is filtered in a small platinum tube, which is subsequently put, with its contents, into the combustion tube and burnt in oxygen. The platinum tube is made of stout foil, and is fitted with a small disc of perforated platinum to support the asbestos for filtering; the air-tight connection, with the necessary glass tube, is made by means of soft india-rubber tubing, one end of which is inserted in the platinum. The ends of the glass tube are conical, so that the connection may be made without injury to the platinum. Combustions should be conducted in porcelain tubes, as these last longer and can be heated more strongly than glass tubes, and the platinum tube should be made to fit well, so that the oxygen may pass mainly through the filter and its contents.

D. A. L.

Apparatus for Estimating Carbon in Steel. By A. B. Clemence (*Chem. News*, **48**, 206).—The author has introduced an apparatus to avoid the errors attached to the old process of filtering in a glass funnel, &c., and to do away with the expense and inconvenience of the platinum funnel, porcelain tube, combustion furnace method (preceding Abstr.). The apparatus consists of a platinum tube $11\frac{1}{2}$ inches long, with a diameter of $\frac{3}{4}$-inch for 7 inches, the remaining $4\frac{1}{2}$ inches being $\frac{3}{16}$ inch diameter. In use, an asbestos plug is placed at the point in the tube where the contraction commences, the carbon is filtered on this, washed well with hot water, any adhering carbon being swept down by moist asbestos, the tube is then dried at 150—170° for an hour. A hard rubber stopper with glass tube passing through is now put into the wide end, through which the current of oxygen enters, a single thickness of filter-paper, 2 inches wide, being wound round the tube by the stopper, and kept wet by a stream of water; the tube, at the part where the filter is placed, is heated with a Bunsen burner for an hour, at the end of which time the potash bulbs can be weighed. The author takes from 3 to 5 grams of borings, which he dissolves in cuprammonium chloride, 36 grams to 120 c.c. water for 3 grams of steel; when the deposited copper is completely dissolved, he proceeds as above described. Good results have been obtained.

D. A. L.

Volumetric Estimation of Manganese. By J. B. MACKINTOSH (*Chem. News*, 48, 176—177).—It has been suggested that the precipitate obtained by treating the boiling nitric acid solution of a manganese salt with potassium chlorate is not pure MnO_2, but a mixture of $10MnO_2 + MnO$. This being of importance in the titration of manganese, the author has studied the subject, and publishes his observations in the present paper.

The experiments are based on the facts that potassium permanganate has an oxidising power equal to five of oxygen for every two of manganese, and that the same quantity of manganese, in the state of dioxide, has an oxidising power equal to 2 atoms of oxygen; so that, if a solution of permanganate is reduced to dioxide, the oxidising power of the dioxide thus formed will be equal to that of two-fifths the quantity of the permanganate solution originally taken. The analyses were conducted in the following manner:—The permanganate was decomposed with hydrochloric acid and concentrated. The hydrochloric acid was removed by boiling with excess of nitric acid, and the manganese precipitated by successive alternate additions of potassium chlorate and nitric acid, until no more yellow fumes were observed. When cool the precipitate was filtered through asbestos, washed with nitric acid and with water, and then treated with a volume of oxalic acid, with a known permanganate equivalent, and a little sulphuric acid. The excess of oxalic acid was determined by permanganate, and the oxidising power of the precipitate found by subtracting the excess from the whole quantity. The results obtained are as follows:—

Permanganate used.	Oxidising power of precipitate in terms of permanganate.	Theoretical for MnO_2.	Per cent. of theoretical corrected for burette error.	Average true per cent.
45 c.c.	17·80 c.c.	18 c.c.	99·37	—
35	13·93	14	100·07	99·99
25	9·90	10	99·86	—
15	5·96	6	100·67	—

Great importance is attached to the method of precipitating the manganese; for by adding the potassium chlorate at once, and boiling until the action ceases, an error of from 1 to 2 per cent. is almost certain. The author points out that not too much value must be set on the above results, as of course there are many experimental errors involved in the process. It is, however, safe to conclude that the precipitate obtained in this process, when the necessary precautions are taken, is not $10MnO_2 + MnO$ (which would have an oxidising power = 90·91 per cent.) but MnO_2. D. A. L.

Arsenic in Glass. By W. FRESENIUS (*Chem. News*, 48, 147).—In connection with the removal of arsenic from apparatus, &c., used in cases of judicial investigation, the author has observed that the glass of the vessels employed contained arsenic. A sample of Bohemian glass contained 0·20 per cent., of hard glass 0·08, and another sample of hard glass a trace. The author attributes the browning of glass when heated to arsenic and not to lead. Further experiments show that alkaline solutions take up arsenic from glass; acids do not. D. A. L.

Microscopic Examination of Water for Organic Impurities. By J. Brautlecht (*Chem. News*, **48**, 180).—100 c.c. of the water are treated with five drops of a solution containing 1 part of aluminium sulphate, 1 part hydrochloric acid, and 8 parts of water, and one to three drops of ammonia; the precipitate is filtered off and redissolved in 10 to 15 drops of dilute acetic acid; and the clear solution thus obtained is examined under the microscope both before and after the addition of saffranine. By the addition of $\frac{1}{2}$ per cent. gelatin, permanent preparations on Koch's principle may be obtained.

D. A. L.

Detection and Estimation of Trinitrophenol (Picric Acid). By G. Christel (*Arch. Pharm.* [3], **21**, 190—200).—This paper contains an examination of the principal reactions of trinitrophenol made with a view to its qualitative detection and quantitative estimation. The aqueous solution of picric acid is not precipitated by neutral solutions of lead or copper salts; neither is ammonium picrate, unless the solution is alkaline, when lead acetate gives a reddish-yellow precipitate, and copper sulphate a yellowish-green precipitate in dilute solutions, and a bright green in concentrated solutions. A solution containing half a milligram of picric acid in 5 c.c. of water is not at once precipitated by a solution of cuprammonium sulphate, but on standing for 24 hours a distinct precipitate is obtained, which is insoluble in ammonia, but is decomposed by water. Solution of basic lead acetate is a very delicate test for picric acid, yielding a bright yellow precipitate. A solution containing the tenth of a milligram of picric acid in 5 c.c. of water, gives after 12 hours a distinct precipitate, and a solution containing the twentieth of a milligram in 5 c.c. of water a strong opalescence, which subsequently forms a distinct sediment. When this sediment is decomposed by the addition of 1 drop of sulphuric acid, and the solution is rendered alkaline with ammonium hydrate and evaporated to dryness, a residue is left which, when dissolved in a little water and warmed with a drop of potassium cyanide solution, gives a distinct red colour. The yellow colouring matters of the bark of *Quercus tinctoria* (quercitron), and the root of *Broussonetia tinctoria* also give precipitates with basic and neutral lead acetate, but the precipitates do not give the reaction with potassium cyanide when treated as above described. An aqueous solution of methyl green precipitates solutions of picric acid. The green precipitate dissolves in ammonia, forming a deep yellow solution, which is precipitated by basic lead acetate, and this precipitate gives the reaction with potassium cyanide. This test cannot be applied for the detection of picric acid in beer, for 1 litre of beer which contained 5 mgrms. of picric acid was not precipitated by a solution of methyl green. Solutions of picric acid are precipitated by stannous chloride, and if a small quantity of ammonia is added, the solution becomes red. The same reaction is obtained when a solution, prepared by adding potassium

hydroxide to a solution of stannous chloride until the precipitate at first formed is redissolved, is added to a solution of picric acid. The red colour is due to the formation of dinitroamidophenol (picramic acid): hydrogen and ammonium sulphides give a similar reaction. If a solution of picric acid or a picrate is acted on with zinc and dilute sulphuric acid, a yellowish-red turbid solution is obtained, which, when poured off and mixed with alcohol, develops a green colour, changing through blue to a violet-green. For the detection of picric acid in sweetmeats or other coloured substances containing sugar, the potassium cyanide reaction can be applied directly; or the colouring matter may be extracted with alcohol, the residue from this solution, after dissolving in water, precipitated by lead acetate; and the potassium cyanide reaction obtained after decomposing the precipitate in the manner above described. For the detection of picric acid in wool or cellulose, the hydrochloric acid solution may be reduced by zinc, and the reaction with alcohol obtained. The substance may also be digested with ammonia, and the potassium cyanide reaction tried with this solution. The detection of picric acid in beer cannot be accomplished by means of lead acetate, on account of the other substances in the liquid, which are precipitated by this reagent; neither can the colouring matter be removed by animal charcoal, for this also retains the picric acid. For the detection of picric acid in beer, the author recommends the following method:—200 c.c. of the beer are evaporated to a syrupy consistence on the water-bath, and then digested in a flask with 50 c.c. of alcohol (90 per cent.), the mixture being allowed to stand for 24 hours, when it is filtered, and the residue washed with 31 c.c. more alcohol. The mixed filtrates are evaporated to the consistence of a syrup and acidified with two or three drops of dilute sulphuric acid. The mixture is then extracted with five or six times its volume of ether, the latter removed, the solution again acidulated and extracted with ether. The ethereal solutions are spontaneously evaporated, and the residue dissolved in 5 or 10 c.c. of water, the solution filtered, neutralised with ammonia, and tested by one of the methods above described. For the estimation of picric acid, the author proposes a colorimetric method, based on the potassium cyanide reaction. The ethereal residue is diluted to 10 c.c. with a little ammonia, 5 or 10 drops of a 10 per cent. potassium cyanide solution added, and the liquid, after heating it to 80°, is diluted to 100 c.c. with dilute ammonia. The colour produced is compared with that given by a certain quantity of a standard solution of picric acid, 100 c.c. of which contain 0·1 gram of pure picric acid, the operation being conducted in the same way.
W. R. D.

Detection of Hydrocyanic Acid in Chemico-Judicial Investigations. By H. BECKURTS (*Chem. News*, **48**, 199).—After pointing out that the presence or absence of hydrocyanic acid or poisonous metallic cyanides in the presence of a harmless cyanide, is not efficiently demonstrated by treatment with tartaric acid and distillation, &c.; the author recommends as efficient, Jacquemin's process, namely, distilling the sample to be tested with concentrated solution of sodium hydrogen carbonate, and testing the distillate for hydrocyanic acid;

or Barfoed's process, in which the mass is acidified with sulphuric or tartaric acid and agitated with ether, which takes up hydrocyanic but not hydroferrocyanic acid. D. A. L.

Soap Analysis. By A. R. Leeds (*Chem. News*, **48**, 166—168).—The soap, cut in thin shavings, is dried at 100°; the loss is *water*. It is then exhausted with light petroleum, and the extract containing the *free fats* is dried and weighed. The residue is exhausted with 95 per cent. alcohol, and the extract of it containing any *free soda* is titrated with sulphuric acid, using phenolphthalein as indicator. The neutralised liquid is largely diluted with water, the alcohol boiled off, and a large excess of normal sulphuric acid added. The whole mass is boiled, cooled and filtered, and the precipitate of *fatty acids and resin* is well washed with hot water, then dried, and weighed. The *resin* is determined by Gladding's method (*Amer. Chem. J.*, 3, 416), and the amount subtracted from the last total, the difference being the amount of *fatty acids*.

The filtrate from the sulphuric acid is neutralised with normal soda, the *combined soda* calculated, evaporated to dryness, and the *glycerol* extracted with absolute alcohol, dried and weighed, any residue is added to the fatty acid and resin precipitate. The residue from the first alcoholic exhaustion is washed with cold water; the washings are divided into four equal parts; and the *sodium carbonate, chloride, sulphate,* and *silicate* determined in the separate portions. The residue containing the *starch* and *insoluble inorganic matter* is dried and weighed, the starch being subsequently converted into glucose, and titrated with Fehling's solution. D. A. L.

Technical Chemistry.

Employment of Limed Coal in Gas Making. By J. A. Wanklyn (*Chem. News*, **48**, 174—176).—The coal is mixed with 2½ per cent. of lime previous to being put in the retort. The lime is slaked before mixing. The author claims many advantages for this introduction, viz., increase in the yield of ammonia to the extent of 20—36 per cent.; of liquor to the extent of about 35 per cent.; of tar 6 per cent.; and of gas, which is also improved in quality, being fragrant instead of unpleasant to the smell, and not deteriorated in illuminating power. These advantages are supplemented by a considerable decrease in the quantity of hydrogen sulphide and carbon bisulphide, and in fact the author anticipates the abolition of lime-purifiers if this liming (Cooper's) process is introduced. The coke, too, is much improved by this addition of lime; it is more readily combustible, and does not give off sulphurous anhydride when burnt. In the author's opinion gas works will cease to be the nuisance they now are when the process is introduced. D. A. L.

Methods for Coking Coal. By W. Smith (*Chem. News*, **48**, 185—187).—In the present paper the author reviews the various methods now employed for the production of coke from coal. The simplest, the *Meiler* or *mound* method, is that in which the coal is burnt in mounds, similar to those employed for the production of wood charcoal; the coke produced is good, and freer from sulphur than oven-coke, but it is not so hard. The *beehive oven* produces a coke almost unsurpassable for metallurgical purposes, but wastes all bye-products. The *Appolt oven* and the *Coppée oven* are constructed so as to use the gases and vapours produced during the coking for heating the ovens. The coke is excellent. The *Jameson oven* is a modification of the beehive oven, and is constructed with a floor of perforated quarles instead of the solid floor of the latter; these perforations are connected with a short vertical flue below the floor, and from this a pipe passes at right angles to the hydraulic main, and to exhaust appliances, the exhaustion being carried on as is usual in gas works. The gas produced is not employed in the operation, and can therefore be conveyed to a distance and used for heating purposes. The coke is good. The ammoniacal liquor contains a large quantity of ammonium sulphate, and according to Jameson, the yield of liquor is equal to a production of 5—15 lbs. ammonium sulphate for a ton of coke. The yield of tar or "oils" is from 6—15 gallons per ton of coke; it contains neither benzene, nor naphthalene, nor anthracene, only a small quantity of toluene, but large quantities of xylene mixed with paraffins. The chief bulk of the Jameson tar consists of oils (sp. gr. 0·960, and boiling at 250—350°), which are of little value for burning, and of only secondary value as lubricants. They have no fluorescence. A considerable proportion of the oils distils above 350°, and deposits paraffins, melting at 58°. The oils boiling between 200° and 300° contain a fairly large proportion of phenols, some of which resemble the constituents of wood-tar creasote. They contain a mere trace of phenol, but more cresols, and the largest quantity boils from 250—300°. The 300° fraction is resinous, and perfectly soluble in caustic soda with a red colour. Some other of these phenols yield reds and blues with alkalis, but of no stability or value. In *Simon-Cariès oven* the coking process is one of destructive distillation, and is similar to that of a gas works. The temperature employed is very great, 2200° or even 3000° being reached. The gas is burnt in the ovens. The ammoniacal liquors are of good strength, 6—7° T. The tar, black and thick (sp. gr. 1·20), is exceedingly rich in naphthalene and anthracene, contains as much benzene, toluene, xylene, and phenol as any London tar, and is moreover free from paraffins. The coke is very good; it has not the silvery glance of the beehive and Jameson oven coke, but is quite as solid, hard, and compact. These properties are obtained by using large charges of coal (4½ tons), piled up in masses of great height (6 feet or so), and considerable thickness (19 inches), but not too thick for the heat of the oven to penetrate sufficiently well. Mellor has introduced a process for separating the benzene from gas, which consists in washing the latter with strong nitric acid in earthenware towers filled with broken glass, and as benzene is soluble in nitrobenzene, the same acid strengthened with sulphuric acid is repeatedly passed down the tower. The benzene can be removed from this solution by steam-distilling. Another process with the same object in view is due to G. E. Davis: refrigerated coal-gas is washed with refrigerated heavy coal-tar oils, which remove the benzene. The author is of opinion that the Simon-Carvès method, especially if combined with one of these benzene removing processes, is the coking process of the future. D. A. L.

Atmospheric Dust. By A. Schuster (*Bied. Centr.*, 1883, 354).—Sand taken from the neighbourhood of the Great Pyramid, and Nile mud contain a considerable quantity of magnetic particles, some measuring 0·1—0·2 mm. These particles may be derived from exploded meteorites, which by reason of insufficiency of oxygen in the upper atmosphere have not yet been oxidised. E. W. P.

Existence of Germs in the Air at Great Heights. By P. Giacosa (*Gazzetta*, **13**, 176).—The author's experiments were made on the summit of Monte Marzo (2756 m. above sea-level), and at the foot of the same mountain (2300 m.), with the following results:—Schizomycetes exist in quantities diminishing as the altitude increases. Throughout the experiment (first three days of August) the air on the top of the mountain contained germs of leaven, and the air at the foot of the mountain was sometimes found to contain cells of the same fungus. Germs of the common moulds are likewise abundant at both altitudes. In no instance were any forms observed which could be referred to animal organisms. H. W.

Properties of Antiseptics and of the Volatile Products of Decay. By G. le Bon (*Bied. Centr.*, 1883, 350—352).—The action of antiseptics is weaker the further the decomposition has proceeded. The best antiseptics are as follows, commencing with the strongest:—Potassium permanganate, chloride of lime, ferrous sulphate acidified with acetic acid, phenol, and sodium and potassium glycoborates. The action of these compounds as antiseptics is different from their action as microbes; they cannot arrest decay, but may prevent its commencement. As a rule antiseptics have but little action on bacteria; in phenol these organisms live for a long time. At present it is uncertain whether the volatile alkaloïds from decomposing animal matter are poisonous, but in a few cases death has occurred after inhaling the volatile products given off by decomposing matter. It is dangerous to exhume a corpse, and the air of churchyards is poisonous. E. W. P.

The Future of the Chlorine Industry. By F. Hurter (*Dingl. polyt. J.*, **249**, 126—133).—The only hope that the Leblanc process will not be completely wrecked by the ammonia-soda process is that the world requires chlorine as well as soda. Weldon, Solvay, and Mond are doing their best to combine the manufacture of chlorine with the ammonia-soda process. The author attempts to show in what way the ammonia-soda process may endanger the manufacture of chlorine, and how the same may be prevented.

1. *Replacing Chlorine by other Bleaching Agents.*—Perceiving the difficulty of utilising the chlorine from the calcium chloride liquors obtained in the ammonia-soda process, Mond has recently patented a very ingenious method for obtaining calcium peroxide, and for its application as a bleaching and disinfecting agent, but as calcium peroxide is insoluble, it will probably be necessary to convert it into hydrogen peroxide by treatment with a dilute acid, before it can be used for bleaching, &c. The process consists in introducing into a cupola dried blocks of a mixture of barium carbonate, pitch, and sawdust, and heating to about 1200°. The barium carbonate is converted into barium oxide, and the carbonaceous products are burnt out. The mass as it descends meets a current of air, which cools the oxide to about 500°, when it absorbs oxygen and is changed into barium peroxide. This when cold is decomposed by means of carbonic anhydride and water, under pressure, into barium carbonate and hydrogen peroxide. The former is used afresh, whilst calcium peroxide is prepared from the hydrogen peroxide by adding milk of lime to it. Calcium peroxide is a hydrate of the formula $CaO_2,8H_2O$, containing 7·4 per cent. of available oxygen, equivalent to 32·8 per cent. of available chlorine. According to Lunge, the manufacture of barium hydroxide is carried out on a large scale in France, and consequently the production of the peroxide should present no difficulty.

The peroxides are all very powerful oxidisers. According to Thomsen, the amount of heat produced by oxidation with hydrogen peroxide is 23,064 units larger per molecule than by the direct oxidation with free oxygen. In spite of its energetic oxidising action, hydrogen peroxide is so slow a bleaching agent that it appears as though it is not available oxygen but chlorine that is required for the bleaching of vegetable fibres. Gerhardt attributes the bleaching action of chlorine to the facility with which it is substituted in organic substances in the place of hydrogen. The author has found that by igniting bleached cotton with soda the presence of chlorides can be detected in the melt, whilst unbleached cotton when similarly treated does not exhibit this reaction. Hydrogen peroxide is the only compound which could be prepared cheaply enough to compete with bleaching powder, but on account of its slow action competition will be impossible. Other bleaching agents have from time to time been recommended, all of which are in reality oxidising agents. If, therefore, available chlorine and not oxygen effects the bleaching of vegetable tissues, it is highly improbable that these substances will ever supersede chloride of lime.

2. *Production of Hydrochloric Acid.*—It has not yet been possible to prepare chlorine directly from sodium chloride. In the Leblanc process the sodium in common salt is replaced by hydrogen derived from sulphuric acid, which costs nearly 2000 marks per ton, whilst in the ammonia-soda process it is calcium, which costs only about 15 marks per ton. Besides calcium and hydrogen, there are no elements suitable for the purpose which could be obtained at a smaller cost.

Solvay and Weldon have been endeavouring to utilise the calcium chloride liquors for the preparation of chlorine. Their process consists in replacing the calcium in calcium chloride by hydrogen. The calcium chloride is mixed with clay, formed into lumps, and subjected to the action of superheated steam at a high temperature. A very dilute hydrochloric acid is produced, from which the excess of steam is removed by the addition of concentrated calcium chloride liquors before the hydrochloric acid is condensed. The process is not only very costly, but requires a very large plant. It is therefore not likely to endanger the Leblanc process, which promises to remain the chief source of chlorine.

Vorster and Grüneberg recommended some years ago to heat sodium chloride and clay, and obtain sodium silicate and hydrochloric acid. Their process, however, was abandoned, as the reaction was found to require an extremely high temperature, and the cost for repairs was too excessive.

Other Chlorine Processes.—By decomposing sodium chloride with sulphuric acid, the resulting gaseous or liquid hydrochloric acid can be used for the preparation of chlorine, according as the Deacon or Weldon process is employed. With Hargreaves' process liquid hydrochloric acid only can be used, as the gas contains too much nitrogen and too little oxygen. The conversion of hydrochloric acid into chlorine necessitates the presence of another element with which to combine the hydrogen, the only element which has a greater affinity for hydrogen than chlorine being oxygen. The affinities between hydrogen and chlorine and hydrogen and oxygen approach each other so closely that the mere change from the liquid state to that of a gas alters the proportions. In consequence of these variations a direct decomposition of liquid hydrochloric acid by oxygen is impossible, whilst in the gaseous form hydrochloric acid can be decomposed directly by oxygen. To prepare chlorine from liquid hydrochloric acid a certain amount of chemical energy must be supplied in addition to oxygen, *i.e.*, nascent oxygen, which is liberated from an oxide with evolution of heat, is required. Since the oxide must contain more oxygen than is equivalent to the chlorine, which afterwards forms chloride, a peroxide is required. There is no better material than manganese for the purpose. Although barium and lead form two oxides and only one chloride, the transformation of the chloride into peroxide in the case of barium will always be difficult on account of the large differences in the heat of formation of the two compounds, whilst in the case of lead, its price and high equivalent weight render it useless. Weldon's process can be superseded only by a peroxide which is cheaper than the expense of recovering the manganese dioxide, or which itself can be regenerated at a less cost. The disadvantage in connection with the Weldon process is that it only yields theoretically one-third of the hydrochloric acid as chlorine. This difficulty is said to be removed by Weldon's new process (No. 2). Magnesium manganite obtained by process No. 1 is decomposed with hydrochloric acid in the chlorine stills. One-fourth the chlorine contained in the hydrochloric acid is generated, and a solution of manganese and magnesium chlorides formed. The latter is evaporated to a syrupy consistency, mixed with a certain amount of solid manganite, formed into balls, introduced into an apparatus similar to the Hargreaves, and exposed to a current of heated air, when 90 per cent. of the chlorine contained in the mixture is liberated, magnesium manganite being formed.

The author is of opinion that where still-work has to be done, the chloride of lime cannot be obtained at a lower cost, as the only saving in Weldon's new process is the lime required for oxidation, about 500 kilos. of bleaching powder; the labour in this process, however, forms a much greater item, so that bleaching powder made by the new process will cost fully as much, if not more than that obtained by the old process.

By comparing the Deacon process with Weldon's No. 2, we find that it is the only process in use in which gaseous hydrochloric acid can be decomposed into chlorine by a simple reaction, $2HCl + O = H_2O + Cl_2$, accompanied by evolution of heat. The decomposition is accelerated by catalytes. On account of its capability of being dissociated at a high temperature, cupric chloride is the cheapest and most efficient catalyte: moreover, copper is the only metal which forms two oxides and two chlorides, in all of which the combination is of a very loose character. It appears, therefore, highly probable that the Deacon process will continue to be the only one available for the conversion of gaseous hydrochloric acid into chlorine.

The author concludes this paper with the following remarks:—No other chloride is better adapted for the manufacture of chlorine than hydrogen chloride. If the latter is to be decomposed in the liquid state, the decomposition can be effected only by means of manganese dioxide, as there is no other peroxide so readily regenerated from the chloride. If hydrogen chloride is to be decomposed in the gaseous state catalytes are required, and should it be possible to obtain a cheaper catalyte than copper the apparatus now in existence would be equally applicable. Neither the Weldon process nor the Deacon process is perfect; both are capable of improvement, especially the Weldon process, inasmuch as the quantity of chlorine which it yields is considerably less than that which should be obtained from the hydrochloric acid consumed. D. B.

Schaffner and Helbig's Process for the Recovery of Sulphur. By A. M. CHANCE (*Dingl. polyt. J.*, **249**, 33—35).—Chance (*Jour. Soc. Chem. Ind.*, **2**, 202) gives an interesting account of his results and experiences in working with the Schaffner and Helbig sulphur recovery process. The residue is worked up in the decomposers in the following manner:—The solution of magnesium chloride—whose temperature must not exceed 60°, otherwise sulphuretted hydrogen will be evolved—is introduced into the decomposer, and the residue is thrown in, after which the mixture is heated by means of wet steam, in order to expel the air above the charge, and prevent its admission into the decomposer; thus the formation of an explosive mixture is rendered impossible. The heating by means of dry steam is then proceeded with, the mixture being well agitated all the time. The best results are obtained with jacketted decomposers, although cast-iron steam coils are attacked less readily than wrought-iron jackets. For carbonating the liquors containing magnesium hydroxide and calcium chloride, vertical vessels without agitators are the most useful. The deeper the column of liquid and the greater the percentage of carbonic anhydride, the quicker and better are the results obtained. The average strength of the carbonic acid gases was 26 per cent. To work off 8 tons of residue from five to six hours are required. The lime mud is sifted, filter-pressed, and washed. The first washings are concentrated in steam boilers, together with the stronger liquors, whilst the last washings are thrown away. No mention is made of the action of the magnesium chloride liquors on the plates of the steam boilers. The sulphuretted hydrogen gas is collected in gas-holders, the inlet and outlet being connected with a water-seal to prevent explosions. The burning of the sulphuretted hydrogen gas for the manufacture of sulphuric acid has been a great success, but a satisfactory process of recovering sulphur direct from the gas has not yet been introduced. The loss of magnesium chloride corresponds with 4 to 4·5 tons per 100 tons of sulphate, or 20 tons per 100 tons sulphur, more than one-half the loss being attributable to mechanical defects, which should be gradually reduced.

In discussing the value of the lime mud and its adaptability for the manufacture of soda, Chance shows that, as the mud leaves the presses it contains about 50 per cent. of moisture, which must be removed, an operation which in itself is a great disadvantage; moreover, the resulting crude soda contains large quantities of chlorides as well as calcium carbonate. Referring to the probable cost of working the process, a detailed estimate is given, from which it is concluded that it would no longer pay should the price of pyrites be reduced by one-half, especially if it were found that the resulting lime mud was of no value for black ash making. The future of this process depends on a good method of extracting pure sulphur from the generated sulphuretted hydrogen.

Weldon mentions that England and America alone consume 150,000 tons of Silician sulphur per annum, or 50 per cent. more than the total quantity capable of being yielded by the whole English soda industry. Schaffner's sulphur, which is absolutely pure, should easily displace Sicilian sulphur. As to the market price of sulphur, Muspratt and Mactear show that, although recovered sulphur has been offered at considerably less than Sicilian sulphur, great difficulty has been experienced in selling it.

Hurter gives analyses of soda waste and soda liquors obtained from crude soda made exclusively from recovered lime mud by Chance. The waste obtained from four samples of black ash contained in the dry state—

	Soluble soda.	Total soda.	Calcium sulphide.
I.	0·550	1·77	30·00
II.	0·440	0·97	33·40
III.	0·360	1·52	29·1
IV.	0·175	0·73	23·4

Ordinarily the waste contains 40 per cent. calcium sulphide. 1 litre of the vat liquors obtained from the crude soda contained—

Na_2O.	$NaHO$.	Na_2S.	Na_2SO_4.	$NaCl$.	$Na_4Fe(CN)_6$.
165·2	44·27	5·08	6·77	42·57	0·01 gram.

D. B.

Manufacture of Sulphuric Acid in America. (*Dingl. polyt. J.*, **249**, 48.)—Until quite lately sulphuric acid has been manufactured in America almost exclusively from sulphur. On account of the rapid rise in the price of sulphur, the manufacture of pyrites acid has recently been commenced by various manufacturers, but by far the largest proportion of acid is still made from sulphur. The price of American sulphur acid compared with English pyrites acid, is said to be so high that English superphosphate, prepared from American phosphate, can be sold in America at prices against which the American manure manufacturers have a difficulty to compete. The sulphur for 10 tons (= 9071·8 kilos.) sulphuric acid 66° costs 83 dollars; the cost of Spanish pyrites, however, amounts to only 49 dollars.

Besides Rio Tinto pyrites, a variety of native iron sulphide of great purity has recently been brought into the American market. It is obtained from the Davis mine in Massachusetts, and contains 47 per cent. of available sulphur. Zinc, lead, and lime are present only in minute traces, whilst arsenic is quite absent. The following is the composition compared with the Spanish ore:—

	S.	Fe.	Cu.
Spanish pyrites..............	47·87	40·93	3·82
Pyrites from the Davis mine ..	50·30	42·83	3·07

	Pb.	Zn.	CaO and MgO.	As.	SiO_2.
Spanish pyrites............	0·62	0·10	0·19	0·26	5·42
Pyrites from the Davis mine			0·61		3·19

D. B.

Manufacture of Aluminium. (*Dingl. polyt. J.*, **249**, 86—88.)—It is stated that Salinders is the only place in the world where aluminium is manufactured, about 2400 kilos. of metal being produced annually. The sodium used in the manufacture is obtained by igniting sodium carbonate with carbon in presence of a small quantity of lime, which is said to facilitate the distillation. The double chloride of aluminium and sodium is prepared by strongly heating a mixture of alumina, carbon, and sodium chloride in a current of chlorine. The resulting double chloride is then fused with the sodium in small reverberatory furnaces, cryolite being added as flux.

Much has recently been said in the newspapers with respect to an invention by which it is supposed that Webster of the Aluminium Crown Metal Works, Hollywood, has greatly cheapened aluminium. The preparation of 1 ton of aluminium is said to cost only 2,000 marks. The method consists in strongly heating bauxite with sodium carbonate, decomposing the sodium aluminate with carbonic anhydride, heating the deposited alumina with carbon in a current of chlorine, and fusing the resulting double chloride of aluminium and sodium with sodium and cryolite. This process is neither new nor is it possible to produce aluminium at a lower cost than at Salinders. Webster has also patented a method for preparing alumina for the manufacture of aluminium, which relates to the obtainment of anhydrous alumina from potash alum. The method is impracticable and costly.

Morris obtains aluminium by treating a mixture of alumina and carbon with carbonic anhydride. A solution of aluminium chloride is mixed with pulverised charcoal or lampblack, evaporated to a thick paste, cooled, and made into balls, which after drying are placed in iron tubes and heated. The last traces of chlorine are removed by passing steam through the tubes. The heat is then increased to dull redness and carbonic anhydride introduced. The carbon reduces the carbonic anhydride to oxide, and this is said to reduce the alumina to aluminium. D. B.

Electroplating Zinc with Nickel. By MEIDINGER (*Dingl. polyt. J.*, **249**, 90).—Meidinger states that in electroplating with nickel, copper, brass, and iron can be well coated, whilst zinc is coated with difficulty. It is therefore recommended to slightly amalgamate the zinc before it is electroplated with nickel by placing it in a solution of mercuric chloride or nitrate acidified with sulphuric or hydrochloric acid. The nickel then deposits well, adheres firmly, and takes a good polish. It is thought that the zinc plates brought into commerce are treated in this manner, as they are more brittle than pure zinc should be. It is therefore necessary not to let the amalgamation go too far. It has been difficult to electroplate German silver with nickel, and the author is of opinion that in this case also amalgamation would give good results. D. B.

Asphalt or Bitumen of Judea. By B. DELACHANAL (*Compt. rend.*, **97**, 491—494).—A specimen of bitumen of Judea, obtained from Palestine through M. de Lesseps, was in the form of large, somewhat friable lumps, very deep brown in colour, but not black, and breaking with a conchoïdal fracture. When heated, it gave off hydrogen sulphide, and was found to contain 3·02 per cent. of sulphur. A commercial sample of bitumen of Judea contained 3·14 per cent. of sulphur. The bitumen does not leave more than 0·273 per cent. of ash, hence the greater part of the sulphur does not exist in the form of metallic sulphides. When bitumen of Judea is heated, it softens, melts, and at a sufficiently high temperature gives off hydrogen sulphide and gaseous hydrocarbons, together with a dark-coloured oil, whilst a bulky carbonaceous residue is left in the retort. This oil can be separated into several fractions which closely resemble the products obtained by the distillation of crude petroleum. The oils are partly soluble in fuming nitric acid, leaving a residue of paraffin which solidifies at 15°. C. H. B.

Manufacture of Cellulose. (*Dingl. polyt. J.*, **249**, 23—29 and 124—126.)—The use of sulphurous anhydride in the manufacture of cellulose is becoming of more importance every day. In 1876 Mitscherlich recommended treating finely-divided wood under pressure with a solution of calcium bisulphite obtained by placing calcium carbonate in a tower and introducing water into the top and sulphurous anhydride into the bottom. Paper made from the resulting cellulose was found to be exceedingly tough, and has been sold as a second quality parchment-paper, although it does not possess the qualities which characterise this paper. The details of Mitscherlich's process have since been kept secret. Francke works with solutions of calcium, magnesium, or sodium sulphite of 4° to 5° B., at a pressure of 4 to 5 atmospheres, the operation being completed in 12 to 15 hours. He uses rotary horizontal cylindrical boilers lined with lead, the lining being independent of the outer casing, thus forming a separate boiler. The essential theoretical difference between the lime and the magnesia process is that the resulting calcium sulphate, being almost insoluble, remains in the lignose, whilst the magnesium sulphate is removed during the washing operation. At present it is uncertain whether other differences exist between the two processes.

The cost of pulp by Eckmann's method. depending on the use of magnesium sulphite, is 26 marks per 100 kilos., the selling price being about 40 marks. During last summer this method was tested by a number of French paper manufacturers with the following results:—The quantity of wood employed was 4395 kilos. in the form of fir planks. The loss by removal of knots in chopping, grinding, &c., amounted to 825 kilos. The remaining 3570 kilos. yielded 1437 kilos. dry cellulose corresponding with 32·68 per cent. of the original wood. The latter contained 21 per cent. of moisture, so that the yield on the dry substance is equal to 40 per cent. This is considerably less than the yield obtained by the Francke-Mitscherlich process; the quality of the pulp, however, is far superior. According to recent trials made by Eckmann, it is shown that it is possible to obtain at will either isolated cells or fibrous bundles by using either hydrogen magnesium sulphite, or magnesium sulphite. In the former case, the colouring and glutinous substances are completely dissolved, whilst in the latter case a portion of the gluten remains in the fibres.

Archbold macerates the woody tissue with dilute milk of lime, saturates with sulphurous anhydride at a pressure of 4 to 5 atmospheres, and washes the mass with water.

Tilghman's method consists in boiling in closed vessels wood, esparto or flax, with sulphurous anhydride or calcium bisulphite, or both.

Pictet recommends the use of liquid sulphurous anhydride. Finely-divided wood is first immersed in water, and for every litre 120 grams of liquid sulphurous anhydride is added. At a temperature of 85° a pressure of 7 atmospheres is produced, so that the incrustating substances of the wood are strongly attacked. The pulp has the grey colour of the original wood, but may be easily bleached.

In discussing the sulphite treatment, Bourdilliat contradicts the statement that sulphuric acid is formed when wood is boiled with sulphites; moreover, he believes that the sulphurous anhydride dissolves the incrustating substances of the wood, bleaches the colouring matters, and deposits finely-divided sulphur in the fibres, whilst the resins, which are attacked by sulphurous anhydride, form soaps with the base of the bisulphite. These, together with the sulphur, remain in the fibre and add considerably to its weight; the loss during the washing operations is therefore not of fibre but of the mass-compound of sulphur, resin, and lime.

Cross is under the impression that the action of the magnesium sulphite is to prevent the oxidation of wood and lignified cellulose when heated with water under pressure. For comparing the success of the different sulphite processes, the test for lignose with aniline sulphate is said to give unsatisfactory results: it is preferable to treat the cellulose first with chlorine and then with sodium sulphite; if lignose is present, a magenta colour is produced. D. B.

Alcohol from Melon-juice. By LEVAT (*Compt. rend.*, **97**, 615—616).—Melon-juice does not undergo fermentation directly, but on boiling it with very dilute sulphuric acid, the sugar in the juice is inverted, and fermentation then takes place readily, 5 litres of alcohol being obtained from 30 kilos. of melons. C. H. B.

Clouding and Fining of Wines. By J. NESSLER (*Bied. Centr.*, 1883, 342—344).—Seven varieties of Greek wines, when exposed to low temperatures, become cloudy, but a young wine clouded as the temperature rose; the substance rendered insoluble by the lowering of the temperature redissolved as the temperature rose, but when some wine had been withdrawn from the cask, while it was cloudy, the wine refused to clear. Fining with albumin, &c., prevents cloudiness, and the browning and thickening which so frequently occur are due to decomposed husks introduced during manufacture. To fine wines which have refused to clear by means of albumin, "Spanish earth" (100—200 grams per hectolitre) is recommended; this is also the best material to use in the preparation of sparkling wines.

E. W. P.

Plastered Wine. By M. NENCKI (*Bied. Centr.*, 1883, 345—347). —This paper is an answer to questions laid before the author by the municipal authorities of Berne. Plastered wines are not of necessity prejudicial to health, although in a few cases they may be so, and then only when a strongly "plastered" wine has been regularly used. Probably Marsala, &c., which is more strongly "plastered," may be harmful, but the author has no proof as to whether it is or is not so. Natural wines may contain as much as 0·503 gram K_2SO_4 per litre. Plastering should introduce into the wine only a quantity of sulphates equivalent to 2 grams K_2SO_4, and no more. Free sulphuric acid has occasionally been detected in wine; this arises from the formation of ethyl sulphate, which has been mistaken for the other acid.

E. W. P.

Barley and Malt. (*Dingl. polyt. J.*, **249**, 133—139.)—Bungener and Fries have found that boiling water containing 1 per cent. salicylic acid, readily dissolves starch, forming a thick syrupy mass, which, on cooling, deposits tabular crystals of starch. On boiling

4 to 5 grams of finely ground barley with 150 c.c. water and 1·5 gram salicylic acid for three-quarters of an hour, all the starch is dissolved. The hot opalescent colourless liquid is filtered, and the residue washed with hot water until the filtrate ceases to react with iodine. Hydrochloric acid is then added to the starch in the filtrate, and the resulting glucose determined by means of copper solution. The results are 1 to 2 per cent. higher than those obtained when the starch is dissolved in water at 135°. In the latter case, a dark-coloured solution is formed, probably due to decomposition.

According to Aubrey, five samples of Alsatian Chevalier barley (1882 crop) contained the following ingredients, calculated on the dry substance:—

	I.	II.	III.	IV.	V.
Starch	62·73	58·20	60·39	65·49	66·34
Nitrogen	1·9008	1·9456	1·6208	1·6400	1·7456
Proteïds corresponding with nitrogen	11·88	19·16	10·13	10·25	10·91
Phosphoric acid.	1·053	1·082	1·064	1·030	1·062

Similar samples, from the year 1880, made into malt and dried at 81°, gave the following results:—

The barley contained			Germinating power.	Yield of extract from dry substance per cent.	Maltose in extract per cent.	Maltose : non-maltose = 1	Saccharification in minutes.
Starch.	Nitrogen.	Phosphoric acid.					
62·57	1·659	1·015	99	81·62	63·96	0·56	30
65·35	1·443	0·910	99	84·36	62·32	0·60	45
65·14	1·646	1·115	98	84·09	65·25	0·53	30
61·20	1·646	1·023	97	83·26	63·02	0·58	30
64·20	1·625	0·965	100	80·67	64·17	0·55	30
65·78	1·819	1·098	100	79·70	64·49	0·55	30

Schwarz has investigated different kinds of American barley. He shows that the weight of the grain is no criterion as to the amount of solid matter, starch, proteïds (nitrogen × 6·25), and ash contained in the barley. The subjoined table illustrates the results of his investigation:—

Quality.	Weight of grain.	Percentage of water.	The dry substance contains			
			Starch per cent.	Proteïds per cent.	Ash per cent.	Phosphoric acid per cent.
Minnesota barley	30·9	14·13	67·31	13·58	2·77	1·050
Scotch, quality II	35·4	14·35	63·77	13·34	2·82	0·985
Scotch, quality I	34·5	11·90	64·85	11·93	2·86	1·031
Choice Scotch	31·2	14·33	65·20	11·67	3·28	0·934
Wisconsin barley	32·6	16·14	65·47	10·80	2·83	0·997
Scotch Wisconsin barley	35·2	14·34	66·12	9·25	2·74	0·929
Canada, quality II	29·0	15·31	65·33	10·27	3·16	0·969
Canada, quality I	32·8	16·96	68·53	12·73	3·74	0·996
West Canada	30·7	13·29	67·54	11·01	3·02	0·954
Chevalier California	43·7	13·31	68·33	10·42	2·86	0·980
State barley	35·0	11·24	66·35	11·45	2·72	0·935
Canada barley	28·6	10·46	66·48	10·47	2·92	0·856

With regard to the changes in weight and volume which barley and malt undergo, Chodounsky found that kiln-dried malt, immediately after being dried, shows a diminution in volume, whilst malt, when kept, increases both in weight and volume. 100 hectolitres of barley yield 97 to 99 hectolitres of kiln-dried malt, and 99 to 101 hectolitres of stored malt.

Lintner states that the defects in the present malting processes are due mainly to the want of uniformity of temperature in the germinating heaps, and the difference in the amount of moisture which exists in the various layers. The gradual discharge of carbonic anhydride, and the defective admission of oxygen, has a marked effect on the malt. These imperfections are said to be removed by the pneumatic malting process, in which the barley, after germination, is thrown on a plate having fine perforations; the air underneath the plate is then exhausted. Thus the heat is withdrawn and the carbonic anhydride removed in a regular stream, so that the germinating grain is situated in a bath of pure air, having always the same temperature and containing the same amount of moisture. To effect this the air is previously purified and heated to the necessary temperature.

D. B.

The System on which Rice may be Used in Brewing. By A. Markl (*Bied. Centr.*, 1883, 348).—The analyses of rice published by Braconnot show that it is better adapted for brewing than barley, but owing to its higher sp. gr., precautions must be taken to prevent its settling to the bottom of the mash-tub; to obtain the best results, the rice must be previously boiled and steamed before mashing; the wort may be strongly hopped, and then kept cool to ensure normal fermentation.

E. W. P.

Fermentation of Bread. By G. Chicandard (*Compt. rend.*, 97, 616—617).—A reply to Marcano, Mousette, and Boutroux.

Alteration of Flour by Age. By BALLAND (*Compt. rend.*, **97**, 346—347).—The proportion of water is slightly variable, and alters with the hygrometric condition of the atmosphere. Fatty matters experience no sensible alteration in weight, but become rancid. The saccharine substances decrease in amount, but the diminution bears no relation to the degree of acidity. The degree of acidity depends on the nature of the grain, flour from soft grain becoming acid more rapidly than flour from hard grain. This acidity is apparently connected directly with the alteration of the albuminoids, which at first exist in the form of insoluble gluten, but gradually decompose without loss of weight. The amylaceous constituents would seem to remain unchanged. Flour which has not been finely sifted keeps badly, and is always more acid; it contains a higher proportion of woody, fatty, and saccharine substances, and more gluten. Flour kept in bags alters more rapidly than flour preserved in closed vessels. For the same degree of sifting, flour obtained by millstones keeps as well as that obtained by cylinders; the acidity is independent of the grinding. The farinaceous portion of the grain in contact with the external envelope is more acid than the internal portion; it contains the same amount of gluten, but alters more rapidly. C. H. B.

Notes on Milk and Butter. By M. SCHMÖGER and others (*Bied. Centr.*, 1883, 418—419).—Experiments were made to discover whether it is better to cool milk before skimming or not. The instrument used was a tubular cooler, similar to that of Rossler, but with oval tubes instead of circular. It worked well, bringing the milk in a short time to within 2° of the temperature of the water employed. The cooled milk was compared with some from the same milking not artificially cooled; the results were decidedly in favour of the former. Experiments in butter-making were made with the Holstein, Lefeldt, and a rocking churn of American invention, using sweet and sour cream.

	Fat left in buttermilk.	
	Sweet cream.	Sour cream.
Holstein system	0·71 per cent.	0·85 per cent.
Lefeldt "	1·51 "	0·84 "
Rocking churn........	1·20 "	0·50 "

Average duration of process was less by the Holstein process than by the two others. J. F.

Artificial Butter Colourings. By E. SCHMITT (*Ann. Agronomiques*, **9**, 255—257).—Amongst the substances employed for this purpose, the author enumerates marigold and carthamus flowers, saffron, carrot juice, and turmeric; more recently coal-tar colours have been introduced, such as coralline-yellow and Victoria-yellow, and also lead chromate. The two most widely sold colourings are Krick's "Orantia" and Trannoy's "Carottine"; the author shows that annatto is the basis of both. "Orantia" can be exactly imitated by digesting 50 grams annatto with 100 grams crystallised sodium carbonate, dissolved in a litre of water, and evaporating down to half a litre. "Carottine" is a much better preparation, and may be imitated by digesting 125 grams annatto in half a litre of oil; a mixture of equal parts of annatto and turmeric root will give a lighter yellow. It is used in the proportion of a teaspoonful to 25 litres of cream, and the colour diffuses very rapidly and uniformly throughout the butter.

J. M. H. M.

New Dyestuffs. (*Dingl. polyt. J.*, **248**, 340—343.)—Whereas the monosulphonic acids of phenylamidoazobenzene produce reddish-yellow to orange dyes, the corresponding tri- and tetra-sulphonic acids yield pure yellow shades. For the preparation of the polysulphonic acids of phenylamidoazobenzene, $NHPh.C_6H_4.N_2.C_6H_5$, 20 kilos. of the latter are treated in the cold with 100 kilos. fuming sulphuric acid containing 20 per cent. anhydride. The mixture is warmed to 60—70°, and the temperature reduced after three or four hours. The mass is then thrown into water, treated with milk of lime, and the calcium compound with the sulphonic acids converted into sodium salts. This polysulphonic acid is obtained also by heating to 70—80° 20 kilos. of the monosulphonic acid with 80 kilos. fuming sulphuric acid, and completing the process as before. These dyes are brought into commerce as potassium or sodium salts in the dry state.

For the production of artificial indigo from the orthamido-derivatives of acetophenone and phenylacetylene, the Badische Anilin und Soda Fabrik treats a concentrated solution of acetylorthamidoacetophenone, or of acetylorthamidophenylacetylene in carbon bisulphide in the cold with an equal weight of dry bromine. A crystalline bromine compound is formed, which is dissolved in 10—20 times its weight of concentrated sulphuric acid. Dilution of this with water causes the precipitation of colourless flakes; these dissolve in warm soda solution to a clear deep yellow liquid, from which indigo separates out on contact with the air .

According to the Farbwerke, late Meister, Lucius, and Brüning, tolylaldehyde from metaxylene is converted by nitration into metamethylorthonitrobenzaldehyde. This on treatment with twice its weight of acetone, and 25 times its weight of a 2 per cent. solution of soda, is readily transformed into methyl-indigo, a substance closely resembling natural indigo, but from which it may be distinguished by its ready solubility in water. From the same source, processes for the preparation of azo-dyes from the trisulphonic acids of β-naphthol are given. The trisulphonic acid is obtained by treating β-naphthol with fuming sulphuric acid containing 20 per cent. anhydride at 140—160°, until the mass gives a pure green fluorescent solution with ammonia. Combined with various diazo-compounds this acid yields yellow, orange-red, and bluish-red dyes, of which the three following are specially adapted for dyeing cotton:—(1.) A red dye, obtained by the action of the diazo-compound of α-naphthylaminesulphonic acid on sodium β-naphtholtrisulphonate in presence of ammonia. (2.) A bluish-red dye, resulting from the action of the diazo-compound of amidoazobenzene on sodium β-naphtholtrisulphonate in presence of ammonia. (3.) A bluish-red colouring matter, obtained from the diazo-compound of amidoazobenzenesulphonic acid. In the above three cases the dye is thrown down as a bulky precipitate on mixing a solution of sodium β-naphtholtrisulphonate with that of any of the diazo-compounds. The precipitate is purified by dissolving it in water and reprecipitating with salt. D. B.

New Coal-tar Dyes. (*Dingl. polyt. J.*, 248, 252—256.)—According to C. Reichl, a new phenyl colouring matter is obtained by the cohobation in molecular proportions of an alkaline xanthate and resorcinol dissolved in a small quantity of water or alcohol, so long as carbon bisulphide is returned. Water is added to the dark yellow liquid obtained, which is then filtered, and the colouring matter precipitated with hydrochloric acid from its previous combination with the alkali. It may be obtained by recrystallisation from hot water in slender yellow needles, insoluble in cold, but readily soluble in hot water; alcohol, acetic acid, and alkalis dissolve it with ease. Wool and silk are dyed a brilliant yellow in a weak acid solution. Orcinol, quinol, pyrogallol, naphthol, and quinone similarly treated also yield yellow dyes.

For the preparation of a monosulphonic acid of β-naphthylamine and β-naphthol, the Baden Anilin und Soda Fabrik allow sulphuric acid (96 to 97 per cent.) to act on β-naphthylamine at a temperature of 100° to 105°, the sparingly soluble modification of the monosulphonic acid being exclusively formed. By converting this into the diazo-compound and decomposing the latter with water, β-naphtholmonosulphonic acid is obtained, the acid sodium salt of which is sparingly soluble in hot alcohol. By evaporating the aqueous solution of the free acid, it is split up into β-naphthol and sulphuric acid. When the alkaline solution of the acid is brought in contact with the diazomonosulphonic acid of azobenzene, orange-coloured flakes are thrown down. This azo-colouring matter dyes ponceau-red shades.

A process for preparing red and brown azo-dyes from anthrol, anthrolsulphonic acids, and dioxyanthracene has been patented by the Actien. Ges. f. Anil. Fab. Berlin. The claims are the pairing of anthrol, anthrolsulphonic acid, anthroldihydride and its sulphonic acid, as well as α- and β-oxyanthrol with diazobenzene and its homologues, diazonaphthalene, diazoanisoïl, the sulphonic acids of these diazo-bodies, with diazoanthraminesulphonic acid, diazoamidoazobenzene and its homologues, and mono- and di-sulphonic acids of these diazo-compounds. The products containing the sulphuryl-group are soluble in water, the remainder dissolve in alcohol. D. B.

Composition of Turkey-red Oil. By L. Liechti and W. Suida (*Ber.*, 16, 2453—2458).—Glycerol trioleate and triricinoleate were treated with sulphuric acid, and the products separated in a similar manner to that employed in the manufacture of Turkey-red oil. The products of the reaction in each case consist essentially of two substances, of which the one is more soluble in ether, the other in water. The compound soluble in water derived from glycerol trioleate is *glyceryl sulphate hydroxyoleate*, $C_{42}H_{78}O_{12}S = SO_4[C_3H_5(OH).C_{18}H_{33}O_3]_2$, an oily substance of acid nature, very soluble in water and alcohol, more sparingly in ether, carbon bisulphide, and benzene. When heated with water, it yields glycerol, hydroxyoleic acid, and sulphuric acid. It unites with bromine in the cold. When mixed in aqueous solution with metallic acetates, it yields salts, of which the following have been analysed:—Copper salt, $C_{42}H_{71}O_{12}SCu_2$; barium salt, $C_{42}H_{76}O_{12}SBa$; silver salt, $C_{42}H_{76}O_{12}SAg_2$; aluminium salt, $(C_{42}H_{74}O_{12}S)_3Al_4$; zinc salt, $C_{42}H_{71}O_{12}SZn_2$.

Glyceryl sulphate trihydroxyoleate,

$$C_{42}H_{78}O_{16}S = SO_4[C_3H_5(OH).C_{18}H_{33}O_5]_2,$$

the corresponding derivative from glyceryl triricinoleate, closely resembles the preceding compound in all its properties. The following salts have been analysed:—Copper salt, $C_{42}H_{76}O_{16}SCu$; barium salt, $(C_{42}H_{77}O_{16}S)_2Ba + C_{42}H_{76}O_{16}SBa$; silver salt, $C_{42}H_{76}O_{16}SAg_2 + C_{42}H_{77}O_{16}SAg$; aluminium salt, $(C_{42}H_{74}O_{16}S)_3Al_4$.

The substances soluble in ether proved to be identical with the hydroxyoleïc acids contained in the foregoing conjugated compounds. They are both crystalline, insoluble in water, readily soluble in ether, alcohol, carbon bisulphide, and benzene. *Hydroxyoleic acid*, $C_{18}H_{34}O_3$, melts at 56—58°; the following salts have been analysed:—Normal copper salt, $(C_{18}H_{33}O_3)_2Cu$; acid copper salt, $(C_{18}H_{33}O_3)_2Cu + 2C_{18}H_{34}O_3$; acid barium salt, $(C_{18}H_{33}O_3)_2Ba + 2C_{18}H_{34}O_3$; acid calcium salt, $(C_{18}H_3O_{33})_2Ca + 2C_{18}H_{34}O_3$; aluminium salt, $(C_{18}H_{33}O_3)_6Al_2$. *Trihydroxyoleic acid*, $C_{18}H_{34}O_5$, melts at 64°; the following salts were obtained:—Copper salt, $(C_{18}H_{33}O_5)_2Cu$; barium salt, $(C_{18}H_{33}O_5)_2Ba + 2C_{18}H_{34}O_5$; aluminium salt, $(C_{18}H_{33}O_5)_6Al_2$; silver salt, $C_{18}H_{33}O_5Ag$.

The reaction occurring in the manufacture of Turkey-red oil is therefore expressed by the equations—

$$2C_3H_5(C_{18}H_{33}O_2)_3 + 7H_2SO_4 = C_{42}H_{78}O_{12}S + 6SO_2 + 4H_2O + 4C_{18}H_{34}O_3.$$

$$2C_3H_5(C_{18}H_{33}O_3)_3 + 13H_2SO_4 = C_{42}H_{78}O_{16}S + 12SO_2 + 10H_2O + 4C_{18}H_{34}O_5.$$

In confirmation of this view, it was found that on heating sulphuric acid with oleic acid, hydroxyoleïc acid was obtained, and that a mixture of glycerol, oleic acid, and sulphuric acid, when heated, yielded glycerol sulphate hydroxyoleate. Compounds similar to the last named were prepared by heating oleic and sulphuric acids with mannite, grape-sugar, starch, cellulose, or dextrin. They are all soluble in water, give metallic derivatives, and are decomposed when boiled with alkalis, with separation of hydroxyoleic acid.

A. J. G.

Explosives and their Application. (*Dingl. polyt. J.*, **248**, 509—513).—Dolliak attributes the presence of metal-dust in gunpowder to the wear and tear of the machines used for finely dividing and intimately mixing the powder.

Straw nitrocellulose is more unstable and therefore less secure than gun-cotton. This is due to the fact that although before nitrating the straw it is digested in a solution of potash, the cellulose of the straw fibre is not separated entirely in the pure state, but is contaminated with fat, wax, resin, or pectins, which form unstable nitro-compounds.

For the preparation of a new gun- and blasting-powder, Himly and Frützockler-Falkenstein grind and mix together the following substances in proportions so that when the mixture is ignited complete combustion occurs: nitre, potassium chlorate, and a solid hydrocarbon. The mixture is treated with a light hydrocarbon, and the plastic mass made into flat cakes, from which the liquid hydrocarbon is expelled by evaporation. The solid residue is then broken up into grains of the required size.

Reid recommends to moisten the explosive compound containing nitrocellulose with alcohol and dry it, whereby a hard and uniform mass is obtained.

It is stated that a determination of the heat produced and an estimation of the gaseous products formed by the combustion of an explosive, is not sufficient to show its value. The lead test in this case is said to give more accurate results. The active force of a variety of explosives was determined according to this test with the following results:—

	Proportion of hollow spaces in the lead test.	Active force according to trials made at the following places:—		
		St. Gothardt.	Ramsbeck.	Zankeroda.
Nitroglycerol........	1000	—	—	—
Blasting gelatine	1000	1000	1000	1000
Gelatine dynamite ..	770	—	—	730
Kieselguhr dynamite	700	698	683	688
Mercury fulminate ..	300	—	—	—

The following comparison by Steiner illustrates the working of a lignite coal mine with gunpowder and dynamite No. II, the total output being 50,000 tons:—

With the use of	Produce.				Current expenses, fl.	Working profit, fl.
	Tons at 2·60 fl.	Tons at 1·60 fl.	Tons without value.	Total for 50,000 tons fl.		
Gunpowder............	39,400	7100	3500	113,800	80,500	33,300
Dynamite, No. II	31,600	9200	9200	96,880	74,000	22,880

These results confirm the fact that dynamite is less suitable than gunpowder for blasting coal, as its shattering effect is more powerful than that of gunpowder.

General and Physical Chemistry.

Separation of Rays of High and Low Refrangibility. By F. v. ASSCHE (*Compt. rend.*, **97**, 838—840).—A thin layer of selenium, obtained by compressing a drop of the fused substance between plates of glass at 250°, and allowing it to cool slowly under pressure, only transmits the rays between Fraunhofer's lines A—C. The amount of absorption increases with the thickness of the layer. When a beam of white light is passed first through a solution of alum and then through a film of selenium, all the luminous rays are arrested. A thin film of selenium, if heated to 250°, is apparently opaque to all luminous radiation. C. H. B.

Atmospheric Absorption by Aqueous Vapour. By W. W. ABNEY and R. FESTING (*Proc. Roy. Soc.*, **35**, 328—341).—In the course of some investigations on the atmospheric absorption in the infra-red of the solar spectrum, the authors established the coincidence of the absorption-bands of the spectrum with those due to water. They have further confirmed Langley's researches as regards Cauchy's formula for refraction.

In this paper, the spectrum is examined, which is obtained by using the crater of the positive pole of the electric light as a source of radiation by means of a thermopile, and the variations produced by placing layers of water of different thickness in front of the slit. The diagrams show that the thermograms of the water spectra are absolutely coincident with the absorption in the photographs, but the former method is probably the more delicate.

By means of the thermograms, the solar temperature may be approximately estimated; for Dewar has shown that the temperature of the source of heat is nearly proportional to the square root of the total variation represented by the area of the thermogram curve. The temperature of the crater is calculated at about 6000, and in the prismatic solar spectrum the scale is 4·5 times that of the scale of the crater thermogram; the highest solar temperature, therefore, would be $\sqrt{4·5} \times 6000 = 12,700$, a value far higher than that put forward by Siemens.

Among other results, the existence of a large quantity of solar radiation, due to low temperature, is shown to be more than probable. V. H. V.

Radiant Matter Spectroscopy. By W. CROOKES (*Proc. Roy. Soc.*, **35**, 262—271).—Whilst studying the phenomena presented by various substances when struck by the molecular discharge from the negative pole in a highly exhausted tube—the so-called radiant matter—the author observed a bright citron line or band: this appeared more markedly when the substance under examination was converted into the sulphate by evaporation with strong sulphuric acid. Preliminary evidence tended to show that this band was due to calcium, for most native compounds of this element produced it, and it became better defined when solutions of these substances were precipitated by ammonium oxalate. But if the calcium compound gave no band originally, it could not be brought out by any process, chemical or physical. Tentative experiments established that this line was due to some member of the yttrium and its allied families present in samarskite, and by the method of differences these were ultimately restricted to the four following: mosandrum, lithium, ytterbium, and yttrium. By a long series of separations, this citron band was shown finally to be due to yttrium, whose sulphate in a "radiant matter" tube consists essentially of a broad red band, an intensely brilliant citron band, and two equally brilliant green bands.

The above investigations show that yttrium is more widely distributed than has been suspected hitherto. From the results of quantitative spectrum analysis it is seen that amongst other substances a specimen of coral contains 1 part of yttrium in 200 parts; strontianite, 1 part in 500; chondrodite from Mount Somma, 1 part in 4,000; calcite, 1 part in 10,000; ox-bone, 1 part in 10,000; a meteorite (Alfianello), 1 part in 100,000; and tobacco-ash, 1 part in 1,000,000. V. H. V.

Line Spectra of Boron and Silicon. By W. N. HARTLEY (*Proc. Roy. Soc.*, **35**, 301—304).—Among other spark spectra of saline solutions, those of boron and silicon present a particular interest. In the spectrum of sodium diborate, three sharp lines λ 3450·3, λ 2497, and λ 2496·3 appear, and if the solution of the salt be sufficiently strong, the sodium lines are not visible. A detailed description and the wave-lengths of the spark spectrum of silicon compounds are given, and it is noted that a certain group of these lines is attributed by Liveing and Dewar to the element carbon, although the author did not observe them in his spectrum of graphite. Probably the specimen of graphite used by Liveing and Dewar, although purified with the greatest care, contained traces of silicon, for not only graphite, but other elements, as aluminium and iron, are invariably contaminated with traces of silicon. V. H. V.

Ultra-violet Absorption Spectra of Albuminoïds. By J. L. SORET (*Compt. rend.*, **97**, 642—644).—Diluted white of egg albumin precipitated by hydrochloric acid and redissolved in excess, β-albumin dissolved in hydrochloric acid, purified albumin, protalbin, artificial protalbin, pepsino-pseudopeptone, pancro-pseudopeptone, caseïn from milk, serum from the blood of the pig, mucin from *Helix pomatia*, globulin, myosin, and syntonin all give practically the same spectrum, which is characterised by an absorption-band coincident with the cadmium line at 17, and a band of no absorption at 18. This fact indicates that all these albuminoïds contain a common principle to which the absorption-band is due. Gelatin, which differs from albumin in other respects, is much more transparent to ultra-violet rays, and does not give the absorption-band.

Hydrochloric acid has no sensible effect on the character of the spectrum, but slightly diminishes the general absorption. Sodium hydroxide or ammonia, on the other hand, produces considerable alteration; the band of no absorption, coincident with the cadmium line at 18, disappears entirely; whilst the band at 17 remains unaltered or diminishes in intensity, and the curve from this point decreases regularly to the end of the spectrum. In many cases a faint absorption-band appears between 14 and 16; in others the band is reduced to a simple inflection. That is to say, the general absorption between 17 and 22 increases considerably, and the absorption-band becomes almost invisible and is displaced towards the more refrangible end. On neutralising the soda with hydrochloric acid, the original spectrum reappears without any sensible alteration. Sodium hydroxide alone is very transparent to this region of the spectrum. These results show that alkalis produce an alteration in the molecular constitution of albuminoïds, and afford further proof that the latter contain a common principle.

Other organic bodies, such as sarcine and tyrosine, which combine with acids and bases, behave in a similar manner. Their spectra are not affected by hydrochloric acid, but are altered by alkalis, the change consisting in an alteration in the position of the bands or in their intensities, some of them disappearing altogether.

C. H. B.

Production of Electricity by Evaporation, and Electrical Neutrality of Vapour arising from Electrified Surfaces of Liquids. By L. J. BLAKE (*Phil. Mag.* [5], 16, 211—224).—Of the hypotheses proposed to explain the origin of atmospheric electricity, two have received considerable support among physicists, namely, the production of electricity by simple evaporation, and the convection of electricity upon the surface of any evaporating liquid.

In this paper the hypotheses are investigated experimentally by means of Kohlrausch's condenser with moveable plate, and an electrometer, which is described at length.

As regards the former hypothesis, the tabulated results indicate no production of electricity by simple evaporation. Similarly as regards the latter hypothesis, experiments on the evaporation of distilled water, sodium chloride solution, absolute alcohol, concentrated sulphuric acid, and sea water, showed that there is no convection of electricity from the electrified surface of a liquid when evaporating. In some experiments with sea water, the kind of electricity upon the surface of the condenser was of opposite sign to that of the water, whereas, had convection occurred, the reverse would have been the case.

In order to put the hypothesis to a favourable test, experiments were made with evaporating mercury, but with negative results, and thus it must be concluded that the vapour arising from electrified still surfaces of liquids is electrically neutral. V. H. V.

Effect of Temperature on the Electromotive Force and Resistance of Batteries. By W. H. PREECE (*Proc. Roy. Soc.*, 35, 250—257).—As a continuation of former researches (cf. Abstracts, 1883, p. 840), the effect of an increase of temperature on the electromotive force and resistance of secondary batteries containing plates of lead and lead peroxide in sulphuric acid of various degrees of concentration. From an inspection of the tables and diagrams in the original paper, it is seen that the effect produced by heating the secondary batteries is the same in kind, but different in degree, from that on the Daniell cell. The E.M.F. practically remains constant, but the internal resistance diminishes with rise of temperature, increasing again as the temperature is lowered. Variations of strength of acid do not produce any very marked effect. The following short table illustrates the above remarks:—

Percentage of acid.	Resistance in ohms.		Decrease per cent.
	0°.	100°.	
10	0·0752	0·046	61·0
20	0·08	0·457	57·0
30	0·062	0·0338	58·0
Mean...........	0·0724	0·425	59·6

V. H. V.

Benzene as an Insulator. By H. Hertz (*Wied. Ann.*, 20, 279—284).—Rowland and Nichols have established that in certain insulating crystals dielectric polarisation is not accompanied with the formation of any residual charge. They consider this latter phenomenon to be a necessary consequence of non-homogeneity of the insulating material. This view led the writer to examine a series of liquids, of which benzene is the most advantageous, as of a sufficient resistance and not giving any residual charge.

The apparatus used was practically a modification of a Leyden jar, in which the zinc plates, in circuit with a battery and electrometer, were the inner and outer coatings, and a layer of benzene the dielectric. The following phenomena were observed. At first the resistance was too small for measurement, and the residual nearly one-tenth of the original charge. After a short time these properties diminished *pari passu* until at the end of 24 hours the benzene became a perfect insulator, without any residual charge. The conductivity displayed at first by the benzene doubtless arises from impurities, and it is shown that the transference of the benzene from one vessel to another, or the introduction of the trace of any powder, will increase the conductivity of the benzene. On the other hand, the decrease of conductivity is due in part to the action of the current.

Electrically pure benzene seems to be the best approximation to an ideal insulating liquid, both as regards resistance and residual charge; its sole disadvantage is its volatility.

The residual charge, which makes its appearance in impure benzene, arises from a subsequent polarisation, of whatever nature it may be, and not from an interpenetration of free electricity.

V. H. V.

Electrical Resistance of Insulators. By G. FOUSSEREAU (*Compt. rend.*, **97**, 996—998).—The resistances were determined in the manner previously described, by measuring the time required to charge a condenser at a given difference of potential across the particular substance. The resistance of porcelain varies with the temperature in the same manner as that of the more highly insulating varieties of glass: it is 751 at 60°, and 0·052 at 180°.*

The resistance of sulphur, previously fused and then allowed to cool slowly in the prismatic condition, is 7·39 at 112·1°, and 3930 at 69°; below the latter temperature, the conductivity is inappreciable. When the same sulphur is allowed to remain at the ordinary temperature for some time, so that it devitrifies, its conductivity gradually increases: in one case the resistance after one day was 1170 at 17°; after two days, 705 at 17°. Octahedral sulphur shows no trace of conductivity at the ordinary temperature, and the conductivity only becomes appreciable at about 80°. It would appear from these facts that sulphur has a higher resistance when crystalline.

When sulphur melts, its resistance diminishes to one-fortieth its original amount. If the temperature is gradually raised from 114° to 150°, the resistance gradually diminishes as the temperature rises, and it varies between these limits in the ratio of 9 to 1. When the temperature rises to 160°, the sulphur becomes darker coloured and pasty, and its resistance increases. If the liquid is again cooled to the melting point, it retains a resistance higher than the original resistance, and the difference is greater the higher the temperature to which the sulphur has been heated, the longer it has been kept at this temperature, and the more quickly it has passed 155° in the process of cooling, this being about the temperature at which the inverse change takes place. By repeatedly heating the sulphur in this way to a high temperature, its original resistance at the melting point can be increased twelvefold.

When sulphur is allowed to cool in the prismatic form and is then remelted, it shows a diminished resistance at the same temperatures. Similarly, when octahedral sulphur is repeatedly crystallised in the prismatic form, its resistance at 115° is gradually reduced to one half. These results agree with Gernez' supposition that one variety of sulphur fully acquires the properties of another variety, only after repeated crystallisations.

The resistance of carefully dried ordinary phosphorus is 84,000 megohms at 15°, and 15,000 megohms at 42°; it is of the same order of magnitude as that of liquid sulphur. The resistance of liquid phosphorus is 2·32 megohms at 25°,† and 0·34 megohm at 100°.

C. H. B.

---

* All the resistances except those of phosphorus are given in millions of megohms per cubic centimeter.

† This is the temperature given in the original paper. Apparently it should be 45°.

A High Pressure Electric Accumulator. By F. J. SMITH (*Phil. Mag.* [5], 15, 203—204).—Grove's gas battery cannot be conveniently used as an accumulator, or secondary battery, owing to the small quantities of gases contained in it. Its use may however be extended by storing the electrolytic gases under high pressure in a suitably constructed apparatus, such as the following. In a strong lead vessel, partly filled with 10 per cent. sulphuric acid, are enclosed platinised platinum cylinders in inverted tubes, the terminals being brought through insulating stoppers: with this arrangement a pressure of seven atmospheres can be easily used. It appears from preliminary experiments that the E.M.F. of this accumulator varies considerably with the pressure. V. H. V.

Measurement of Electromotive Force. By E. REYNIER (*Compt. rend.*, **97**, 1056—1059).—The author measures the maximum electromotive force of a couple with a single electrolyte by means of a cell in which the active surface of the positive plate is 300 times that of the negative plate. and he measures the minimum electromotive force by means of a cell in which the surface of the negative plate is very much greater than that of the positive plate, the measurement in this latter case being made immediately after the battery has been working on short circuit for several hours. The maximum and minimum electromotive forces of several couples are given in a table.

The author concludes that the electromotive force of a couple with a single electrolyte must be regarded as the true electromotive force of the system, and its increase up to the maximum results from the addition of products formed by the action of the air. The effect of these products must not be confounded with the chemical energies due to the couple itself. C. H. B.

Chemical Affinities in Terms of Electromotive Force. By C. R. A. WRIGHT and C. THOMPSON (*Phil. Mag.* [5], 16, 25—48).

On the E.M.F. of Clark's Cell.—In this paper are described a series of experiments on the E.M.F. of Clark's cells ($Hg|Hg_2SO_4|ZnSO_4|Zn$), compared with one another and with other cells, by means of the quadrant electrometer, so that they never generated any current, other than the minute leakage current. With cells constructed strictly in accordance with Clark's directions, a slight rise in E.M.F. was observed during the first few days, then the values became and remained constant. Increase of dilution of the zinc sulphate solution increased the E.M.F., whilst dissolved air produced no alteration; the presence of mercuric sulphate, in the form of turpeth mineral, caused a progressive decrease of the E.M.F., amounting to about 4 per cent. after 6–20 months. It was found that an increase of one degree in temperature produced a diminution 0·04 per cent. in the E.M.F.; and from the experiments with five cells described in this paper, it follows that between 2° and 27° the E.M.F. of the cell for any temperature t may be determined by the formula

$$1·457\{1 - (t - 15·5) \times 0·000041\} \text{ volt},$$

assuming Clark's original valuation to be correct.

On the Work done during Electrolysis.—Previous researches by the authors have established that, when a current is passed through an electrolytic cell, the amount of energy expended in performing a given amount of electro-chemical work (apart from that transformed into heat) is not constant, but *increases algebraically with the current density*. In this connection, experiments by Favre appear to show that certain forms of electromotor cells can generate currents capable of doing more work externally to the cell than corresponds with the net chemical action, this extra work being gained at the expense of the sensible heat of the cell, which becomes cooled by the currents. Although Favre's results have been refuted by Weber, yet experiments described at length in the present paper point to the following results :—

(1.) When an electrolytic cell is of such a nature that the counter E.M.F. is negative, the E.M.F. developed is less the greater the density of the current generated. With small current densities, the E.M.F. has a maximum value, identical in some cases with the E.M.F. representing the algebraical sum of the chemical affinities involved; in other cases the maximum E.M.F. is below that due to chemical action.

(2.) Some kinds of combinations, more especially those in which lead is the metal dissolved, develop a greater E.M.F. than that due to chemical action. Recent experiments of Braun (*Ann. Phys. Chem.* [2], **16**, 561) confirm these general results, in proving that some combinations give an E.M.F. sensibly identical with that calculated from thermo-chemical data, whilst others fall short of and some exceed these values.

(3.) When the electrolytic cell is not an electromotor, the *counter E.M.F. increases in amount with the current density*. When the + electrode is of such a nature as to combine with the products of electrolysis, the rate of increase is slower the greater the chemical affinity between the so-called nascent products of electrolysis.

(4.) Whether the cell be an electromotor or not, there is always a greater or less degree of nonadjuvancy owing to the development of heat in place of electricity; the particular extent to which this non-adjuvancy extends appears to be a complex function, not only of the chemical nature and physical condition of its surface, but also of the degree of concentration of the electrolyte.

When a gas is one of the permanent products of electrolysis, *the greater the surface condensing power of the material of the electrode, the less is the degree of non-adjuvancy.* V. H. V.

Conditions Affecting Area of Electrification. By A. Tribe (*Phil. Mag.* [5], **16**, 90—95).—The areas of electrifications on an analysing silver plate in a solution of copper sulphate, can be determined by measuring the copper and silver peroxide respectively deposited on the plate; the former gives the area of —, the latter that of the + electrification. The influence of strength of current, temperature, and strength of electrolyte is examined; in all cases an inequality in the magnitude of the electrifications of opposite strength was observed; generally the area of + electrification is the greater, but with rise of temperature the relation is reversed. These experiments, taken in connection with others by the author on dissymmetry in the electrolytic discharge, in which it was inferred that the electromotive force on the + side of the trough is the greater, seem to be related to Faraday's observation that negative electricity discharges into the air at a somewhat lower tension than positive electricity; for if this be true of molecules of air, it is probably also true of molecules of other fluid media, as copper sulphate. A difference in the E.M.F. of the molecules in corresponding positions is therefore a feature of dissymmetry of certain electrolytic fields. This effect is observed in the phenomena mentioned above, viz., the differences in the area of like electrifications in analysing plates placed in corresponding positions. V. H. V.

Distribution of Electricity on Hollow Conductors in Electrolytes. By A. Tribe (*Phil. Mag.* [5], **16**, 384—386).—It would *à priori* be concluded that the closest analogy exists between the distribution of electricity on hollow conductors in electrolytic and dielectric fields. In this paper this conclusion is confirmed experimentally.

Hollow silver tubes were placed in an electrolytic cell containing copper sulphate, midway between the electrolytes and perpendicular to them; through the cell a current of one ampère flowed for six minutes. It was found that the intermediate space of no electrification was far greater within than without the tube. Similarly the silver tube exerted a sort of protective action on a plate of silver enclosed within, but not in metallic connection with it. But in these experiments the area of + was always greater than that of − electrification (see preceding Abstract). Other experiments were also made, substituting tubes of wire gauze of various diameters for those of metallic silver, and a similar result arrived at. As foreseen, increase of diameter of tube decreases the power of protection from electrification. V. H. V.

Electrolysis of Sodium Chloride and its Industrial Applications. By E. Rotondi (*Gazzetta*, **13**, 279—280).—The author's first experiments were made with a glass cylinder closed at bottom with parchment-paper and placed within a glass jar, both vessels containing a saturated solution of sodium chloride. On passing a current through the liquid, the positive pole of the battery being placed in the inner vessel, chlorine was there evolved, and hydrogen in the outer vessel, where also sodium hydroxide was formed, which was subsequently converted into carbonate by a stream of carbonic anhydride. In other experiments the inner vessel was made of porous earthenware—in others again of poplar wood. By these means solutions of sodium carbonate were formed, equal in strength to those obtained by Leblanc's process. In all the experiments, however, free chlorine was detected after a certain time in the inner vessel, its presence there being due to an alteration in the diaphragm. To avoid this inconvenience, the inner vessel was filled with distilled water, and the outer with a solution of sodium chloride, which was kept constantly saturated. With this arrangement, the chlorine separated at the anode, being insoluble in the saturated solution, was evolved in the free state, and thus the alteration of the diaphragm and the formation of chlorinated compounds were avoided.

The electrolysis of sodium chloride in this manner may be utilised in several branches of industry, as in the bleaching of vegetable fibres, in calico-printing, &c., since by the expenditure of a moderate amount of mechanical power to generate the electric current, a powerful bleaching and oxidising agent may be obtained, together with caustic or carbonated alkali. H. W.

Relation between Radiation, Energy, and Temperature. By W. W. Abney and R. Festing (*Phil. Mag.* [5], 16, 234—229).—In this paper a series of determinations is quoted of the radiation and of the energy of incandescent lamps, when currents of varying strength were passed through the filaments. A Grove's battery was used as the source of energy, the intensity of which was measured by a tangent galvanometer, and the radiation of the lamp by a thermopile, whose surface was coated with lampblack. The lamps were heated in ovens heated to 300°, and the change of resistance measured directly by resistance coils.

The results obtained may be summed up thus: the *current* can be expressed as a function of the potential; the *radiation*, after a certain temperature has been reached, bears a simple proportion to the energy expended; the *resistance* can be formulated as a function of the energy, and therefore of the radiation; and the *temperature* appears to be a simple function of the resistance. The curves expressing the relation between the first two quantities, current and potential, can be represented by the equation $c = ap + bp^{\frac{3}{2}}$; from this equation can be deduced another for the value of the energy in water, $w = p^2(a + bp^{\frac{1}{2}})$; the resistance in ohms would be $\frac{1}{a + bp^{\frac{1}{2}}}$, whilst the form of the equation between energy and resistance is expressed thus: $w = \left(\frac{1 - ar}{br}\right)^4 \times \frac{1}{r}$.

Appended are the results of typical experiments with four different patterns of lamps, in which the dimensions of the carbon filaments differ considerably. V. H. V.

Heats of Combustion and Formation of Carbon Bisulphide and Carbonyl Sulphide. By J. Thomsen (*Ber.*, 16, 2616—2619). —The heat of combustion of liquid carbon bisulphide, according to Favre and Silbermann, is 258,400 c., or calculated for the gaseous condition, 264,800 c.; according to Berthelot's experiments, it is 253,300 c. The author's results both with carbon bisulphide and carbonyl sulphide, COS, are the following:—

Reaction.	Heat of combustion.	Reaction.	Heat of formation.
$(CS_2 + O_6)$	265,130 c.	(C,S_2)	− 26,010 c.
$(COS + O_3)$	131,010 „	(C,O,S)	+ 37,030 „
		(CO,S)	+ 8,030 „

The heat of combustion of carbon bisulphide in the liquid condition is 6400 c. less, and the heat of formation 6400 c. greater than in the gaseous state. A. K. M.

Heat of Formation of the Oxychlorides of Carbon, Phosphorus, and Sulphur. By J. Thomsen (*Ber.*, 16, 2619—2621).—The results are contained in the following table:—

Reaction.	Heat.	Reaction.	Heat.	Reaction.	Heat.
(C,O,Cl_2)..	55,140 c.	(CO,Cl_2)	26,140 c.	$(COCl_2,Aq)$ ..	57,970 c.
(P,O,Cl_3)..	145,960 „	(PCl_3,O)	70,660 „	$(POCl_3,Aq)$ ..	72,190 „
(S,O_2,Cl_2) .	89,780 „	(SO_2,Cl_2)	18,700 „	(SO_2Cl_2,Aq) ..	62,900 „

A. K. M.

Densities of Solutions of Salts. By C. Bender (*Ber.*, **16**, 2556—2559).—From an examination of solutions of salts containing a number of gram-molecules to a litre, the author has arrived at a general law, according to which the density can be calculated from the number of gram-molecules of the anhydrous salt contained in a litre of the solution at a given temperature, namely, 15° and 18°. This depends on the supposition that an atom of an element (also certain groups of atoms) has a definite solubility value independent of the second atom or group of atoms with which it is united in a salt, as was shown by Valson (*Compt. rend.*, **77**, 806) in the case of moderately concentrated solutions. The author gives the following equation, $d_\mu = d_{\mu(\sigma)} + \mu(m_b + m_s)$, for determining the density of a solution, μ being the number of gram-molecules of the salt, $d_{\mu(\sigma)}$ the density of a solution of ammonium chloride containing the same number of gram-molecules to the litre, m_b the solubility value of the metal, and m_s that of the acid radicle. Water at 4° is taken as unity. The following is an example in which the density of a solution of copper nitrate at 15° is to be calculated: $\mu = 3$, $m_b = 0·0437$ (obtained from following table), $m_s = 0·0163$, and $d_{\mu(\sigma)} = 1·0451$. The calculated density is accordingly 1·2251, that found being 1·2250. The following values of m_b and m_s for different metals and acid radicles are in some cases only approximate:—

	At 15°.	At 18°.		At 15°.	At 18°.

The author disputes some points in connection with Nadejdine's law (*Beiblatter, z. Ann. Phys. Chem.*, 1883, 678). A. K. M.

Influence of Pressure on the Temperature of Volatilisation of Solids. By W. Ramsay and S. Young (*Proc. Roy. Soc.*, **35**, 308—310).—Experiments were undertaken in order to ascertain whether solids have definite volatilising points under different pressures, and whether these pressures are identical with their vapour-tensions. A solid has a limited surface, which cannot on heating be increased by formation of bubbles; it would *à priori* be expected that increasing the supply of heat, the temperature of the solid would rise until a temperature is reached at which the rate of evaporation is equivalent to the rate at which heat is communicated to it. By such reasoning, the existence of hot ice was maintained by Carnelley and others.

If, then, the rate of evaporation at the surface of a solid is independent of the extent of that surface, but influenced only by the rate at which heat is communicated to it, and as in the case of liquids, by the pressure to which it is exposed, it follows that solids have definite temperatures of evaporation, corresponding to definite pressures, as liquids have definite boiling points. Experiments with ice and camphor show that these pressures are sensibly the same as the maximum tensions of the vapours of these solids at corresponding temperatures.

In the case of ice, the maximum temperature attainable under any given pressure is indicated by Thomsen's ice-steam line.

V. H V.

Nature of Solution. By W. W. J. Nicol (*Phil. Mag.* [5], 15, 91—101).—The phenomenon of solution is usually explained by the formation of a hydrate, more or less stable, of the substance to be dissolved, this hydrate diffusing throughout the mass of the liquid with production of a homogeneous solution. But this hypothesis fails to explain the alteration in the solubility of salts when simultaneously dissolved, the greater or lesser solubility of various salts, and the greater or lesser increase of solubility of salts with rise of temperature. Further, the experiments of Wiedemann and of the author on sodium sulphate tend to prove that the crystalline salt parts with its water of crystallisation at 34°, whether in solution or not. Thus the dilemmas arise of an explanation of solution by hydration, and increased solubility by diminished hydration, whilst an example of a salt is offered, which dissolves in the anhydrous state, and is then less soluble than when hydrated.

In this paper the following hypothesis is brought forward: the solution of a salt in water is a consequence of the attraction of the molecule of water for a molecule of salt, exceeding that of the molecules of the salt for one another. At the saturation point, the attraction of dissimilar molecules is counterbalanced by that of similar molecules.

This hypothesis receives experimental support, not only from Kremer's researches on the influence of the temperature at which crystallisation takes place, on the sp. gr. of the salt, but also by Berthelot's determinations on the heats of solution of various salts before and after fusion. The latter has established that the solution of that form of salt which crystallises at ordinary temperatures, is attended by absorption of heat, due to the heat absorbed by the liquefaction of the salt exceeding that of its combination with water; or in other words, the work to be done in separating the molecules of salt requires a greater expenditure of energy in the form of heat than that given out by the union of the water with the salt.

Again, in most cases the volume of the solution is usually less than the sum of the volumes taken together of the salt and water before solution. In this connection the experiments of Gerlach show that the amount of contraction does not increase regularly as the amount of salt dissolved increases. This is in accordance with the theory enunciated above, that the greater the amount of salt already in solution, the less is the result of the attraction of dissimilar, but the greater that of similar molecules.

Again determinations by Gerlach and Kremer on the coefficient of expansion of salt-solutions have proved that for weak solutions of salts the coefficient of expansion is in most cases greater than that of water; and the same obtains with strong solutions up to a certain temperature. In a solution, the effect of heat on the attraction of water for water, and of water for salt, will be to produce expansion, but on the attraction of salt for salt, to produce contraction. In dilute solution this last need not be considered, so that the net result is an expansion due not only to that of water, but also to the attraction of the water for the salt. If this theory be correct, it will be possible to connect together the molecular volume of solids and their solubility.

V. H. V.

Solubility of Salts in Water at High Temperatures. By W. A. TILDEN and W. A. SHENSTONE (*Proc. Roy. Soc.*, **35**, 345—346).—This paper contains a brief description of experiments made with a view of determining the solubility of salts in water at temperatures above its boiling point.

As a general result it may be stated that solubility and fusibility are phenomena intimately connected: for increase of solubility consequent on a rise of temperature above 100° is the greatest in the most fusible, and least in the least fusible. If the results are represented graphically, taking for abscissæ degrees of temperature, and for ordinates the quantities of salt dissolved in 100 parts of water, then the higher the melting point, the more nearly the curves approximate to a straight line.

These relations can be illustrated by potassium chlorate and potassium haloïd salts. As regards sodium sulphate, the solubility increases from 6—34°, the melting point of the decahydrated salt, $Na_2SO_4,10H_2O$; then the solubility diminishes until a temperature of 120° is reached. From 120° to 140° there is no appreciable change, but at 160° there is a notable increase of solubility, which is still further increased at 180° and again at 230°.

Parts by Weight of Anhydrous Na_2SO_4, *dissolved by 100 parts of Water at*

0°.	34°.	100°.	120°.	140°.	160°.	180°.	230°.
5	78·8	42·7	41·95	42	42·9	44·25	46·4

In view of these facts the act of solution can no longer be explained by the formation of hydrates of the dissolving salt. V. H. V.

General Law of the Freezing of Solvents. (*Compt. rend.*, **97**, 825—831.)—A report by Cahours, Berthelot, and Debray on Raoult's memoir. (See Abstr., 1882, p. 1260; 1883, p. 278.) C. H. B.

Freezing Point of Alkaline Solutions. By F. M. RAOULT (*Compt. rend.*, **97**, 941—943).—The following results were obtained:

Base.	Mol. weight.	Reduction in freezing point caused by 1 gram of the base in 100 grams of water.	Mol. reduction.
Barium hydroxide	171·0	0·290	49·7
Strontium „	121·5	0·396	48·2
Calcium „	74·0	0·648	48·0
Lithium „	24·0	1·558	37·4
Sodium „	40·0	0·905	36·2
Potassium „	56·0	0 630	35·3
Thallium „	221·0	0·150	33·1
Cæsium „	149·6	0·237	35·5
Rubidium „	102·4	0·360	36·9
Tetramethylammonium hydroxide	91·0	0·404	36·8
Trimethylethylammonium „	105·0	0 353	37·1
Ammonia	17·0	1·117	16·9
Methylamine	31·0	0·638	19·8
Trimethylamine	59·0	0·342	20·2
Ethylamine	45·0	0·411	18·5
Propylamine	59·0	0·312	18·4
Aniline	93·0	0·164	15·3
Nicotine	162·0	0·124	20·2

It is evident that in accordance with the general law, soluble bases may be divided into two classes, one of which gives a molecular reduction between 33 and 48 (mean = 39), whilst the other gives a molecular reduction between 16 and 20 (mean = 19), or practically one-half. The differences between the molecular reductions of individual members of each group are considerably greater than in the case of acids. The first group may in fact be divided into two sub-groups: one containing the hydroxides of dyad metals with a molecular reduction of about 48, and the other the hydroxides of monad metals with a molecular reduction of about 35.

Berthelot, Menschutkin, and the author have previously shown that potash and soda displace ammonia, methylamine, ethylamine, triethylamine, trimethylamine, and aniline almost completely from their salts in dilute alcoholic solution. The author also finds that barium hydroxide and rubidium hydroxide displace ammonia completely from ammonium chloride, and that trimethylethylammonium hydroxide displaces ammonia almost completely from ammonium iodide. Hence it may be said that any member of the first group can almost completely displace any member of the second group from its salts in dilute solution. A similar relation has been found to hold in the case of the two groups of acids, and it may be stated as a general law that strong acids and strong bases in solution in water produce the normal molecular reduction of the freezing point (about 40), whilst feeble acids and feeble bases produce the abnormal molecular reduction (about 20). It is worthy of note that all the organic acids and bases, with the exception of the hydroxides of organic ammonias, are found in the second group. The relation which exists between the chemical energies of acids and bases and the molecular reduction in the freezing point of water, does not however hold good in the case of all solvents. In the case of certain solvents, acetic acid for example, strong acids, such as sulphuric and hydrochloric acids, produce only half the reduction in freezing point which is produced by weak acids, such as benzoic acid and phenol. The relation observed in the case of water is probably due to the fact that the strong acids and bases have a greater attraction for water, and therefore their molecules are more completely separated by solution, whilst the weak acids and bases have very little attraction for water, and their molecules consequently remain united together after solution, most probably in pairs. This latter supposition would explain the fact that they produce only half the normal molecular reduction. C. H. B.

Perfect Elasticity of Solid Bodies: a New Relation between Solids and Liquids and Gases. By W. Spring (*Ber.*, **16**, 2723—2728).—The author has subjected a large number of metals and metallic salts to a pressure of 20,000 atmospheres, and determined their density before and after the operation. As a rule no alteration in density and, consequently, no permanent change in volume, is produced by the pressure, excepting that due to cavities in the solids. If the solid is capable of existing in a denser allotropic modification, then a permanent compression ensues.

When a bar of metal is bent, the concave portion experiences pressure and the convex undergoes expansion. If the bar remains curved after the force which altered its shape is removed, the result is due to a passage of matter from the concave to the convex side. The limit of elasticity of a solid is the critical moment at which the particles begin to "flow" under the influence of the forces exerted on them.

A body is brittle when its particles no longer have the power of "flowing" under pressure. W. C. W.

Determination of Atomic Weights by Means of Metallic Sulphates. Atomic Weights of Copper, Zinc, and Nickel. By H. Baubigny (*Compt. rend.*, **97**, 854—856, 906—908, 951—954).—The principal source of error in previous determinations of the atomic weights of metals by means of their sulphates has been the difficulty of expelling the last traces of free acid and moisture without at the same time partially decomposing the sulphate. The author finds that all sulphates, with the exception of those of gold and the platinum metals, may be heated for several days at 440°, the temperature of boiling sulphur, without undergoing any decomposition, and that, even at this high temperature some sulphates lose the last traces of free acid very slowly. By this method the preparation of sulphates in a definite form is easier than the preparation of chlorides. Ferric sulphate, for example, can readily be obtained quite pure as a white salt with a pinkish tinge. The normal anhydrous sulphates thus obtained can be completely converted into oxides by heating them at a high temperature in a platinum boat placed inside a platinum tube heated by a muffle, one end of the tube being open to the air. The use of the platinum tube renders it easy to ascertain whether any spirting has taken place, and also protects the oxide from the reducing gases of the furnace. In an actual determination, the purified sulphate is placed in a weighed platinum boat, and the latter is placed inside a glass tube which is heated in sulphur vapour until the sulphate ceases to lose weight. The boat with its contents is then put inside the platinum tube in the muffle and heated until all the acid is expelled. After the residual oxide has been weighed, it is dissolved in hydrochloric acid and the solution tested with barium chloride. This method is of course inapplicable to sulphates which volatilise without decomposition, or to sulphates which yield oxides which are volatile at high temperatures, like those of barium and strontium. In such cases the synthetical method must be adopted, the last traces of water and free acid being expelled by heating at 440°.

The atomic weights given below have been calculated on the assumption that the atomic weight of oxygen is 16.

Copper.—Pure metallic copper or pure artificial atacamite was dissolved in dilute sulphuric acid, and the solution carefully evaporated. Determinations were made with the first crop of crystals, and also with the residue obtained by evaporating the mother-liquor left after the separation of a second crop of crystals. The mean of the determinations is Cu = 63·468 if S = 32·074, or Cu = 63·396, if S = 32.

Zinc.—Distilled zinc was treated with a quantity of sulphuric acid insufficient to dissolve it, and the filtered solution was evaporated to dryness. The residue was heated at 440°, dissolved in water, a portion of the zinc precipitated by hydrogen sulphide, and the liquid digested with the precipitate for some time in order to remove cadmium, lead, &c. The liquid was then filtered, the zinc precipitated as sulphide, the precipitate washed with very dilute sulphuric acid, and then dissolved in sulphuric acid, and the solution evaporated. The mean of the determinations is Zn = 65·408 if S = 32·074, or Zn = 65·334[*] if S 32.

Nickel.—The commercial nitrate was very carefully purified, and was eventually converted into the anhydrous sulphide by saturating a solution of the sulphate with hydrogen sulphide, and heating it in closed vessels at 100°. The nickel sulphide thus obtained was dissolved in aqua regia and the solution evaporated with excess of sulphuric acid. Nickel sulphate obstinately retains traces of free acid even at 440°, and prolonged heating is necessary in order to obtain it perfectly pure. The monoxide left on ignition of the sulphate has no tension of dissociation at the melting point of gold, even in a vacuum. The mean of the determinations is Ni = 58·748 if S = 32·074, or Ni = 58·678 if S = 32.

C. H. B.

Molecular Weight of the Amines: Trimethylamine. By J. DEWAR and A. SCOTT (*Proc. Roy. Soc.*, **35**, 347—349).—The substituted ammonias are peculiarly fitted to reveal the small differences from whole numbers in the conjoint values of atomic weights of carbon and hydrogen. By selecting amines of sufficiently high molecular weights, butylamine for example, it is possible to integrate these small positive and negative increments: and, theoretically, it should be possible to ascertain whether the atomic weight of hydrogen differs from unity, when O = 16 is taken as the standard, provided the atomic weight of carbon be accepted as sufficiently well defined by independent investigations. The crude base was transformed into tetrethylammonium bromide, decomposed by dry distillation, separated from the chloride with potassium hydroxide, and fractionally distilled. The portion boiling between 90—91° was treated with nitrous acid to eliminate traces of the primary and secondary amines, and finally converted into the bromide. The relation between this salt, Et_3NHBr, and silver was then determined, and the average result of fairly concordant experiments gave as the molecular weight of the bromide 182·012. The value foı triethylammonium is 102·061; and if from this be subtracted Stas' value for ammonium, 18 074, the resultant, 83 987, is the molecular weight of the hydrocarbon C_6H_{12}.

---

[*] *Note by Abstractor.*—This number is identical with that recently obtained by Marignac (*Zeitsch. Anal. Chem.*, 1884, 133).

These results are sufficient to prove that if the atomic weight of hydrogen be taken as unity, the atomic weight of carbon is 12, and thus the addition of 6 atoms of carbon to 12 of hydrogen results in a compound, whose molecular weight is the integer 84. But this value may be due to the summation of positive and negative variations from the respective values 12 or 1 respectively.

This investigation will be continued, and Schützenberger's hypothesis on the variability of the atomic weight of carbon will be made the subject of a future discussion. V. H. V.

Demonstration of the Increase of Weight of Bodies on Combustion. By M. Rosenfeld (*Ber.*, **16**, 2753—2758).—In order to show the increase in weight which potassium, sodium, magnesium, tinfoil, sulphur, carbon, and a taper undergo on combustion, the author employs a Nicholson's areometer instead of a balance.

In the experiment with tinfoil, it is necessary to affix a thin iron or brass wire (25 cm. long) across the pan of the areometer. The tinfoil hangs on each end of this wire.

For sulphur and charcoal, a small tube containing soda-solution is used. The tube is closed by a cork through which two narrow tubes pass; the longer tube dips into the soda. The sulphur or charcoal and the absorption tube are placed on the scale of the areometer. The sulphur is then brought into a hard glass tube, through which oxygen is passed. The tube is heated, and the products of combustion are passed into the absorption tube, which is again placed on the areometer after the experiment. A somewhat similar arrangement is used in the case of the taper. W. C. W.

Lecture Experiments. By M. Rosenfeld (*Ber.*, **16**, 2750—2752).—I. The preparation of mercuric oxide may be shown by heating potassium amalgam at 225° in a long-necked flask. The flask is closed by a cork through which two tubes are inserted. One tube dipping down to the surface of the mercury is connected with a gasometer filled with oxygen. Through the second tube, the excess of oxygen escapes into a cylinder filled with water, standing in a pneumatic trough.

II. Zinc oxide is prepared by melting about 40 grams of zinc in a flat evaporating basin. A small piece of sodium is added, and a current of air is forced on the surface of the metal.

III. To obtain nitrogen from the air, the author recommends that the oxygen should be removed by means of a sheet of burning tinfoil. W. C. W.

Inorganic Chemistry.

Purification of Hydrochloric Acid. By E. BENSEMANN (*Arch. Pharm.* [3], **21**, 291).—Hydrochloric acid can be entirely freed from arsenic by diluting it with water, adding potassium chlorate in small quantity, and warming the liquid. On distilling this mixture, hydrochloric acid free from arsenic is obtained, but of course it contains free chlorine. W. R. D.

Some Reactions of Ozone. By A. WAGNER (*Zeits. Anal. Chem.*, **22**, 316—318).—On placing a piece of filter-paper, soaked in a boiling ethereal solution of anthracene, in a bottle containing phosphorus partially covered with water, anthraquinone is formed. Similar treatment causes aniline hydrochloride to turn brown, whilst exposure to air through which strong electric sparks are passing, produces a reddish-brown colour. In like manner diphenylamine gives a deep brown when the ozone is produced by phosphorus, and a lemon-yellow when the electrical discharge is used. Diphenylaminesulphonic acid similarly treated becomes blue, passing into green in the former case, and deep blue in the latter. P. F. F.

Colour of Water. By W. SPRING (*Bied. Centr.*, 1883, 289—291). —Fresh distilled water in tubes 5 metres × 4 cm. appears of a sky-blue colour, which however changes after a few hours to a pale green; but if 0·0001 of mercuric chloride is added to the original water, no change occurs; if it be added to the green water, a blue-green tint is obtained, but never the original colour; it is therefore concluded that the change from blue to green is effected by minute organisms. A beam of light sent through the column of water is invisible (laterally?), consequently the colour is natural to the water and not to reflection from minute particles. Amyl and ethyl alcohol, and acetic acid are colourless. Pure blue water treated with lime and then with carbonic anhydride appeared at first black, changing to brown, yellow, and green; similar results were obtained with baryta-water containing free silicic acid and sodium silicate. The final conclusions drawn are:—light does not pass through a thick layer of water containing solids in suspension; the yellow colour is due to suspended matter, or to that matter forming a saturated solution; as carbonates are deposited, the colour approaches more nearly to blue. In natural blue waters, calcium and magnesium carbonates, silica and alumina are in solution; whilst in the green they are partly undissolved through a deficiency in the carbonic anhydride. In the blue Rhine we have 786 $CaCO_3$ and 79·5 CO_2, whilst in the green Rhine 1056 $CaCO_3$ and 76 CO_2. E. W. P.

Hydrated Carbon Bisulphide. By F. P. VENABLE (*Amer. Chem. J.*, **5**, 15—19).—The author confirms Ballo's statement that the white substance obtained by the rapid evaporation of carbon bisulphide is a hydrate, as it cannot be formed in dry air under conditions similar to those in which it is readily formed in moist air. The temperature of —12°, given by Wartha as that of its formation or decomposition, does not appear to be correct. (For previous experiments on this subject see *Watts's Dictionary*, Suppl. 2, 264.)

A. J. G.

Modification of Noack's Method of Preparing Carbonic Oxide. By L. P. KINNICUTT (*Amer. Chem. J.*, **5**, 43—44).—Noack has recently shown that carbonic oxide can be prepared by passing carbonic anhydride over heated zinc-dust (*Ber.*, **16**, 75). It may however be prepared more conveniently by heating a mixture of magnesite with twice its weight of zinc-dust. After the first five minutes, the gas is nearly pure carbonic oxide. A. J. G.

Manufacture of Phosphoric Acid. By E. W. RUNYON (*Pharm. Journ.* [3], **14**, 48).—The preparation of phosphoric acid free from arsenic has hitherto been a matter of difficulty, as commercial phosphorus is always contaminated with arsenic, which is not removed in the ordinary process of oxidation by nitric acid. It has been proposed to remove the arsenic from the acid thus prepared by hydrogen sulphide, but the author finds that owing to the long time occupied in removing every trace of arsenic, this method is not a practicable one. He recommends the process proposed by Wenzell, which depends on the aerial oxidation of the phosphorus by exposure in trays in presence of water: full details of the apparatus used are given in the paper. The solution of phosphorous acid obtained is heated, whereupon the arsenic separates in the metallic condition, and after being kept at a temperature of about 190° for 30 minutes, the separation is complete. This liquid (sp. gr. 1·75) is diluted with an equal bulk of water, filtered through paper, and oxidised by nitric acid in the ordinary way. W. R. D.

Borax in California. By AYRES (*Arch. Pharm.* [3], **21**, 297).—The borax imported from California is principally obtained from two lakes, Borax Lake and Clear Lake, which are about 80 miles north of San Francisco. Borax Lake is about three-quarters of a mile long, and has an average depth of four feet. Crystals which were taken from the mud at the bottom were found to be pure sodium pyroborate; 1·077 gram of total solid residue were yielded by 30 grams of the water. This residue contained 0·618 gram of sodium carbonate, 0·204 gram of sodium chloride, and 0·178 gram of borax.

W. R. D.

Silver Nitrate and Ammonia. By A. REYCHLER (*Ber.*, 16, 2421—2424).—Monammonia silver nitrate, $AgNO_3,NH_3$, was described by the author (Abstr., 1883, 902) as a nitrate of argentammonium, a view which is found to be incompatible with the behaviour of this compound when treated with ethyl iodide. Ethyl iodide reacts with it at the ordinary temperature, heat being evolved, and silver iodide, ethyl nitrate, and diammonia silver nitrate formed, thus:—

$$2AgNO_3,NH_3 + nEtI = AgI + Et.NO_3 + AgNO_3,(NH_3)_2 + (n-1)EtI.$$

The diammonia silver nitrate is also acted on by ethyl iodide, with formation of silver iodide, ethyl nitrate, and ammonia, thus:—

$$AgNO_3,(NH_3)_2 + nEtI = AgI + EtNO_3 + 2NH_3 + (n-1)EtI.$$

Some ethylamine is also produced by the action of the ammonia on the ethyl nitrate and ethyl iodide. If monammonia silver nitrate were a derivative of argentammonium, then ethyl iodide would react with it, so as to form ethylamine nitrate, as follows:—

$$AgNH_3.NO_3 + EtI = AgI + NEtH_3.NO_3.$$

But in light of the above reactions, the author is inclined to regard monammonia silver nitrate either as a molecular compound of ammonia with silver nitrate, or as a compound having the following constitution: $OH.NO(NH_2).OAg$. P. P. B.

Atomic Weight of Beryllium. By J. E. REYNOLDS (*Proc. Roy. Soc.*, 35, 248—250).—Although specimens of beryllium used for determinations of the specific heat of the metal were impure, yet the results are all in one direction, that is, indicating apparent gain in specific heat with increased purity of material. The spectroscopic evidence of Hartley (Trans., 1883, 316) shows that beryllium is the first member of a dyad series of elements, of which calcium, barium, and strontium are probably homologues. Thus two independent methods of research tend to prove that the atomic weight of 9·2 is the more correct, and that beryllium is the first member of Mendelejeff's second series of elements. V. H. V.

Reply to the Above Paper. By T. S. HUMPIDGE (*Proc. Roy. Soc.*, 35, 358—359).—In this paper, exception is taken to the statement of Reynolds that the results of determinations of the specific heats of beryllium are higher, the less the proportion of impurities. But even admitting this, it is hardly probable that the specific heat of the *fused* metal could be 50 per cent. greater than that of the *crystalline* metal. The author has prepared purer samples, analyses of which are promised. As regards the observations of Hartley, the slight spectroscopic resemblance between beryllium and the alkaline earth-metals can hardly outbalance all the weighty chemical and physical differences between them; and even if beryllium is a dyad, its nearest homologues are decidedly magnesium and zinc, not calcium, strontium, and barium. V. H. V.

Diffusion of Didymium. By A. COSSA (*Gazzetta*, **13**, 280).—This metal, besides being found in apatites, scheelite, and various kinds of limestone, occurs in large quantity in the sphene of the syenite of the Biellese and of the Collegno limestone. The frequent association of didymium-compounds with those of calcium in homogeneous and perfectly crystallised minerals is regarded by Cossa as a confirmation of his opinion, that didymium, at least in compounds in which it is associated with calcium, may be regarded as a bivalent metallic radicle. H. W.

Magnesium Bromide and Iodide. By O. LERCH (*J. pr. Chem.* [2], **28**, 338—356).—Although magnesium bromide has been prepared by the action of bromine vapour on a strongly heated mixture of carbon and magnesium oxide, it could never, owing to its non-volatility, be purified and analysed. The author has observed that bromine vapour combines directly with magnesium with the greatest readiness at a very high temperature, namely, at the melting point of the metal. By heating small pieces of magnesium in a vertical hard glass tube before the blowpipe, so that only the lower end of the tube is heated, and admitting bromine vapour by a smaller tube passing through the magnesium almost to the bottom of the larger tube, magnesium bromide may be obtained in quantity. The greatest caution is required in this dangerous operation. *Magnesium bromide* is a white crystalline mass, having the appearance of magnesium chloride. It is easily oxidised on exposure to air, is not volatile, and is more hygroscopic than the chloride. Analysis agrees with the formula $MgBr_3$; but owing to the action of this metal on glass at a high temperature, the estimated quantity of bromine is slightly lower than that calculated. The salt was also obtained by evaporating a solution of hydrated magnesium bromide and ammonium bromide to dryness, and driving off the latter by heat; also by melting anhydrous magnesium chloride with ammonium bromide.

Magnesium Iodide.—This salt was also obtained by heating pieces of magnesium in a vertical tube to the melting point, and adding slowly small quantities of iodine; the reaction takes place with great violence. The iodide sinks below the molten metal, and also somewhat attacks the glass. It has the same appearance as the bromide, but melts at a higher temperature, and is more readily oxidised on exposure to the air. Analysis agrees with the formula MgI_2. The salt was also obtained from hydrated magnesium iodide and ammonium iodide, and by melting magnesium chloride with ammonium iodide.

Hydrated magnesium bromide is obtained by the action of bromine on magnesium dust and water. Crystallised over sulphuric acid, it is obtained in hygroscopic crystals, and analysis agrees with the formula $MgBr_2 + 6H_2O$.

Hydrated magnesium iodide, obtained in a similar way to the above, has the formula $MgI_2 + 8H_2O$.

Magnesium potassium bromide was formed by adding to a known quantity of hydrated magnesium bromide sufficient potassium bromide to form the double salt $2(KBr),MgBr_2 + 6H_2O$, as mentioned by

Löwig (*Repert.*, **29**, 261). On evaporating the solution over sulphuric acid, potassium bromide containing only 2 per cent. magnesium bromide crystallised out at first, and for some time after crystals containing no definite quantity of magnesium bromide were obtained; finally, however, a salt was obtained of a composition similar to that of carnallite, $KCl,MgCl_2 + 6H_2O$. Analysis agreed with the formula $KBr,MgBr_2 + 6H_2O$. A deficiency of over 2 per cent. of bromine was observed; but on analysis of carnallite prepared by crystallisation from its mother-liquor, there was a similar deficiency of chlorine, probably owing in both cases to the difficulty of purifying the very deliquescent crystals.

Magnesium ammonium bromide ..	$MgBr_2,NH_4Br + 6H_2O$
Magnesium potassium iodide	$MgI_2,KI + 6H_2O$
Magnesium ammonium iodide	$MgI_2,NH_4I + 6H_2O$.

The halogen compounds of magnesium are similar in their behaviour towards water, in melting only at a high temperature, and in solidifying to crystalline masses; they differ in their behaviour to the air, for whilst the chloride is but slowly decomposed at the melting point, the bromide is more easily decomposed and the iodide with great rapidity at ordinary temperatures. The hydrated and double salts show the same characteristics respectively as do the halogen compounds. The author purposes continuing his investigation.

A. B.

Cadmium Oxide. By J. Thomsen (*Ber.*, **16**, 2616).—The author has shown that hydrochloric, hydrobromic, and hydriodic acids exhibit the same heat of neutralisation with sodium hydroxide in aqueous solution, and that practically the same result is obtained when the above acids are neutralised with baryta, magnesia, zinc oxide, and copper oxide. Cadmium oxide is distinguished from the magnesium group by many of its chemical properties, and by its heat of neutralisation, which is greater for hydrobromic than for hydrochloric acid, and greater for hydriodic than for hydrobromic acid: in this respect it bears more resemblance to the heavy metals:—

$$CdO_2H_2,2HClAq = 20,290 \text{ c.}$$
$$CdO_2H_2,2HBrAq = 21,560 \text{ ,,}$$
$$CdO_2H_2,2HIAq = 24,210 \text{ ,,}$$

A. K. M.

Spontaneous Oxidation of Mercury. By D. Macaluso (*Gazzetta*, **13**, 485—489).—The author has shown, by a series of careful experiments, that mercury is not oxidised by exposure to pure dry air or to pure aqueous vapour, but that in a mixture of the two, oxidation takes place, with production of the well-known grey pellicle of suboxide. This action is analogous to the formation of mercurous chloride when mercury is left in contact with gaseous hydrogen chloride or its aqueous solution in presence of air, whereas in pure hydrogen chloride, or its pure aqueous solution perfectly deprived of air, no such formation takes place.

H. W.

Double Fluorides and Oxyfluorides of Titanium. By A. Piccini (*Compt. rend.*, **97**, 1064—1067).—When an aqueous solution of titanium trichloride is added gradually to a concentrated solution of ammonium fluoride, or, better, when a solution of the normal fluotitanate in a solution of ammonium fluoride is reduced by electrolysis, the compound $TiF_3,3NH_4F$ is obtained as a crystalline violet precipitate, slightly soluble in water, but insoluble in a solution of ammonium fluoride. If this precipitate is washed successively with water, a concentrated solution of ammonium fluoride, and strong alcohol, and exposed to the air, its violet colour changes to dirty yellow, and when perfectly dry, it has a deep yellow colour. This yellow substance dissolves completely in water, but the solution decomposes even at the ordinary temperature with evolution of bubbles of gas. When the aqueous solution is evaporated in a vacuum or by exposure to air, small brilliant transparent yellow regular octohedrons are obtained, often mixed with very slender yellow needles. If, however, the aqueous solution is mixed with ammonium fluoride, a precipitate is obtained which consists of the regular octohedrons alone. These crystals are insoluble in a solution of ammonium fluoride, but dissolve readily in water, forming a golden-yellow solution, which, when acidified with dilute sulphuric acid, bleaches, and is bleached by a solution of potassium permanganate, with evolution of oxygen. Ammonia produces a yellow flocculent precipitate, soluble in cold dilute sulphuric acid with formation of a reddish-yellow solution, which behaves in a similar manner with a solution of potassium permanganate. If the reddish-yellow solution is mixed with potassium hydrofluoride, a portion of the titanium is precipitated as $TiF_4,2KF + H_2O$, and the liquid is decolorised and gives Barreswil's reaction. The octohedral crystals have the composition $TiO_2F_2,3NH_4F$, and it would appear that the oxygen is in a condition similar to that in which it exists in hydrogen peroxide. This compound is the first example of a substance passing from a lower form to the highest form, in presence of the most stable or normal compound. As prepared by exposure to air, the yellow substance contains a considerable proportion of normal fluotitanate, and it is probably formed in accordance with the equation $2(TiF_3.3NH_4F) + O_2 = TiF_4,3NH_4F + TiO_2F_2,3NH_4F$, the violet compound absorbing oxygen and splitting up into the normal salt and the oxysalt.

When hydrogen peroxide is added to a sulphuric acid solution of titanic acid in the proportion $TiO_2 : H_2O_2$, a reddish-yellow liquid is obtained, which gives Barreswil's reaction on adding a further small quantity of hydrogen peroxide. If the liquid is now neutralised with ammonia, a yellow solution is obtained, from which neutral ammonium fluoride precipitates yellow octohedra identical with those obtained by the other method. If sufficient ammonium fluoride is not present, the liquid remains slightly coloured, and when evaporated in presence of air, it deposits very slender yellow needles similar to those obtained by the first method. These needles consist of a hydrated oxyfluoride containing less fluorine than the octohedral compound.

This series of oxyfluorides throws light on the nature of the reaction between titanic acid and hydrogen peroxide. They are evidently derived from the radicle of the acid formed by TiO_3, in which an atom of oxygen has been replaced by two atoms of fluorine, as in the case of the oxyfluomolybdates and the oxyfluotungstates. They differ in constitution from the latter, however, in that they correspond with a higher state of oxidation. The octohedral salt is decolorised by hydrofluoric acid, the oxygen being replaced by fluorine atom for atom, that is to say, the couple O_2 is equivalent to two atoms of fluorine: $TiO_2F_2 + 2HF = TiF_4 + H_2O_2$. In crystalline form, the compound $TiO_2F_2,3NH_4F$ is analogous to $NbOF_3,3NH_4F$, which contains the same number of atoms. C. H. B.

Mineralogical Chemistry.

Dopplerite. By A. Mayer (*Landw. Versuchs.-Stat.*, 29, 313—315).—The sample of dopplerite was obtained from peat beds in Holland: it contained 84·6 per cent. water, and in the dried substance was found 4·2 per cent. ash. The relation of carbon, hydrogen, and oxygen in the remainder led to the empirical formula $C_{17}H_{18}O_3$. The ash constituents were chiefly calcium carbonate and ferric oxide. Dopplerite is perfectly soluble in caustic potash or soda, but only partially in ammonia. Acids precipitate it from solution, and salts of alkaline earths throw it down in combination with base. A calcium salt was thus obtained having 8·1 per cent. of lime. J. K. C.

Natural Fluorine Compounds. By P. Groth (*Jahrb. f. Min.*, 1883, 2, Ref., 324—327).—This paper gives a detailed description of the fluorine minerals, analyses of which have already been published by Brandl (Abstr., 1882, 1176).

1. *Cryolite* is monoclinic: $a:b:c = 0·9662:1:1·3882$, $\beta = 89° 40'$. The planes occurring most frequently are ∞P, $0P$, $+ \mathrm{P}\!\!\!\!-\infty$, $\not{P}\infty$. The chemical formula calculated from Brandl's analyses is $3NaF,AlF_3$.

Pachnolite is monoclinic: $a:b:c = 1·1626:1:1·5320$, $\beta = 89° 40'$. ∞P, $-P$, $0P$ are the planes occurring most frequently. The rhombic section is very characteristic of pachnolite, that of thomsenolite being rectangular. The chemical formula is NaF,CaF_2,AlF_3.

Thomsenolite is monoclinic: $a:b:c = 0·9959:1:1·0887$, $\beta = 87° 37\frac{1}{2}'$. The most important forms are ∞P, $+ P$, $0P$. The chemical formula is NaF,CaF_2,AlF_3,H_2O.

Ralstonite crystallises in octohedrons. The formula is

$$3(Na_2MgCa)F_2,8AlF_3,6H_2O.$$

Chiolite has the formula $5NaF,3AlF$.

Arksutite is probably a partially altered cryolite, that is a mixture of cryolite and pachnolite. *Hagemannite* is probably thomsenolite mixed with siliceous brown ironstone. *Gearksutite* appears to be the final product of the alteration of cryolite, whereby Na is replaced by Ca and water taken up.

2. *Fluellite* is rhombic: $a : b : c = 0·77 : 1 : 1·874$. Forms observed are P and 0P. Sp. gr. = 2·17. The formula is $AlF_3 + H_2O$.

3. *Prosopite* is monoclinic: $a : b : c = 1·318 : 1 : 0·5912$, $\beta = 86° 2'$. Forms observed are ∞P, ∞Ꝑ∞, +P, 2Ᵽ2, Ꝑ∞, −3Ꝑ$\frac{3}{2}$, ∞Ᵽ2. The formula is $CaAl_2(FHO)_8$. B. H. B.

Zinc Blende and Prehnite from Cornwall, Lebanon Co., Pa. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 322—323).—In cavities of the magnetite from Cornwall Ore Bank, fine crystals of zinc blende occur associated with prehnite, magnetite, iron pyrites, and chlorite. They have a sp. gr. of 4·033, and gave on analysis :—

S.	Zn.	Co.	Fe.	Total.
32·69	66·47	0·34	0·38	99·88

Prehnite forms crystalline incrustations upon magnetite. It has a sp. gr. of 3·042, and gave on analysis :—

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	H_2O.	Total.
42·40	20·88	5·54	27·02	4·01	99·85

B. H. B.

Artificial Alisonite. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 324).—At the smelting works at Argo, Colorado, octohedral crystals have been observed in the furnace bottoms. They have an iron-black colour, metallic lustre, sp. gr. = 5·545, and gave on analysis the following results :—

S.	Ag.	Cu.	Pb.	Fe	Total.
15·23	2·16	51·33	31·15	trace	99·87

B. H. B.

Rezbanyite, a New Mineral Species. By A. FRENZEL (*Jahrb. f. Min.*, 1883, 2, Ref., 314).—This mineral occurs at Rezbanya, associated with cosalite. It has a metallic lustre, a lead-grey colour and black streak. H. = 2·5 to 3. Sp. gr. = 6·09 to 6·38. It forms compact masses with copper pyrites and calcite, or is disseminated through quartz. From the analyses, the formula of rezbanyite is calculated to be $4PbS,5Bi_2S_3$. B. H. B.

Alloclasite. By A. FRENZEL (*Jahrb. f. Min.*, 1883, 2, Ref., 314—315).—In order to determine the composition of this mineral, which still remains doubtful, the author made six analyses of compact material, and although the results obtained were rather variable, he is of opinion that Groth's formula (CoFe)(AsBi)S, is the correct one for this mineral. B. H. B.

Kupfernickel from Colorado. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 324).—In Silver Cliff, Colorado, rounded masses of kupfernickel occur in granular limestone. Sp. gr. = 7·314. The analysis gave :—

As.	Sb.	S.	Cu.	Ni.	Co.	Fe.	Total.
46·81	2·24	2·52	1·59	44·76	1·70	0·60	100·22

B. H. B.

Corundum. By F. A. Genth (*Jahrb. f. Min.*, 1883, 2, Ref., 316—319).—This paper is a description of a few remarkable occurrences, as a continuation of the paper formerly published by the author (this Jour., 1874, 549).

1. *Corundum altered into spinel* is found at the Carter Mine, Madison Co., N.C. It has a sp. gr. of 3·751. The spinel finally passes into chlorite.

The analysis, after deducti ilica and corundum, gave the following results :—

Al_2O_3.	Fe_2O_3.	CuO.	NiO.	ZnO.	FeO.	MgO.	Total.
66·74	1·34	0·09	0·33	0·22	11·94	19·34	100·00

Corundum altered to a slight extent into spinel has also been found at Shimersville in Lehigh Co. Sp. gr. = 4·056. After deducting 1·47 per cent. SiO_2, the analysis gave :—

Al_2O_3.	Fe_2O_3.	FeO.	MgO.	TiO_2.	Total.
56·42	13 17	22·95	4·94	2·62	100·10

2. *Corundum altered into zoisite* is of rare occurrence.

3. *Corundum altered into felspar and damourite* occurs at Unionsville. The analysis gave :—

SiO_2.	Al_2O_3.	Fe_2O_3.	MgO.	CaO.	Na_2O.	K_2O.	Ignition.	Total.
62·62	22·59	0·22	0·18	1·94	7·41	2·52	2·45	99·93

Another interesting occurrence is that at the Black Horse Tavern, near Media in Delaware Co. Sp. gr. = 2·611. The analysis gave :—

SiO_2.	Al_2O_3.	Fe_2O_3.	MgO.	CaO.	BaO.	Na_2O.	K_2O.	Ignition.	Total.
58·42	23·14	0·18	0·35	3·13	2·56	3·68	7·06	1·54	100·06

The Presley Mine in Haywood Co., N.C., has furnished some remarkable specimens of corundum altered into albite and muscovite. Analyses of the albite (I) and of the muscovite (II) are given :—

	SiO_2.	Al_2O_3.	Fe_2O_3.	MgO.	CaO.	Na_2O.	K_2O.	Ignition.	Total.
I.	65·52	22·25	trace	—	1·96	9·54	0·53	0·22	100·02
II.	45·26	36·33	1·96	0·14	0·35	0·48	11·09	4·50	100·11

Corundum altered chiefly into damourite has been found at Belt's Bridge, Iredell Co., N.C. After deducting 3·51 per cent. of corundum, the analysis of the mica gave :—

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	Li_2O.	Na_2O.	K_2O.	Ignition.	Total.
45·96	38·22	0·61	0·37	trace	0·74	9·21	4·89	100·00

From the same locality a fragment of a hexagonal prism was found. It consisted of a core of grey corundum surrounded by mica enclosing tourmaline, and disseminated through the unaltered tourmaline are rounded masses of garnet. The analysis of the mica gave:—

SiO_2.	Al_2O_3	Fe_2O_3.	CaO.	Li_2O.	Na_2O.	K_2O.	Ignition.	Total.
44·03	40·16	trace	3·14	trace	1·42	6·66	5 04	100·45

4. *Corundum altered into Margarite.*—This change is far less common than that into potassium mica. Remarkable specimens occur at Hendrick's Farm, Iredell Co. The analysis of the purest margarite obtainable gave:—

SiO_2.	Al_2O_3.	Fe_2O_3.	MgO.	CaO.	LiO_2.	Na_2O.	K_2O.	Ignition.	Total.
32·55	48·87	0·60	0·23	10·48	trace	2·38	0·43	4·34	99·88

5. *Corundum altered into fibrolite* is found at Norwich, Conn., and at Shoup's Ford, Burke Co., N.C.

6. *Corundum altered into cyanite* is found at Statesville, Iredell Co., and in Wilkes Co., N.C.

The author comes finally to the conclusion that since the great gravel deposits in the S. States of N. America were formed, no alteration of the corundum in these deposits has taken place.

B. H. B.

Gahnite. By F. A. Genth (*Jahrb. f. Min.*, 1883, 2, Ref., 321—322).—In the Deake Mica Mine, Mitchell Co., N.C., a mineral occurs which the author recognised as gahnite. It is apparently without form, has a splintery to conchoidal fracture and a dark green colour. H. = 7·5. Sp. gr. = 4·576. It gave on analysis the following results:—

Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CuO.	ZnO.	MgO.	Total.
54·86	4·50	1·14	0·29	0·30	38·05	0·79	99·93

Gahnite has also been found at the Cotopaxi Mine, Chaffee Co., Colorado. Carefully selected material gave on analysis the following results:—

Al_2O_3.	Fe_2O_3.	FeO.	ZnO.	MgO.	Total.
60·76	0·58	4·56	23·77	10·33	100·00

The gahnite from Cotopaxi is frequently coated with a white earthy mineral, soluble in strong boiling hydrochloric acid. It gave on analysis the following results:—

Ignition.	SiO_2.	Al_2O_3.	Fe_2O_3.	CuO.	PbO.	ZnO.	MgO.	Total.
13·82	28·08	18·20	4·32	0·82	1·80	1·75	29 85	98·64

Lead and zinc are probably present as carbonates, the Fe_2O_3 as such, and if these impurities be deducted, the composition places the mineral near ripidolite.

Another alteration of the gahnite is that into a micaceous chloritic mineral, which gave on analysis:—

SiO_2.	Al_2O_3.	FeO.	CuO.	ZnO.	MgO.	Ignition.	Total.
31·15	13 12	10·74	0·77	0·39	29·23	11·78	97·18

B. H. B.

Apatite from Horrsjöberg, Sweden. By IGELSTRÖM (*Jahrb. f. Min.*, 1883, 2, Ref., 312—313).—Apatite occurs at Horrsjöberg, together with disthene, lazulite, rutile, menaccanite, damourite, talc, triplite, and quartz, in beds conformable to the surrounding gneiss. The analysis gave:—

P_2O_5.	Ca.	FeO. MnO.	
41·14	50·56	trace	B. H. B.

Turquoise Found at Alexandria. By A. FRENZEL (*Jahrb. f. Min.*, 1883, 2, Ref., 315).—The analysis of a turquoise found at Alexandria gave the following results:—

P_2O_5.	SO_3.	Al_2O_3.	Fe_2O_3.	CuO.	H_2O.	Organic matter.	Total.
28·14	0·68	41·09	1·08	4·54	20·96	4·49	100·98

It had a dark-green colour. H. = 5; sp. gr. = 2·39. It probably was brought to Alexandria from Sinai. B. H. B.

Roemerite, Botryogen, and Native Magnesium Iron Sulphate. By J. BLAAS (*Monatsh. Chem.*, 4, 833—849).—Berzelius, in 1815, described as "red iron vitriol" a mineral which was afterwards more exactly investigated by Haidinger, from whose analysis it appeared to be a hydrated sulphate of iron and magnesium. The crystals were found to be monoclinic, and from their tendency to aggregate in spherical groups, attached like bunches of grapes, the mineral received the name of *botryogen*.

Grailich, in 1858, described a new mineral, *roemerite*, which, from an analysis by Tschermak, appeared to be a hydrated sulphate of iron and zinc, and from a crystallographic examination by Grailich himself was inferred to be monoclinic, and closely related to botryogen. More recently a mineral having the characters of roemerite, but in better defined crystals, has been obtained from Persia, and examined by the author, who has shown that it has the chemical composition of roemerite, and that the crystals belong, not to the monoclinic, but to the triclinic system, exhibiting the axial ratio $a : b : c = 0·8791 : 1 : 0·8475$, and the axial angles $bc = 89° 44'$; $ac = 102° 17'$; $ab = 85° 18'$. The paper gives elaborate details of the crystallographic and optical characters of the mineral.

The differences between roemerite and botryogen may be tabulated as follows:—

	Roemerite.	Botryogen.
Crystalline form	Triclinic	Monoclinic
Habit.................	Tabular	Short prismatic
Colour	Light to dark-brown violet	Hyacinth-red to yellow
Dichroïsm.............	Weak	Very decided

The author has also examined another mineral from Fahlun in Sweden, hitherto regarded as botryogen. It forms stalactites or crusts, orange-coloured on the surface, white beneath, the orange colour disappearing when the mineral is moistened and kept for some time in a closed vessel. On closer examination, the mineral is seen to be formed of several portions, partly superposed, partly intergrown, the lowest layer consisting of a green crystalline mass resembling ferrous sulphate, but much lighter in colour, and having here and there a radiate structure. Above this is a layer composed chiefly of small splinters of magnesium sulphate imbedded in a yellowish-white fibrous mass. Chemical examination showed the presence of magnesia in the substratum consisting chiefly of ferrous sulphate, and, on the other hand, the crystals of magnesium sulphate were found to contain ferrous oxide.

An analysis of these crystals separated from the whitish-green substratum gave 31·57 per cent. SO_3, 7·25 FeO, 9·05 MgO, 1·64 Al_2O_3, and (by difference) 50·49 water.

The compound $Fe_2SO_4 + 7H_2O$ is known to be dimorphous, crystallising in the monoclinic system as *melanterite*, and in the rhombic as *tauriscite*, while $MgSO_4 + 7H_2O$ is likewise dimorphous, separating in monoclinic crystals, like those of melanterite, at temperatures between 25° and 30°. It is therefore not surprising that these two members of the isomorphous group $R''SO_4 + 7H_2O$ should occur together in nature, as well as when artificially crystallised.

H. W.

Rutile and Zircon from the Itacolumite of Edge Hill. By F. A. Genth (*Jahrb. f. Min.*, 1883, 2, Ref., 322).—The itacolumite rocks of the Potsdam sandstone of Edge Hill, Bucks Co. Pa, contain exceedingly minute yellow grains consisting of rutile. Associated with the yellow grains are small crystals of tourmaline, menaccanite, and colourless or brownish-white zircons, showing the planes ∞P, P, $\infty P\infty$, $3P3$.

B. H. B.

Chemico-mineralogical Studies on Italian Minerals. By A. Funaro and L. Busatti (*Gazzetta*, 13, 433—436).—1. *Wollastonite from Sardinia.*—This mineral is found at S. Vito, a mineralogical district of Sarrabus in Sardinia, implanted on certain schists in small needles grouped in stars or rosettes. Colour light-grey. Transparent or translucent. Lustre strong and nacreous, especially along the cleavage-planes. Powder white. Hardness, 4·5. Density, 2·7 to 2·8. Heated before the blowpipe in small splinters, it melts with great difficulty, and only along the edges, to a tumefied transparent glass. Gently heated with strong hydrochloric acid it dissolves and gelatinises. Its analysis gives: 49·78 SiO_2, 45·12 CaO, 1·20 MgO, 2·20 Fe_2O_3, 0·6 H_2O = 98·90, whence, regarding the greater part of the water as combined with the ferric oxide, and the excess as an impurity, varying in specimens of the mineral from different localities, we find, reducing the numbers to 100 parts: 51·80 SiO_2, 46·95 CaO, and 1·25 MgO; and hence, calculating the magnesia together with the lime, we deduce the formula $SiCaO_3$.

The rock on which this wollastonite is implanted is dark-coloured, almost black, compact, tenacious, and possesses considerable hardness. It is composed of silica, alumina, and graphite, with mere traces of earthy-alkaline metals, perhaps due to wollastonite penetrating its mass, and not separable by mechanical means. When examined with the microscope in very thin sections, it appears to be composed of granulo-crystalline silica diffused through a petro-siliceous groundmass or magma, exhibiting scattered reddish spots referable to limonite, and numerous black, opaque, irregularly disseminated masses, apparently consisting of graphite, and so abundant in certain sections as to render the specimen perfectly opaque. In this rock, the wollastonite appears in small crystalline masses recognisable by its fibrous structure, absence of colour, and the tints which it exhibits in polarised light.

2. *Chlorite from the Bottino* (*Serravezza*).—The chlorite of this mineralogical district in the Apuan Alps occurs massive and in radiate groupings, amongst the beautiful crystallisations of metallic sulphides in the quartzoso-metalliferous vein of the said district.

Aspect scaly; colour apple-green. Lustrous and minutely crystalline. The powder appears under the microscope to consist of minute greenish scales or crystalline laminæ joined together in a spiral column. The crystalline laminæ, usually of rounded outline, often exhibit the form of regular hexagons. When very thin, they are perfectly transparent, slightly dichroic, and exhibit faint interference colours. Hardness about 1·5. Density 2·8 to 2·9. With borax the mineral forms a bead, reddish-yellow while hot, changing as it cools to light green, and finally to yellow. Heated in a closed tube, it gives off water, turns brown, and retains that colour if heated to redness on platinum foil. Strong hydrochloric acid attacks it, eliminating at first a small quantity of carbonic anhydride, and on prolonged ebullition decomposes it completely, with deposition of gelatinous silica.

Quantitative analysis of several specimens showed the absence of alkaline bases and the presence of traces of lime in a few specimens only. The chief constituents are iron in the ferrous state, alumina, silica, and magnesia. By quantitative analysis of a specimen free from lime, Funaro obtained the results given on the first line of the following table, those on the second and third lines having been obtained respectively by Erlenmeyer and Nies (Rammelberg's *Handbuch der Mineralogie*, i, 495).

SiO_2.	Al_2O_3.	FeO.	Fe_2O_3.	MgO.	CaO.	H_2O.	CO_2.		
23·69	21·63	34·33	4·27	4·82	—	7·00	4·12	=	100·06
25·72	20·69	27·79	4·01	11·70	—	10·05	—	=	99·96
23·67	21·26	29·41	8·17	1·75	1·28	8·83	1·01	=	98·38

Achiardi in his *Mineralogia della Toscana* (ii, 231) mentions this chlorite, which, with reference to its external characters, he regards as a *ripidolite*, and especially as belonging to the variety called *aphrosiderite*. This conclusion is in accordance with the analyses above given. The constant presence of carbonic acid in this aphrosiderite leads to the idea that its normal composition has undergone some alteration, inasmuch as the carbonic acid must be regarded as combined with the ferrous oxide or the magnesia, and not as entering into the chloritic molecule. H. W.

Mineralogical Notices. By G. FREDA (*Gazzetta*, 13, 498—499).—1. *Green Humites from Monte Somma.*—Large crystalline grains having a light green colour and vitreous lustre. H. 6·5. Sp. gr. 3·21. Infusible before the blowpipe; loses 1·08 per cent. when strongly heated. II. *Cupriferous Variety of Pyroxene.*—Irregular kidney-shaped lumps of various sizes, having a fine sky-blue colour, and very fine granular texture. H. 5·5. Sp. gr. 3·19. Melts before the blowpipe to a glass having the colour of turquoise; its powder, which has an ashy colour, assumes a fine roseate tint when heated in the air. III. With some specimens of the last-described substance, there occurs a colourless highly translucent mineral, having a dull glassy lustre; hardness a little less than that of fluorspar, and sp. gr. = 3·05; it melts before the blowpipe to a limpid glass. IV. *New Case of Metamorphism of Leucite.*—In certain crystalline masses from Somma there occur, in the midst of a mixture of melilite, magnesia-mica, and pleonast, large scattered nodules of leucite, presenting the singular character of being formed of a white opaque zone enclosing a yellow glassy nucleus of undecomposed leucite.

The following are analyses of these minerals:—IV *a* is the white zone; *b* the same deprived of calcium carbonate; *c* the leucite nucleus.

Alteration of Talc into Anthophyllite. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 320—321).—In Pennsylvania unaltered olivine rock has never yet been found. An enstatite rock has, however, been found containing small grains of olivine. It is best developed at Castle Rock, Delaware Co., and near Wood's chrome mine, Lancaster Co. Grains of chromite are disseminated throughout all the olivine rock, and throughout the serpentine which has resulted from the alteration of this rock. This is also the case with a talc which occurs near Castle Rock. This talc has a sp. gr. of 2·789 and H. = 2. The analysis gave:—

SiO_2.	Chromite.	Cr_2O_3.	Al_2O_3.	NiO.	FeO.	MgO.	H_2O.	Total.
62·48	0·20	0·13	0·59	0·16	4·95	27·60	4·81	100·92

It is now converted into anthophyllite, for it is enveloped by a radiated fibrous mineral, which encloses, like the original talc, grains of chromite. Its sp. gr. is 2·983. The analysis gave—

SiO_2.	Al_2O_3.	Cr_2O_3.	FeO.	MnO.	NiO.	MgO.	Na_2O.	K_2O.	H_2O.	Total.
56·88	2·45	trace	9·20	0·28	0·17	28·50	0·18	0·03	2·28	99·97

This analysis corresponds with that of the anthophyllite from Hermannschlag. B. H. B.

Talc, Pseudomorphous after Magnetite. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 321).—Near Dublin, in Harford Co., Md., a coarse scaly chlorite, in immediate contact with talc slate, has disseminated through it numerous small octohedrons of talc pseudomorphous after magnetite, an alteration which has never been observed before. In these crystals, the talc scales are arranged parallel to the octohedral planes, whilst in the centre there is occasionally a small nucleus of magnetite, sometimes associated with pulverulent limonite. B. H. B.

Pyrophyllite in Anthracite. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 323).—Pyrophyllite has recently been found near Drifton, Luzerne Co., Pa. It is found in the stratification planes and fissures, and also in the most compact anthracite. Sp. gr. = 2·81.

The analysis of a specimen from Cross Creek Colliery, near Drifton, gave:—

SiO_2.	Al_2O_3.	Fe_2O_3.	H_2O.	Total.
65·77	29·36	0·12	4·85	100·10

B. H. B.

Occurrence of Kaolin in North Sweden. By A. LINDSTRÖM (*Jahrb. f. Min.*, 1883, 2, Ref., 365—366).—From the sketch map given by the author it may be seen that all the localities at which kaolin is found are situated in a zone 11—16 km. broad, and 48—54 km. long, where iron gneiss forms the adjacent rock. B. H. B.

Alteration of Orthoclase into Albite. By F. A. GENTH (*Jahrb. f. Min.*, 1883, 2, Ref., 320).—In the gneiss of Upper Avondale, Delaware Co., Pa., druses have been found lined with crystals of albite, muscovite, and sometimes with beryl, tourmaline, and calcite. The colourless albite crystals form a coating either directly above flesh-coloured orthoclase or, sometimes, with the intermediate development of greyish-white plagioclase. Analyses of the albite (I) and the flesh-coloured orthoclase (II) are given. In some instances there is, between the orthoclase and albite, a greyish felspar, which proves on analysis (III) to be a mixture of albite and oligoclase, the oxygen ratio being 1 : 3·1 : 10 6. At the same locality orthoclase has also been found in colourless crystals (Analysis IV) and in a white cleavage mass (Analysis V).

B. H. B.

Beryl and Allanite from Alexander Co., N.C. By F. A. Genth (*Jahrb. f. Min.*, 1883, 2, Ref., 322).—The analysis of a beryl, with a sp. gr. of 2·703, gave the following results:—

SiO_2.	Al_2O_3.	Be_2O_3.	FeO.	H_2O.	Total.
66·82	18·60	13·61	0·22	0·83	100·08

An analysis of allanite, with sp. gr. = 3·005, from the same locality, gave:—

SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	$(CeDiLa)_2O_3$.	Y_2O_3.	MgO.	CaO.	Na_2O.	K_2O.	Ignition.	Total.

B. H. B.

Occurrence of Gedrite as Essential Constituent of certain Rocks. By H. Sjögren (*Jahrb. f. Min.*, 1883, 2, Ref., 366—367).—Gedrite, a rhombic anthophyllite rich in alumina, occurs as essential constituent of several Scandinavian rocks. An analysis of this mineral from Hilsen gave the following results:—

SiO_2.	Al_2O_3.	FeO.	MnO.	CaO.	MgO.	Ignition.	Total.
43·92	11·34	16·81	1·47	3·02	19·14	1·68	97·38

The alkalis were not determined.

An amphibolite schist from Hilsen, near Snarum, was found on examination to be composed half of gedrite and half of black hornblende; biotite, apatite, rutile, and magnetic pyrites occurring as accessory constituents. B. H. B.

The Phyllites of the Tyrolean Alps. By A. Pichler (*Jahrb. f. Min.*, 1883, 2, Ref., 366). This paper gives the results of the microscopic investigation of the numerous varieties of phyllite (clay-slate) which are found in the Tyrolean Central Alps. Microscopic tourmaline occurs to a great extent, and is very characteristic. An appearance similar to the fluxion structure may frequently be detected.

B. H. B.

Hornblende-diabase from Gräveneck. By A. STRENG. (*Jahrb. f. Min.*, 1883, 2, Ref., 367—369).—This diabase, interesting on account of the large amount of basaltic hornblende it contains, occurs at Gräveneck near Weilburg on the Lahn.

The rock is of a blue to greenish-grey colour. The analysis of the diabase disseminated through it gave the following results:—

SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	Na_2O.	H_2O.	Total.
44·13	2·66	7·45	7·73	7·02	20·46	10·64	0·90	1·00	101·99

Crystals of basaltic hornblende occur more rarely. The analysis of pure material, with sp. gr. = 3·25, gave:—

SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	K_2O.	Na_2O.	H_2O.	Total.
41·35	4·97	13·48	5·14	10·33	10·93	11·44	0·62	2·10	0·48	100·84

Among the other minerals disseminated through the mass, plagioclase, iron-ore, pyrites and apatite may be mentioned. The iron ore is strongly magnetic, and contains 17·81 per cent. of TiO_2. In conclusion, Senfter's complete analysis of this rock is given (this Journal, 1873, 738).

B. H. B.

Diabase rich in Apatite from Gräveneck. By A. STRENG (*Jahrb. f. Min.*, 1883, 2, Ref., 369—370).—This diabase occurs at Gräveneck. It contains an unusual amount of apatite columns with the forms ∞P, P, 0P, ∞P2. The composition of the rock is in other respects quite normal. The analyses gave the following results:—

TiO_2.	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	MgO.	K_2O.	Na_2O.	H_2O.	CO_2.	P_2O_5.	Total.
2·08	46·53	18·07	6·13	7·77	0·30	7·87	3·78	0·55	3·51	2·17	0·51	1·33	100·60

B. H. B.

Nepheline Rocks from the Vogelsberg. By H. SOMMERLAD (*Jahrb. f. Min.*, 1883, 2, Ref., 372).—With the nephelinite of Meiches, a basalt occurs in which Ludwig found the nephelinite in the form of veins 1·5 mm. thick. This proved to be a nepheline-basalt (Analysis I) with sp. gr. = 3·103. The nepheline-dolerite of Gunzenau occurs in blocks. The microscopic examination of the rock showed it to have the normal composition of a nepheline-tephrite, with dark mica and some olivine as accessory constituents. Sp. gr. = 2·745. The analysis gave the results given under II. The phonolites shown on the geological map of the Grand Duchy of Hesse, near Salzhausen and Herchenhain, appear to be trachytoid phonolites poor in nepheline, whilst those near Wohnfeld and Wennigs are basalts with a very coarsely granular structure and light colour. An analysis of the rock from Ziegenhals, near Wohnfeld, is given (III).

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	K_2O.

B. H. B.

Phonolites of Elfdalen. By A. E. TÖRNEBOHM (*Jahrb. f. Min.*, 1883, 2, Ref., 370—371).—The author has discovered three veins of the so-called phonolite of Elfdalen traversing porpyhyry and, perhaps, also sandstone at Heden, in Dalarne. The new material allowed a more exact petrographical examination than has been the case hitherto. The ground-mass is finely granular and crystalline, and is composed of felspar, cancrinite, nepheline, aegirine, titanite, and apatite; whilst felspar and cancrinite occur in porphyritic crystals. The felspar is orthoclase, microcline, and plagioclase. The cancrinite is, when fresh, colourless and perfectly clear, but alters into a brick-red and almost opaque mass, which was formerly thought to be felspar converted into zeolite. For the rock, the author proposes the name Cancrinite-aegirine-syenite. This is not only the first time that cancrinite has been found in Sweden, but also the first time that cancrinite has been proved to be an essential constituent of a rock.

B. H. B.

Analysis of a Meteorite which fell at Alfianello on the 13th of February, 1883. By G. CAVAZZI (*Gazzetta*, 13, 492).—The analysis of this meteorite gave 45·1 per cent. SiO_2, 3·7 S, 26·38 MgO, 19·8 Fe (as sulphide, phosphide, silicate, and metallic), perceptible traces of phosphorus, nickel, and sodium, scarcely perceptible traces of potassium, aluminium, calcium, manganese, and copper. H. W.

Meteorite of Alfianello. By W. FLIGHT (*Proc. Roy. Soc.*, 35, 258—260).—In this paper an analysis is given of a meteorite which fell on February 16th, 1883, at Alfianello, in the district of Verolannova, in the province of Brescia, Italy. The fall was accompanied by a loud detonation heard in the neighbouring provinces.

In structure, the meteorite belongs to the group sporadosideres oligosideres, and resembles aumalite, being nearly identical with the meteorite of New Concord, Ohio.

It was finely granular, containing disseminated metallic grains; its sp. gr. was 3·47 to 3·5.

On analysis, the following numbers were obtained:—

Troilite..................	6·919
Nickel iron	2·108
Soluble silicate	50·857
Insoluble silicate..........	40·116

The soluble silicate contained the following constituents:—

Silica	35·12
Ferrous oxide	51·43
Alumina	1·518
Lime	4·644
Magnesia	7·269

And the insoluble silicate had the composition—

Silica	56·121
Ferrous oxide	13·397
Chromic oxide	8·281
Lime	6·712
Magnesia	17·263

From the results, it appears not improbable that this latter portion contains some tridymite. V. H. V.

Organic Chemistry.

Physical Properties of Petroleums. By S. Pagliani (*Gazzetta*, **13**, 495).—Mendelejeff found, for the petroleum of Baku, a very simple relation between the densities and boiling points of the several fractions, represented by the equation $d = a + bt$, in which a and b are constants, the values of which have to be determined by experiment for different intervals of temperature and for different kinds of petroleum in the same intervals. For the fractions of Baku petroleum boiling at 100—180°, Mendelejeff found $d = 669·5 + 0·80t$, and for the interval 180—240°, $d = 712·9 + 0·56t$, the density of water at 15° being taken as 1000. For the petroleum of Montechino near Montanaro (Piacenza), the author finds the following relations:—

t ..	60—69°	90—100°	130—200°	200—250°
d ..	$504·8 + 2·42t$	$593·1 + 1·68t$	$704·7 + 0·61t$	$608·2 + 0·81t$

These densities are somewhat greater than those found by Mendelejeff for the Russian petroleum. H. W.

Dibromodinitromethane. By S. M. Losanitsch (*Ber.*, **16**, 2730—2731).—The author gives analytical data showing that the compound which he described as dibromodinitromethane is not a mixture of monobromodinitromethane and carbon tetrabromide, as Kachler and Spitzer (*Ber.*, **15**, 471; **16**, 51) assume. W. C. W.

Conversion of Fulminates into Hydroxylamine. By A. Steiner (*Ber.*, **16**, 2419—2420).—In a former communication (Abstr., 1883, 1074) the author has shown that mercury fulminate yields hydroxylamine when treated with hydrochloric acid; a quantitative examination of this reaction shows that both the nitrogen-atoms of the fulminate are converted into hydroxylamine, lending additional support to the hypothesis that fulminic acid is an isonitroso-compound, having the formula HO.NC : CN.OH. Moreover, in mercury fulminate, the mercury can be replaced by acid radicles, by acting upon it with acetic or benzoic chlorides, and the author hopes to obtain a further clue to the constitution of fulminic acid from a study of the compounds formed. P. P. B.

Absorption of Ammonia-gas by Alcohols. By S. PAGLIANI and EMO (*Gazzetta*, **13**, 278).—It has been shown by one of the authors, in conjunction with Nacari, that ammonia-gas, unlike the majority of gaseous bodies, is more soluble in water than in ethyl alcohol. The present paper contains the details of similar experiments with normal propyl and isopropyl alcohols, leading to the following conclusions:—

1. Ammonia-gas is much more soluble in water than in the alcohols mentioned.

2. Ammonia-gas, within the limits of pressure observed (417 to 734 mm.), does not conform, in its absorption by these alcohols, to Henry's law, the values of $\alpha \frac{760}{P}$ not being constant, but tending at any given temperature to diminish with increase of pressure, behaving indeed in this respect as with water.

3. At equal pressure, as for all other gases, the coefficient of solubility of ammonia-gas increases with diminution of temperature.

4. At equal temperatures and pressures, the coefficient of solubility (at least for these three alcohols) diminishes as the molecular weight of the alcohol increases. H. W.

Action of Polyhydric Alcohols on Borax. By W. R. DUNSTAN (*Pharm. Journ.* [3], **14**, 41—44).—The author has previously shown (*Pharm. Journ.* [3], 1325) that when certain polyhydric alcohols, mannitol, erythrol, glycerol, saligenol, pyrogallol and guaiacol as well as dextrose, levulose, lactose, and mycose, are added in aqueous solution to a moderately strong solution of sodium pyroborate, they produce an acid reaction in this alkaline liquid; this acid solution becomes alkaline when largely diluted with water or when heated, in which case the liquid becomes acid again on cooling. If much more of the substance is added than is necessary to produce a distinctly acid reaction, no change is effected by heat or by dilution. These effects are not well defined when litmus is employed as an indicator, but are very distinct with phenolphthaleïn. Glycocine, which has many reactions in common with the above compounds, does not react in this way. In the present paper, the general reaction which gives rise to the above results is investigated. The action of glycerol on sodium pyroborate has been examined by Senier and Lowe (*Pharm. Journ.* [3], 8, 819), who concluded that boric acid, and a more basic sodium borate were formed, but were unable either directly or indirectly to isolate the free boric acid. The author shows that when anhydrous glycerol and anhydrous sodium pyroborate are heated together at 120°, water is given off, and on extracting the mass with ether an uncrystallisable, extremely deliquescent body is obtained, which imparts a green tinge to the Bunsen flame. It was not appreciably acid in reaction, but became so on adding a small quantity of water, when a crystalline mass was formed and recognised as boric acid. This aqueous solution also contained glycerol. The original mass, after being extracted with ether, contained sodium metaborate. Thus the action of anhydrous glycerol on anhydrous sodium pyroborate yields *glycerol-borin*, ($C_3H_5BO_3$), and sodium metaborate; the former compound is decomposed by water yielding boric acid and regenerating glycerol, hence the acidity which is produced when aqueous solutions of sodium pyroborate and glycerol are mixed. The above reactions are represented thus:

$$2C_3H_5(OH)_3 + 2NaBO_2,B_2O_3 = 2C_3H_5BO_3 + 2NaBO_2 + 3H_2O.$$

As water itself is a product of this decomposition, the reaction is never complete, except at high temperatures, owing to the partial conversion of the glycerol-borin into boric acid, thus: $C_3H_5BO_3 + 3H_2O = C_3H_5(OH)_3 + H_3BO_3$. In aqueous solution, the reaction is $2C_3H_5(OH)_3 + (2NaBO_2,B_2O_3) + 3H_2O = 2NaBO_2 + 2H_3BO_3 + 2C_3H_5(OH)_3$. The action of mannitol on sodium pyroborate has been studied by Klein (*Bull. Soc. Chim.*, **29**, 359), who, by precipitating aqueous solutions of these compounds with alcohol, obtained a substance which was not fully examined, but was supposed to be a conjugate acid. In a similar manner Klein obtained a barium biboromannitate. The author points out that Klein's investigation deals only with a secondary reaction, owing to the influence of the water employed in his experiments. By the action of anhydrous mannitol on anhydrous sodium pyroborate at 140°, a mass was obtained which yielded to ether a substance crystallising with difficulty in feathery tufts and giving a vivid green flame reaction. This body was easily soluble in absolute alcohol, the solution being but faintly acid, although the aqueous solution was strongly so, and gave the reaction for boric acid and for mannitol. The mass which had been extracted by ether contained sodium metaborate. These experiments indicate that mannitol decomposes sodium pyroborate in a manner similar to glycerol. The action of dextrose and levulose, when heated with anhydrous sodium pyroborate, was also examined, and in each case a substance was extracted by ether giving a green flame reaction, whilst the residue contained sodium metaborate.

The nature of the primary reaction between sodium pyroborate and glycerol, mannitol, dextrose, and levulose having been thus determined, it was found by further experiments that the change from acidity to alkalinity, occasioned by heat in aqueous solutions, was due to the dissociation of the undecomposed sodium pyroborate and metaborate. When boric acid or other acid is added to an aqueous and therefore partially decomposed solution of sodium meta- or pyroborate, until the liquid is faintly acid, alkalinity is reproduced by the addition of more water as this further decomposes these salts, liberating alkali in quantity more than sufficient to neutralise the acid.

The same result is obtained when the faintly acid liquid is heated, but the acidity is reproduced as the solution cools. W. R. D.

Synthesis of Lecithin. By F. HUNDESHAGEN (*J. pr. Chem.* [2], **28**, 219—255).—As Diaconow has stated that lecithin splits up into neurine and disterylglycerolphosphoric acid on treatment with dilute sulphuric acid, the first step towards the synthesis of lecithin was to prepare this acid, which can exist in two isomeric forms: $(CH_2.OSt)_2CH.O.PO(OH)_2$ or $CH_2(OSt).CH(OSt).CH_2.O.PO(OH)_2$, where $St = CO.C_{17}H_{35}$. Two general methods seemed to be adapted for this purpose, namely, substitution of the hydroxylic hydrogen in glycerolphosphoric acid by stearyl, or the union of phosphoric acid with a glyceryl stearate. From the readiness with which glycerolphosphoric acid decomposes, experiments based on the first method did not yield the desired result, although they gave rise to some new compounds which are described further on.

Amongst the reactions founded on the second method, the action of phosphoric acid, tribasic potassium phosphate, and phosphorus oxychloride on tristearin all failed to form the distearyl acid, but better results were obtained with distearin.

Monostearin was prepared by heating stearic acid with anhydrous glycerol (2·5 parts) in sealed tubes at 200—220° for about 40 hours; and the upper layer consisting of the crude monostearin was purified by repeated crystallisation from alcohol and ether. It melts at 60—62°, and is very soluble in warm alcohol and ether. The *distearin* was prepared by heating molecular weights of stearic acid and crude monostearin in a retort at 150—180°, until the water which distilled over was that which should have been eliminated theoretically; it is advisable to somewhat increase the temperature (to 200°) towards the end of the reaction. To purify the crude product, it is first heated with absolute alcohol (50—60 parts), when the greater part of the distearin remains undissolved, and nearly all the rest is deposited as the liquid cools; the monostearin and stearic acid remain in solution. The distearin is then dissolved in hot light petroleum, agitated with calcium hydroxide to remove the last traces of stearic acid, and the distearin which separates on cooling is repeatedly recrystallised from light petroleum until its melting point is constant at 76·5°. It crystallises from hot alcohol, in which it is but sparingly soluble (1 : 150) in tufts of glistening needles. From ether, petroleum, benzene, &c., in which it is far more soluble, it separates in compact nodules built up of slender needles.

Although there appeared to be another isomeric distearin in the mother-liquors, as well as other easily soluble compounds, the author was unable to isolate them, and therefore confined his investigations to the derivatives of the distearin just described, which he calls α-distearin.

Ammonium distearyl glycerol, $C_3H_5(OSt)_2.ONH_4$, is obtained as a voluminous precipitate consisting of thin prismatic crystals on passing dry ammonia into a warm ethereal solution of distearin. It is somewhat unstable, losing part of its ammonia on exposure to the air, and the whole at 100—120°. The corresponding sodium compound seems to be formed on treating a benzene solution of distearin with sodium; the metal dissolves, with evolution of hydrogen, and the liquid gradually becomes changed into an opalescent gelatinous mass.

Acetyl distearyl glycerol is formed when distearin is heated with acetic anhydride, acetic acid, and metaphosphoric acid at 120°; no doubt acetic anhydride alone with distearin would give the same result. After being purified by crystallisation from alcohol, it melts at 28—30°. It does not crystallise well, and decomposes when strongly heated.

α-Distearylglycerolphosphoric Acid.—This acid is formed when distearin is heated with ethylphosphoric acid, metaphosphoric acid, or phosphoric anhydride. The best method is to heat the distearin with about its own weight of phosphoric anhydride for some hours at 100—110°: the product is macerated under alcohol, digested for some time with warm alcohol to remove adhering phosphoric acid, and finally collected and washed with cold alcohol. The residue containing distearin and the glycerol acid is now extracted with hot alcohol, and excess of finely powdered sodium hydroxide is added to the hot solution, when carbonic anhydride is evolved, and the sodium salt of the acid separates; this is collected at once and washed with hot alcohol. In the washings there is, besides sodium stearate and ethyl stearate, a readily soluble sodium salt of an acid containing phosphorus, probably an isomeric distearylglycerolphosphoric acid; this crystallises in scales melting at about 60°. The crude sodium salt above mentioned is purified by repeated recrystallisation from light petroleum. The free acid may be obtained from this by dissolving it in a little warm acetic acid, decomposing it with dilute sulphuric acid, collecting the acid which is deposited in a flocculent state, and purifying it by solution in ether and evaporation. The acid is, however, more conveniently prepared from the ammonium salt obtained by passing ammonia into a warm petroleum solution of the crude acid, collecting the crystalline precipitate, and washing it with hot alcohol; when this is heated at 130—140° for some time, ammonia is given off, and the free acid is left. It crystallises from its solutions as a fatty mass consisting of minute needles, which soften at 55° and melt at 62·5°. It is easily decomposed when heated with dilute acids. The author has prepared and described the potassium, sodium, ammonium, calcium, ferrous, ferric, copper, lead, silver, and mercury salts of the α-distearylglycerolphosphoric acid. Both the acid and its salts burn with a green-edged flame when strongly heated.

α-Distearylglycerolphosphoric chloride is formed when distearin (4 parts) is heated with phosphorus oxychloride (1 part); hydrochloric acid is evolved, and a very dark-brown liquid is left; this is first freed, as far as possible, from hydrochloric acid and excess of oxychloride by a current of warm air, then taken up with ether, and the ethereal solution mixed with about twice its volume of absolute alcohol, when dark-brown impurities are thrown down and are removed by filtration. The ethereal solution is evaporated in a vacuum, and the crystalline crusts which form again dissolved in a little ether and evaporated. The colourless crystals of the chloride obtained in this way are very soluble in most menstrua, melt at 24°, and are somewhat hygroscopic. It is very readily decomposed; with water at the ordinary temperature, it yields stearic acid, glycerolphosphoric acid, and hydrochloric acid, but no distearylglycerolphosphoric acid.

When distearylglycerolphosphoric acid is warmed with a slight excess of neurine carbonate in alcoholic solution, and then evaporated, an indistinctly crystalline hygroscopic mass is left, which is easily soluble in water, alcohol, and ether. The neutral neurine distearylglycerolphosphate crystallises from the last-mentioned solvents in minute needles. The acid distearylglycerolphosphate,

$$C_3H_5(OSt)_2.O.PO(OH).ONMe_2.C_2H_4.OH,$$

is obtained by mixing neurine and the acid in proper proportions in alcoholic solution and evaporating. Its properties differ entirely from those of lecithin, so that these are isomeric compounds.

The author then gives an account of some neurine compounds. The *hydrochloride* is dimorphous, crystallising in long needles and in thin rhombic plates. The iodide of the hydrochloride, $ClNMe_2.C_2H_4I$, obtained by the action of strong hydriodic acid on the hydrochloride, separates from hot solutions in prisms, and from cold in rhombic plates. The iodide of the hydriodide forms thin iridescent plates. The platinochloride is trimorphous, crystallising in large orange-coloured prisms, in red-brown rhombic plates, and in regular octohedrons; both the other forms gradually change into the rhombic plates. This change can be easily seen under the microscope, and a detailed description of the best methods of observing it is given.

The platinochlorides of other two bases formed during the preparation of neurine are also described; one of these the author believes to be an amine, the other a higher homologue of neurine.

In an appendix, some substances which have been prepared in the course of this research are described.

By the action of metaphosphoric acid at 120—150° on distearin that was not quite pure, the sodium salt of an acid containing stearyl and phosphoric acid was obtained; it is easily soluble in water, and crystallises in needles which melt at about 35°. The sodium salt is insoluble in alcohol, but soluble in ether, and very soluble in water. It is possibly a monostearylglycerolphosphoric acid derived from monostearin existing as an impurity in the distearin.

Another sodium salt, insoluble in water, was obtained by treating ethyl phosphate with distearin in alcoholic solution, distilling off the residue, and converting the acids into sodium salts. The sodium salt is almost insoluble in water and ether, but easily soluble in aqueous alcohol, and crystallises in microscopic scales.

Monostearyldiglycerol, $C_3H_5(OH)(OSt).O.C_3H_5(OH)_2$, was prepared by heating stearic acid and glycerol at 230—250°. It is very soluble in ether and in hot alcohol, crystallising from the latter in microscopic plates which melt at about 30°.

Normal glyceryl phosphate, $C_3H_5\colon PO_4$, seems to be formed when glyceryl tribromide, $C_3H_5Br_3$, is treated with normal silver phosphate. A syrupy substance is obtained which, when heated with water, yields glycerolphosphoric acid. The normal phosphate seems to be decomposed in a somewhat similar manner by treatment with alcohol, for when glyceryl tribromide is heated at 200° with silver phosphate and absolute alcohol, two isomeric *diethylglycerolphosphoric acids* are formed, apparently $CH_2(OEt).CH(OEt).CH_2.O.PO(OH)_2$ and $(CH_2.OEt)_2.CH.O.PO(OH)_2$. The contents of the tubes are filtered from silver bromide, the alcohol removed by distillation, and the syrupy residue dissolved in water and saturated with barium carbonate. On concentrating the clear solution and adding alcohol, the barium salts are precipitated; these may, to a certain extent, be separated by carefully evaporating the aqueous solution of this precipitate; the barium salt of one of the acids thus separates as a white granular precipitate, whilst the amorphous barium salt of the other acid remains in solution. C. E. G.

Behaviour of Dextrose with Ammoniacal Alkaline Silver Solution. By B. TOLLENS (*Landw. Versuchs.-Stat.*, 29, 392—395).—With silver solution containing 0·024 gram Ag to the cubic centimeter, and prepared with equal quantities of silver nitrate and caustic soda dissolved in excess of ammonia, dextrose reduces 12 atoms of silver: the reaction seems to follow the equation $C_6H_{12}O_6 + 6O = 6CH_2O_2$, formic acid being the chief product. The author discusses the bearings of this reaction on the constitution of dextrose, and infers that it does not contain either an aldehyde or ketone group. J. K. C.

A New Saccharin from Milk-sugar. By H. KILIANI (*Ber.*, 16, 2625—2629).—By the action of lime on milk-sugar and on maltose, Cuisinier (*Monit. Scient.*, 1882, 520) obtained the lime salt of a lactone, $C_6H_{10}O_5$, which he named isosaccharin to distinguish it from Peligot's saccharin. In preparing large quantities of isosaccharin, the author has discovered a new saccharin (*metasaccharin*). 1 kilo. milk-sugar is dissolved in 9 litres of water, 450 grams of calcium hydrate added to the cold solution, and the whole allowed to stand for six weeks with repeated agitation; the clear brown solution is separated by a syphon, saturated with carbonic anhydride, and heated to boiling. On evaporating the filtrate to about 2 litres, an abundant separation of calcium isosaccharylate takes place, and, after 24 hours, is filtered off and washed with cold water. After leaving a portion of the filtrate for several months in a closed bottle, a crystalline layer separated at the bottom, whilst mould formed on the surface of the liquid, and on purifying the crystals, a calcium derivative was obtained very sparingly soluble in cold water and crystallising in nodules or hard crusts consisting of microscopic prisms. It is the calcium compound of a new saccharinic acid, its formula being $(C_6H_{11}O_6)_2Ca + 2H_2O$; it loses its water of crystallisation at 120—130°. On decomposing its solution with oxalic acid and evaporating the filtrate, moderately large colourless rhombic crystals of *metasaccharin* are obtained, having a slightly bitter taste, and showing a perfectly neutral reaction. Its formula is $C_6H_{10}O_5$, but its properties are very different from those of Peligot's saccharin and Cuisinier's isosaccharin; it crystallises in the rhombic system: $a : b : c = 0·6236 : 1 : 8988$. Its aqueous solution is lævorotatory $[\alpha]_D = -48·4$, whilst saccharin and isosaccharin are dextrorotatory. It softens at 135°, becomes completely liquid at 142°, and, after resolidifying, melts at 141—142°. It dissolves readily in cold water, its solubility being intermediate between that of isosaccharin and of saccharin; the solution becomes acid on standing, probably through the formation of metasaccharinic acid. It is readily soluble in alcohol, very sparingly in ether. Like saccharin and isosaccharin, it yields salts of the corresponding saccharinic acid by boiling with metallic oxides or carbonates; the copper salt, $(C_6H_{11}O_6)_2Cu + 2H_2O$, forms greenish wart-like clusters of microscopic scales. On repeating the experiment, the author finds that calcium metasaccharin is a constant product of the action of lime on milk-sugar. A. K. M.

Elementary Composition of Wheat-starch, and the Action of dilute Acetic Acid on Starch. By L. Schulze (*J. pr. Chem.* [2], **28**, 311—338).—The author has examined wheat-starch in the manner detailed by F. Salomon in his paper on potato-starch (Abstr., 1882, 1183), for the purpose of satisfactorily deciding whether the formula $C_{30}H_{52}O_{31}$, given by Naegeli, is correct. The results point conclusively, in the author's opinion, to the formula $C_6H_{10}O_5$. Wheat-starch carefully washed first with dilute caustic soda, then with dilute hydrochloric acid, afterwards with water, and finally air dried, was found to consist of 79·696 per cent. pure starch, 20·143 per cent. water, 0·061 per cent. ash, and 1·1 per cent. insoluble residue. Four series of experiments were carried out. I. The conversion of the starch by hydrochloric acid (the reaction is incomplete with sulphuric acid) and estimation of the resulting dextrose by a copper salt (Allihn's method): 100 parts absolutely pure starch (or 127 parts air dried) gave 110·986 parts dextrose, whilst theory requires 111·1 parts for the formula $C_6H_{10}O_5$. II. The conversion by hydrochloric acid and estimation of the dextrose by the sp. gr.; the average of four determinations gave 111·4 parts dextrose per 100 parts chemically pure starch. III. The conversion by hydrochloric acid and the observation of the rotatory power of the resulting dextrose solution; the average of four determinations gave 111·85 per cent. dextrose per 100 parts pure starch. IV. The elementary analysis of the purified air-dried starch, calculated from the amount chemically pure starch contained; the average of six combustions agrees with the formula $C_6H_{10}O_5$.

Little being known of the action of dilute acetic acid on starch, and that little being of a contradictory nature, a number of experiments on various starches with various strengths of acid were made. The best results were obtained with rice-starch in a 10 per cent. solution with 20 per cent. acetic acid. The results show that by heating rice-starch with acetic acid for four hours under pressure, almost the whole is converted into dextrin (Bondonneau's dextrin, α-modification), and only traces of dextrose are formed. By continued action of heat, however, the dextrin is slowly converted into dextrose.

Inulin in the Artichoke. By Pistone and De Regibus (*Pharm. Journ.* [3], **14**, 52).—The bracts of the artichoke, *Cynura scolymus*, were boiled with water and pressed, the liquid filtered, and again boiled and filtered when hot. The solution when slowly cooled deposited a white flocculent substance which, after being washed with boiling water and alcohol, was proved to be nearly identical with Sach's spherocrystals of inulin: it was not coloured by iodine, and was lævorotatory. W. R. D.

Chemical Composition of Woody Tissues. By N. SCHUPPE (*Pharm. Journ.* [3], **14**, 52).—The cellulose obtained from the woody tissues of pine, poplar, mahogany, American and European nut, oak, and alder, by treatment with nitric acid and potassium chlorate, has the same composition as pure cellulose, $C_6H_{10}O_5$. The wood of the European and American nut nearly coincides in composition with cellulose; that of mahogany and oak has the formula

$$C_{14}H_{24}O_{11} = 2C_6H_{10}O_5 + C_2H_4O,$$

and the wood of poplar and alder the formula $C_8H_{14}O_6 = C_6H_{10}O_5 + C_2H_4O$. The proportion of lignin to cellulose is fairly constant in different woods, 17·6 per cent. of lignin to 40·7 per cent. of cellulose. The author considers that lignin has the formula $C_{19}H_{18}O_8$, which is nearly identical with that of catechin, and hence obtains as an approximate formula for woody fibre, $5C_6H_{10}O_5 + C_{19}H_{18}O_8$. Only a trace of gum was found in the wood of conifers, but 3·25 per cent. in poplar and 7·09 per cent. in alder. W. R. D.

Action of Sulphonic Chloride on Secondary Amines. By R. BEHREND (*Annalen*, **222**, 116—136).—In studying the action of sulphonic chloride on ammonia, Regnault (*J. pr. Chem.*, **18**, 98) obtained sulphonamide, $SO_2(NH_2)_2$, but was unable to separate it from the simultaneously formed ammonic chloride. Wenghöffer (*J. pr. Chem.*, **16**, 448), in acting with sulphonic chloride on aromatic amines, obtained only chlorine-substituted amines. The author has studied the action of sulphonic chloride on secondary fatty amines, which behave very differently. The action of sulphonic chloride on dimethylamine has been already described (Abstr., 1881, 716), as also that of sulphonic chloride on the hydrochloride of dimethylamine (Abstr., 1882, 164), whereby dimethylamidosulphonic chloride is formed. An equally good yield is obtained if crude trimethylamine is employed; it is only, however, the dimethylamine in the latter which takes part in the reaction. If a chloroform solution of dimethylamidosulphonic chloride is added to dimethylamine, tetramethylsulphonamide is formed, which can be purified as above:—$SO_2Cl.NMe_2 + 2NHMe_2 = (NMe_2)_2SO_2 + NH_2Me_2Cl$. Tetramethylsulphonamide is decomposed by gaseous hydrochloric acid at 120°, dimethylamidosulphonic chloride and dimethylamine hydrochloride being formed:—$(NMe_2)_2SO_2 + 2HCl = SO_2Cl.NMe_2 + NH_2Me_2Cl$. Aniline and dimethylamidosulphonic chloride yield dimethylphenylsulphonamide, $Me_2N.SO_2NH.Ph$, crystallising in needles, and melting at 84—85°, was prepared. This body dissolves in sodium hydroxide with formation of a sodium compound, $NMe_2.SO_2.NPhNa$, which is decomposed by hydrochloric or carbonic acid, with reproduction of the sulphonamide. Similar compounds were prepared by employing paratoluidine instead of aniline. Dimethylamidosulphonic chloride is only slowly acted on by cold water, but on heating it is principally converted into dimethylsulphonamic acid, a small quantity of acid dimethylamine sulphate being formed at the same time:—

$$(1.)\ SO_2Cl.NMe_2 + H_2O = OH.SO_2NMe_2 + HCl.$$

(2.) $SO_2Cl.NMe_2 + 2H_2O = OH.SO_2.ONH_2Me_2 + HCl$. The ether of this acid was prepared by heating an alcoholic solution of dimethylamidosulphonic chloride with sodium ethylate:—$SO_2ClNMe_2 + NaOEt = NaCl + SO_2(OEt)NMe_2$. On reducing the amidosulphonic chloride with tin and hydrochloric acid, the following reaction takes place:—$SO_2Cl.NMe_2 + 4H_2 = SH_2 + NH_2Me_2Cl + 2H_2O$, whilst with zinc-dust the tetramethylsulphonamide is formed:—$SO_2ClNMe_2 + Zn = SO_2(NMe_2)_2 + ZnCl_2 + SO_2$. Diethylamidosulphonic chloride was prepared in the same way as the corresponding methyl compound; it is, however, far less active than the latter. By the action of dimethylamine on diethylamidosulphonic chloride, the same dimethyldiethylsulphonamide is formed as when diethylamine acts on dimethylamidosulphonic chloride, as was to be anticipated from analogy with the substituted carbamides. P. F. F.

Trimethylamine Aurochloride. By C. E. Zay (*Gazzetta*, **13**, 420—421).—This salt, originally obtained, but not described, by Vincent (*Bull. Soc. Chim.* [2], **27**, 194), is easily prepared by adding a concentrated solution of auric chloride to a solution of trimethylamine hydrochloride, washing the resulting precipitate on a filter with ether, which removes only the excess of gold chloride, whereas water would dissolve some of the aurochloride itself. The dried salt forms a crystalline mass having a fine chrome-yellow colour and an odour of putrid fish. It is permanent in a vacuum, but slowly turns brown on exposure to the air. On heating it, the fishy odour becomes stronger; at 220° the salt melts, and at higher temperatures it decomposes, leaving metallic gold. The salt is anhydrous, and has the formula $NMe_3HCl,AuCl_3$. It dissolves readily in water and in alcohol, but is insoluble in ether. The aqueous solution, when allowed to evaporate at ordinary temperatures, leaves the salt in well-defined transparent brown-yellow crystals, likewise anhydrous. H. W.

Tetramethylammonium Cyanide. By C. M. Thompson (*Ber.*, **16**, 2338—2345).—This compound can be obtained by adding an excess of hydrocyanic acid to a strong solution of tetramethylammonium hydroxide; the solution when evaporated yields a brown crystalline mass, which may be obtained in prisms by recrystallisation from alcohol. The cyanide may also be prepared by decomposing the double cyanide of silver and tetramethylammonium with sulphuretted hydrogen. This cyanide gives the reactions of cyanides, and is decomposed by the weakest acids, with liberation of hydrocyanic acid. It volatilises at 225—227° without melting, producing alkaline vapours having an odour of trimethylamine and carbylamine. Tetramethylammonium cyanide when saponified with caustic potash behaves like potassium cyanide, yielding ammonia, formic acid, and a tetramethylammonium compound.

Double salt of silver cyanide with tetramethylammonium cyanide,

$NMe_4CN,AgCN$, is obtained by adding silver cyanide to a warm solution of tetramethylammonium iodide. It crystallises from hot alcohol in long, slender, colourless needles; is slightly deliquescent, and insoluble in ether. benzene, light petroleum, and chloroform; it melts at 211—212°. This salt is also formed on adding silver cyanide to a solution of tetramethylammonium cyanide. On distillation, this double salt yields a residue of silver cyanide and a distillate containing trimethylamine, carbylamine, and acetonitril; this distillate, treated with an alcoholic solution of trimethylamine and silver cyanide, yields a solid compound containing both cyanogen and silver, which could not be proved to be identical with the double cyanide of silver and tetramethylammonium. Acetonitril and trimethylamine do not appear to combine. P. P. B.

Hexmethylenamine. By L. PRATESI (*Gazzetta*, 13, 437—438).—It is known that trioxymethylene, $C_3H_6O_3$, is easily converted by ammonia into Butlerow's hexmethylenamine, $(CH_2)_6N_4$, which when treated with silver nitrate gives a white crystalline precipitate, permanent or nearly so in diffused daylight when dry, decomposing with slight deflagration when heated. This precipitate, not hitherto analysed, has been found by the author to contain 18·03 per cent. carbon, 3·46 hydrogen (mean of two analyses), 19·32 nitrogen, and 40·60—40·73 silver, leading to the formula $2C_6H_{12}N_4,3AgNO_3$. This compound, slightly soluble in cold water, dissolves more freely in boiling water, but with partial decomposition, producing a specular deposit of silver on the sides of the vessel. From a hot solution, it separates on cooling in needle-shaped crystals. H. W.

Isobutylbiguanide, $C_6H_{15}N_5 = C_2H_6(C_4H_9)N_5$, and its Compounds. By A. SMOLKA (*Monatsh. Chem.*, 4, 815—832).—*Cupric Isobutylguanide Sulphate*, $(C_6H_{14}N_5)_2Cu,H_2SO_4$, is prepared by mixing a solution of cupric sulphate with a solution of isobutylamine (of about 20 per cent.) in such quantity as to form a dark-blue perfectly clear liquid, mixing this solution with dicyanodiamide, and either leaving the mixture to itself at the temperature of the air, or heating it in a sealed tube at about 100°. In the latter case, the salt separates after ten or twelve hours on the sides of the tube, as a dark-red granular film, the liquid at the same time assuming a red-violet colour. At ordinary temperatures, a lighter-coloured deposit is obtained after about a week, and the mother-liquors, if left over night in a vessel cooled by ice, deposit a small additional quantity of the compound lighter in colour than either of the preceding. The formation of this copper-compound is represented by the equation $2C_2H_4N_4 + 2C_4H_{11}N + CuSO_4 = (C_6H_{14}N_5)_2Cu,H_2SO_4$.

This sulphate separates from solution at temperatures above 60° in crimson anhydrous grains; from concentrated solutions at ordinary temperatures, in rose-red crystals with 1 mol. H_2O; and from dilute solutions at 0° in light rose-coloured crystals containing $3H_2O$. The crystal-water is given off slowly, but completely, at 105—110°; more quickly at 125—130°. The salt may be heated to 140° without decomposition.

The *hydrochloride*, $(C_6H_{14}N_5)_2Cu,2HCl + \frac{1}{2}H_2O$, obtained by decomposing the sulphate with barium chloride, crystallises in pale rose-red microscopic needles, often forming hemispherical or kidney-shaped groups, and like the sulphate, bears a heat of 140° without decomposition. 1 part of this salt dissolves in 37·76 parts water, forming a deep violet solution: the salt is insoluble in alcohol. Zinc or iron immersed in the neutral aqueous solution throws down the whole of the copper, leaving in solution the hydrochloride of isobutylbiguanide.

The *nitrate*, $(C_6H_{14}N_2)_2Cu,2HNO_3$, prepared by decomposing the sulphate with barium nitrate, remains, after evaporation of its solution in a vacuum, in rose-red crusts and spherical groups, resembling those of the hydrochloride. When heated on platinum-foil, it decomposes with glimmering combustion, giving off vapours smelling of isobutylamine, and leaving cupric oxide. It is much less soluble than the hydrochloride; the aqueous solution is violet.

Cupric Isobutylbiguanide, $(C_6H_{14}N_5)_2Cu$, is best prepared by treating the hydrochloride or nitrate with soda-lye, whereupon it separates as a bulky rose-coloured precipitate, which, after draining and drying, forms a thick magma of rose-red silky needles, dissolving very sparingly in cold, somewhat more freely in hot water, with red-violet colour, and remaining on evaporation over sulphuric acid in carmine-coloured crystalline granules. It is a strong base, exhibiting great affinity for acids, including carbonic acid; its aqueous solution has an alkaline reaction, and it expels ammonia from sal-ammoniac on boiling. It dissolves readily in dilute nitric and hydrochloric acids, forming at first the corresponding salts of the copper-base, but if the acid is in excess, the copper is dissolved out and a salt of the non-cupreous base is produced.

SULPHATES OF ISOBUTYLBIGUANIDE.—The *normal sulphate*,

$$(C_6H_{15}N_5)_2,H_2SO_4,\tfrac{3}{2}H_2O,$$

is prepared by triturating the corresponding salt of the copper-base with water, rinsing it into a flask, and heating it in a water-bath while a slow stream of hydrogen sulphide is passed through the liquid for several hours. On filtering from the copper sulphide, and evaporating, first on the water-bath and finally in a vacuum over sulphuric acid, the normal sulphate is obtained in large limpid crystalline laminæ, and, after recrystallisation, in transparent triclinic prisms which are permanent in the air, but slowly effloresce in a vacuum over sulphuric acid, and melt and decompose when heated on platinum foil. The crystals dissolve in 3·8 parts water at 16°, forming a neutral solution, which is precipitated by alcohol. The *acid sulphate*, $C_6H_{15}N_5,H_2SO_4,\frac{3}{2}H_2O$, crystallises in large transparent plates, much more soluble than the normal salt, and is precipitated from the solution by alcohol.

HYDROCHLORIDES.—The *normal salt*, $C_6H_{15}N_5,HCl$, obtained by decomposing the warm solution of the normal sulphate with barium chloride, forms, after repeated crystallisation, long thin transparent brittle anhydrous prisms, soluble in 2·5 parts water at 16·5°, melting at 216°, and decomposing when more strongly heated on platinum foil. The *acid salt*, $C_6H_{13}N_5,2HCl$, crystallises with great difficulty from its aqueous solution; from alcohol, it separates in anhydrous needles often grouped in feathery tufts, and is precipitated from its alcoholic solution by ether. It is deliquescent, has an acid reaction, and melts at 194°. The *platinochloride*, $C_6H_{15}N_5,H_2PtCl_6,H_2O$, crystallises from alcohol in fan-shaped groups of yellow four-sided plates; from water in crusts composed of yellow needles.

Isobutylbiguanide, $C_6H_{15}N_5 = C_2H_6(C_4H_9)N_5$, is obtained by decomposing the normal sulphate with the requisite quantity of baryta-water, and, after evaporation in a vacuum over sulphuric acid, forms a thick uncrystallisable syrup. Its aqueous solution has a strongly alkaline reaction, decomposes ammonium salts at a gentle heat, and when added to salts of most of the heavy metals, or to those of Al, Mg, Ca, Sr, and Ba, immediately throws down the corresponding hydroxides, especially those of the three last-named metals. It quickly absorbs carbonic acid from the air, and solidifies to a mass of deliquescent needles consisting of the carbonate.

As regards the position of the alkyl-radicle in isobutylbiguanide, it may be observed that, on heating the compound with chloroform and alcoholic soda-lye, the corresponding carbylamine or isocyanide is given off, and may be recognised by its characteristic odour; and as the formation of isocyanides is very characteristic of amines, it appears not improbable that the alkyl is situated in an amidogen- rather than in an imidogen-group.

If then biguanide be represented, as in the author's paper, by the formula $NH_2.C(NH).NH.C(NH).NH_2$, its isobutyl-derivative must have the constitution $NH(CH_2Pr^\beta).C(NH).NH.C(NH).NH_2$, but if biguanide be correctly represented by Emich's formula

$$NH : C(NH_2).NH.C(NH_2) : NH$$

(this Journal, 1883, Abstr., 973), then isobutyl-biguanide must be constituted as shown by the formula $NH : C(NH.CH_2Pr^\beta).NH.C(NH_2) : NH$.

H. W.

Acetyl-pyrroline and Pseudoacetyl-pyrroline. By G. L. CIAMICIAN and M. DENNSTEDT (*Gazzetta*, 13, 455—465; and *Ber.*, 16, 2348—2357).—The crystallised body melting at 90° which R. Schiff obtained by heating pyrroline with acetic anhydride (Abstr., 1878, 216) was regarded by him as acetyl-pyrroline, in which the acetyl-group took the place of the hydrogen in the imidogen-group of the pyrroline-molecule, that is, as represented by the formula  $AcN\left\langle\begin{array}{l}CH.CH\\ |\quad\ \ \|\\ CH.CH\end{array}\right.$; but the experiments described in the present paper show that in the compound thus prepared the acetyl-group is directly attached to a carbon-atom, as represented by the formula  $HN\left\langle\begin{array}{l}CH.CAc\\ |\quad\ \ \|\\ CH.CH\end{array}\right.$ or  $HN\left\langle\begin{array}{l}CAc.CH\\ |\quad\ \ \|\\ CH.\ CH\end{array}\right.$. For distinction, the latter of these compounds is designated as *acetyl-pyrroline*, the former as *pseudoacetyl-pyrroline*. These two compounds are formed together by the action of acetic anhydride on pyrroline; the latter, however, in much the larger quantity. They may be prepared and separated by heating pyrroline with acetic anhydride and recently fused sodium acetate in an oil-bath, and distilling the resulting black semi-solid mass in a water-bath under reduced pressure; treating the yellow and brown crystalline residue thereby obtained with water; and distilling it in a current of steam. An oil heavier than water then passes over, and when this oil begins to deposit crystals on cooling, the operation is discontinued. The red-brown liquid then remaining in the flask contains in solution nearly the whole of the pseudoacetyl-pyrroline, provided the quantity of water is sufficient; if not, more must be added and the entire solution boiled with animal charcoal. The filtered liquid after 24 hours deposits the pseudoacetyl-pyrroline in very fine needles several centimeters long, which are easily purified by two or three crystallisations from boiling water. The remainder of the pseudoacetyl-pyrroline may be extracted from the aqueous solution by means of ether.

Pseudoacetyl-pyrroline melts at 90°, boils at 220°, and agrees in its other physical properties with the body described by Schiff. It is not, however, resolved into acetic acid and pyrroline by boiling with potash, as stated by Schiff, but the solution on cooling deposits a white solid mass, which is perhaps the potassium-compound; it dissolves on dilution with water, and ether extracts from the solution unaltered pseudoacetyl-pyrroline. On mixing a solution of pseudoacetyl-pyrroline in boiling water with a strong solution of silver nitrate and adding a few drops of ammonia, a white crystalline precipitate is formed of the silver salt $C_4H_2\overline{Ac}\vdots NAg$. This reaction shows distinctly that the acetyl-radicle has entered into the nucleus of the pyrroline, and that the imidogen-group NH has remained unaltered.

By oxidation with potassium permanganate, pseudoacetyl-pyrroline is converted into the potassium salt of an acid having the composition $C_6H_5NO_3 = C_4H_3(CO.COOH)\vdots NH$. This acid may be separated from the solution by acidulation with dilute sulphuric acid, and on agitating the liquid with ether, evaporating the ether, and crystallising the residue from boiling benzene, the acid separates in groups of slightly yellow needles, which give off their water in the exsiccator, and have the composition of an *acetyl-pyrroline-carboxylic acid*, $C_6H_5NO_3,H_2O$. The dehydrated acid has a deep yellow colour, dissolves in boiling benzene, and separates from the solution after treatment with animal charcoal, in groups of very thin yellow needles, which begin to decompose at 113—115° without showing any fixed melting point; when immersed in water they instantly turn white. They are slightly soluble in cold water and dissolve in hot water, forming a slightly yellow solution, which gives a deep red colour with ferric chloride, and does not precipitate normal lead acetate. Heated with slaked lime, it appears to yield pyrroline, as indicated by the odour of the escaping vapours, and the reaction with a deal-shaving moistened with hydrochloric acid. A highly characteristic reaction is exhibited on boiling the acid with hydrochloric acid, a very deep carmine-red solution being thereby produced, somewhat like a solution of eosin. On adding a base, a greenish-yellow colour is produced, changing to red on acidification. The aqueous acid treated with silver nitrate yields a white crystalline precipitate of the salt

$C_4H_3(CO.COOAg)NH$, which dissolves in boiling water, and separates on cooling in colourless needles.

ACETYL-PYRROLINE, $C_4H_4N.C_2H_3O$ =  $\overline{\mathrm{Ac}}N\left\langle\begin{array}{l}CH.CH\\ \,|\qquad\| \\ CH.CH\end{array}\right.$, is the oil which passes over on distilling with steam the product of the action of acetic anhydride and sodium acetate on pyrroline. It is purified by distillation, and passes over between 160° and 200°; a small portion which distils above that temperature and solidifies completely on cooling consists of pseudoacetyl-pyrroline, which is slightly volatile with vapour of water. After a long fractionation of the liquid at 160—200°, a portion is obtained which boils constantly at 176—180°, the greater part at 177—178°. This portion consists of normal acetyl-pyrroline. It may be obtained in larger quantity by the action of acetic chloride on potassium-pyrroline.

Acetyl-pyrroline boils at 177—178°. It has a characteristic odour; is nearly insoluble in water; gives a white precipitate with aqueous mercuric chloride; and dissolves in aqueous silver nitrate, which it reduces after some time. Its vapour reddens a chip of wood moistened with hydrochloric acid; this acid also resinifies the compound. Acetyl-pyrroline dissolves in aqueous potash, and when boiled therewith, is quickly resolved into acetic acid and pyrroline.

ACTION OF BROMINE ON PSEUDOACETYL-PYRROLINE.—Schiff describes an addition-compound obtained by the action of bromine (1 mol.) on pseudoacetyl-pyrroline dissolved in glacial acetic acid. The authors, however, have obtained by this reaction only substitution-products. The action of bromine in molecular proportion on pseudoacetyl-pyrroline yields a mixture of compounds very difficult to separate. The following methods yield better results:—

Monobromopseudoacetyl-pyrroline, $C_6H_6BrNO = C_6H_2Br\overline{\mathrm{Ac}}NH$, is formed, together with the dibromo-compound, by dissolving pseudo-acetyl-pyrroline (10 g.) in a slight excess of glacial acetic acid, and adding bromine (14 g.) dissolved in a small quantity of the same liquid, whereupon a white precipitate is formed, consisting of C_8H_6BrNO, while $C_6H_5Br_2NO$ remains in solution. The monobromo-compound crystallises from boiling alcohol in small white needles, which turn yellow on exposure to light, and melt at 118—120°.

Dibromopseudoacetyl-pyrroline, $C_4H_5Br_2NO = C_4HBr_2.\overline{\mathrm{Ac}}NH$, is prepared by adding 2 mols. bromine to 1 mol. of the base, both dissolved in glacial acetic acid, pouring the liquid into water, and dissolving the resulting white precipitate in boiling alcohol with addition of animal charcoal. The filtered liquid on cooling deposits small white needles, which after a few crystallisations melt at 145—147°, and have a composition approximating to the formula $C_6H_5Br_2NO$, but still contain small quantities of a less highly brominated compound, from which the authors have not yet been able to separate it. The pure dibromo-compound is, however, easily obtained by evaporating the alcoholic mother-liquors to dryness, and crystallising the residue from boiling water, in which it is sparingly soluble, with addition of animal charcoal. The liquid on cooling deposits the dibromo-compound in small white needles, which turn yellow on exposure to light, and after a few crystallisations melt at 143—144°. The mother-liquors contain traces of unaltered pseudoacetyl-pyrroline. The mono- and di-bromo-compounds dissolve readily in aqueous potash, and are precipitated therefrom unaltered on addition of an acid.

Pentabromopseudoacetyl-pyrroline,

$$C_6H_2Br_5NO = C_4Br_3(C_2Br_2HO)NH,$$

is formed on adding bromine (4 mols.) to a solution of pseudoacetyl-pyrroline (1 mol.) in glacial acetic acid, and gently heating the resulting red liquid on the water-bath to complete the reaction. The solution, if an excess of glacial acetic acid has been avoided, deposits the pentabromo-compound on cooling in small colourless needles, which may be purified by a few crystallisations from boiling glacial acetic acid. They melt at 200°. The mother-liquor contains less highly brominated compounds, which may be precipitated by water.

The sixth disposible atom of hydrogen in pseudoacetyl-pyrroline cannot be replaced by bromine by working in the manner above described even with larger quantities of bromine; but this final substitution, might perhaps be effected by heating in sealed tubes.

H. W.

Derivatives of Pyrocoll. By G. L. Ciamician and P. Silber (*Ber.*, 16, 2388—2399).—*Tetrabromopyrocoll*, $C_{10}Br_4H_2N_2O_2$, obtained by heating pyrocoll with bromine in sealed tubes at 100°, is insoluble in most solvents save glacial acetic acid, from which it crystallises in small yellow needles; it is decomposed at 250°. When heated with caustic potash, it is converted into dibromopyrrolcarboxylic acid.

Octochloride or Perchloride of Perchloropyrocoll, $C_{10}H_6(Cl_8)N_2O_2$.—In a former communication (Abstr., 1882, 875) one of the authors has shown that pyrocoll is converted by the action of phosphorus chloride into *perchloropyrocoll*, $C_{10}Cl_6N_2O_2$, and two other bodies having the formulæ $C_{10}Cl_{10}N_2O$ and C_5Cl_7NO. This latter compound the authors regard as perchloride of perchloropyrocoll, and assign to it the formula $C_{10}Cl_{14}N_2O_2$, double that assigned to it in the previous memoir. It crystallises from glacial acetic acid in large cubical crystals, which can be easily separated by mechanical means from the flat prisms of the compound $C_{10}Cl_{10}N_2O$.

By the action of zinc on a solution of perchloride of perchloropyrocoll in dilute acetic acid, *tetrachloropyrroline*, C_4Cl_4NH, is formed. It crystallises from light petroleum in long silky needles, melting at 110°, easily soluble in alcohol and ether, but only sparingly in water. It is very volatile, and emits an odour resembling that of tetraiodopyrroline. In its properties it resembles those of a weak acid, and gives a white precipitate with ammoniacal solutions of silver nitrate.

In explanation of the formation of this substance, the authors suppose, first, that the perchloride takes up water to form the tetrachloride of trichloropyrroline-carboxylic acid, and that this is then resolved into carbonic anhydride and tetrachloride of trichloropyrroline; the latter is converted into tetrachloropyrroline by nascent hydrogen. This series of reactions is represented as follows:—

(1.) $C_{10}Cl_6(Cl_8)N_2O_2 + H_2O = 2C_4Cl_3(COOH)(Cl_4)NH$.
(2.) $C_4Cl_3(COOH)(Cl_4)NH = CO_2 + C_4Cl_3H(Cl_4)NH$.
(3.) $C_4Cl_3H(Cl_4)NH + 2H = C_4Cl_4NH + 3HCl$.

When perchloride of perchloropyrocoll is heated with dilute acetic acid in sealed tubes at 130°, it is resolved into hydrochloric acid, carbonic anhydride, and a compound having the formula $C_4Cl_2O_2NH$, which is either a *dichloromaleïmide* or *dichlorofumarimide*. The formation is represented by the following equations:—

(1.) $C_{10}Cl_6(Cl_8)N_2O_2 + 2H_2O = 2C_4Cl_3H(Cl_4)NH + CO_2$.
(2.) $C_4Cl_3H(Cl_4)NH + 2H_2O = C_4Cl_2O_2NH + 5HCl$.

(Comp. this vol., p. 176.)

This same imide is obtained by the action of chlorine on succinimide at 160°. It crystallises from water in long needles melting at 179°. With ammoniacal silver nitrate solutions, it gives a precipitate of an argentic ammonium compound, $C_4Cl_2O_2N.NH_3Ag$. A compound, which is either monochlorofumarimide or monochloromaleïmide, C_4ClHO_2NH, is formed, together with this dichloro-derivative, when succinimide is treated with chlorine. It crystallises in large colourless shining leaflets melting at 131°.

Caustic potash converts the imide $C_4Cl_2O_2NH$ into a deliquescent acid, which is easily soluble in alcohol, ether, and benzene, and is probably dichloromaleïc acid, $C_4Cl_2H_2O_4$. When heated, it yields a compound less soluble in water, probably the anhydride. When the dichloromaleïmide is heated with water in sealed tubes at 125°, it is resolved into carbonic anhydride, ammonia, and α-dichloracrylic acid.

The conversion of the perchloride of perchloropyrocoll into dichloromaleïmide suggested the possible synthesis of tetrachloropyrroline from the imide, which the authors have carried into effect by acting on the imide with phosphorus pentachloride, taking up with ether, and subsequent treatment of the ethereal extract with zinc-dust and water. P. P. B.

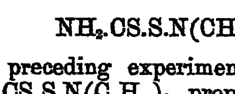
Oxymethylene and Formaldehyde. By B. TOLLENS (*Landw. Versuchs.-Stat.*, **29**, 355—392).—The preparation and properties of formaldehyde have been studied by numerous authors. The chief interest which attaches to this subject is that very possibly formaldehyde is the first assimilation-product of carbonic anhydride in the vegetable organism, and is afterwards converted by polymerisation into the various carbohydrates which form the greater proportion of the plant substance. The author made use of Hofmann's method, the oxidation of methyl alcohol by platinum foil. The best results were obtained when the water-bath in which the methyl alcohol was heated was kept at the temperature of 54—55°. The quantity formed was, however, always small, and averaged about 2 per cent. of the total distillate; it was estimated by an ammoniacal solution of equal parts of silver nitrate and caustic soda. The distillates can be concentrated by further distillation, but the richest product obtained by this method only contained 11·3 per cent. formaldehyde. By drying over sulphuric acid pure oxymethylene may however be obtained, although this method is attended with considerable loss. The vapour-density of oxymethylene was determined, and found to correspond with the formula CH_2O. Various ammoniacal solutions of silver nitrate were used for the exact quantitative estimation of oxymethylene, but no perfectly satisfactory method could be found.

Heated with alkalis or alkaline earths, oxymethylene yields methyl alcohol and formic acid. When the crude distillate of formaldehyde is heated with baryta-water, a yellowish precipitate is thrown down; after freeing this from barium, an amorphous syrup is left behind, which strongly reduces Fehling's solution, and on analysis gives numbers approximating to the formula $C_6H_{10}O_5$. When it is heated with sulphuric acid, formic and lactic acids are formed; the latter was converted into its zinc salt and analysed. The syrup has no action on polarised light, does not undergo fermentation, and yields no lævulic acid when treated with mineral acids. In these properties it agrees with the methylenitan obtained by Butlerow.

In certain preparations of this syrup, small crystals were obtained, but the author is of opinion that they were due to the presence of ethyl alcohol, as they were never formed when perfectly pure methyl alcohol was employed.

J. K. C.

Thioaldehyde and Carbovaleraldine. By L. GUARESCHI (*Gazzetta*, **13**, 500).—When thioaldehyde is oxidised with potassium permanganate it yields sulphuric, acetic, and ethylidenesulphuric acids, together with oxysulphides, including the compound $C_6H_{12}S_2O_3$. By oxidising the same body with zinc permanganate, the author obtained sulphuric acid, acetic acid, and the oxysulphides $C_6H_{12}S_3O_5$, $C_6H_{12}S_3O_4$, and $C_6H_{12}S_3O_2$. The formation of ethylidenesulphuric acid and the oxysulphides points to the conclusion that solid thioaldehyde contains three C_2H_4S-groups joined together by sulphur-atoms, as represented by the formula



$$\begin{array}{ccc} \mathrm{CHMe} & \!\!-\mathrm{S}-\!\! & \mathrm{MeHC} \\ | & & | \\ \mathrm{S} & \!\!-\!\!-\mathrm{CHMe}-\!\!-\!\! & \mathrm{S} \end{array}.$$

Carbovaleraldine is converted by ferric chloride into thiocyanic acid; by potassium permanganate into hydrocyanic, sulphuric, and valeric acids; and by ferric chloride and excess of hydrochloric acid into thiocarbamic acid. It therefore behaves like carbothialdine, and may be regarded as the thiocarbamate of valerilidene,

$$NH_2.CS.S.N(CH.CH_2.CHMe)_2.$$

These and preceding experiments tend to confirm the general formula $NH_2.CS.S.N(C_nH_m)_2$, proposed by Mulder for the carbothialdines.

H. W.

Preparation and Reactions of Crotonaldehyde. By S. B. NEWBURY (*Amer. Chem. J.*, 5, 112—114).—Aldehyde (1 vol.) or paraldehyde is mixed with water (1 vol.) and concentrated hydrochloric acid (2 vols.), the liquid being cooled during mixing, and then allowed to remain for some days at the ordinary temperature until the mixture has become quite dark and opaque. On neutralising it with sodium carbonate, it yields a thick oily layer, which after some hours becomes thick and opaque. The neutralised liquid is separated from the oily layer, repeatedly shaken with ether, the ethereal liquid evaporated, and the residue distilled under a pressure of 2 cm. of mercury, when nearly pure aldol passes over between 90° and 110°; the maximum yield of crotonaldehyde is obtained when this aldol is heated in an oil-bath at 140°. Pure crotonaldehyde boils at 105°. As shown by Kekulé (this Journal, 1872, 616), crotonaldehyde yields dichloropseudobutylene when treated with phosphoric chloride. By the action of bromine on this chloride, *dichloropseudobutylene bromide*, $CMeHBr.CHBr.CHCl_2$, is obtained as a heavy oily liquid, which is decomposed when heated above 100°. On boiling it with dilute potassium carbonate, carbonic anhydride is evolved, but the removal of the halogens is only partial. A fraction, 115—120°, gave numbers approximating to those required for C_4H_6BrClO. Crotonaldehyde unites directly with bromine to form a heavy oily liquid of the formula $CHMeBr.CHBr.CHO$. Its vapour is very irritating. It is decomposed when heated. Attempts to replace the bromine by hydroxyl-groups were unsuccessful. A. J. G.

Nonoic Acids from different Sources. By E. Schmidt (*Ber.*, 16, 2590).—An examination of the nonoic acids obtained from the following sources shows that they are identical and of normal constitution:—1, from normal octyl alcohol from heracleum-oil; 2, from the oxidation of oleic acid; 3, from the oxidation of methyl nonyl ketone; 4, from the distillate of the leaves of *Pelargoneum roseum;* 5, from the fusel-oil of beet-molasses; and 6, from undecylenic acid. A. K. M.

A New Acid Isomeric with Crotonic Acid. By R. Fittig and F. Roeder (*Ber.*, 16, 2592—2593).—A further study of the acid previously obtained by the authors (Abstr., 1883, 730) leaves little doubt as to its being *vinylmalonic acid*, $CH_2:CH.CH(COOH)_2$. It combines with hydrobromic acid to form bromethylmalonic acid, which is decomposed by boiling water into hydrobromic acid and *butyrolactone-carboxylic acid*,  $COOH.CH<\genfrac{}{}{0pt}{}{CH_2-}{COO}>CH_2$; at 120° this is decomposed into carbonic anhydride and butyrolactone. The properties of the acid, $C_4H_6O_2$, obtained by the distillation of vinylmalonic acid differ from those of isocrotonic acid. It crystallises at a low temperature, melts at 18—19°, and boils at 180—181°. The authors think it probable that the formula $CH_2:CH.CH_2.COOH$, represents the constitution of this new acid and not that of isocrotonic acid, and that the isomerism of the latter with crotonic acid is of the kind frequently observed amongst unsaturated acids and unexplained by our present formulæ; this is confirmed by the results obtained by Friedrich (Abstr., 1883, 968) from the chlorisocrotonic acids. A. K. M.

Preparation of Glycollic Acid from Glycerol. By H. Kiliani (*Ber.*, 16, 2414—2416).—The author has already shown that several glucoses and nearly allied compounds yield glycollic acid when oxidised by silver oxide, and has recommended the oxidation of inverted sugar as a method for preparing this compound (*Annalen*, **205**, 191). The acid can, however, be more easily obtained by oxidising glycerol with silver oxide in presence of an alkali. For this purpose 10 grams of glycerol are mixed with 200 c.c. of water and 6 grams of slaked lime added, to this the oxide of silver obtained from 60 grams of silver nitrate is next added, and the whole heated at 60° for some four hours. The product is treated with carbonic anhydride and filtered; on concentrating the filtrate, calcium glycollate separates out. P. P. B.

Optically Active Glyceric and Lactic Acids. By J. Lewkowitsch (*Ber.*, **16**, 2720—2721).—Solutions of ammonium glycerate and ammonium lactate exposed to the action of *Penicillium glaucum* for several weeks become optically active. The glyceric acid solution becomes lævo- and the lactic acid solution dextro-gyrate. The optically active acids have not yet been isolated. W. C. W.

Tribasic Aluminium Oxalate. By Mathieu-Plessy (*Compt. rend.*, **97**, 1033).—An aqueous solution of oxalic acid attacks aluminium at 200°, and also attacks tribasic aluminium sulphate, the product of the action being an oxalate of the composition—

$$C_2O_3,Al_2O_3,2H_2O,$$

which may be regarded as kaolin in which oxalic acid has replaced silica equivalent for equivalent, thus furnishing a further example of the analogy between carbon and silicon. C. H. B.

Monethyl Oxalate. By R. Anschütz (*Ber.*, **16**, 2412—2414).—This compound, which has hitherto remained unisolated, is obtained by heating equal quantities of dehydrated oxalic acid and absolute alcohol at 135.° After cooling, the crude oxalate is decanted from the oxalic acid and submitted to rectification under reduced pressure. *Monethyl oxalate*, C_2O_4HEt, is a transparent, colourless liquid, sp. gr. at 20° = 1·2175 (water at 4° = 1); it has a strongly acid reaction; by water, it is resolved into ethyl alcohol and oxalic acid. It boils at 117° under a pressure of 15 mm., and decomposes when distilled under ordinary pressure, forming ethyl formate and diethyl oxalate, thus: $C_2O_4EtH = H.COOEt + CO_2$: $2C_2O_4EtH = C_2O_4Et_2 + CO_2 + CO + H_2O$. Monethyl oxalate can also be prepared from crystallised oxalic acid and alcohol by a method similar to the one used by the author and Pictet in preparing the ethereal salts of tartaric acid.

P. P. B.

Identity of Isopropylsuccinic Acid with Pimelic Acid from Camphoric Acid. By E. Hjelt (*Ber.*, **16**, 2621—2623).—On oxidising isopropylsuccinic acid, no terebic acid was formed, as might be expected if the assumed constitution of this acid is correct. When treated with alkaline potassium permanganate in calculated quantity a portion becomes completely burnt, another portion remaining unattacked. When heated with nitric acid (4 : 1), it remains unaltered.

In its properties, isopropylsuccinic acid agrees with pimelic acid, and the properties of its salts are also identical with those of the salts of the latter acid, as described by Hlasiwetz, Grabowski, and Kachler. It dissolves readily in water and in ether, melts at 114°, and yields an anhydride at higher temperatures. The calcium salt, $C_7H_{10}O_4Ca$, is anhydrous, and is precipitated as a sandy powder; the barium salt is very readily soluble; the silver salt is sparingly soluble. The identity is further confirmed by a crystallographic examination of this acid, the measurements closely agreeing with those of Ditscheiner and Zepharovich. A. K. M.

Reduction of Pyrotartaric Chloride. By E. HJELT (*Ber.*, **16**, 2624).—Saytzeff having obtained butyrolactone by the reduction of succinic chloride (*Annalen*, **171**, 258), the author has tried the reaction with pyrotartaric chloride. This is a colourless oil boiling at 190—195°; it is gradually decomposed by water with formation of pyrotartaric acid. When its ethereal solution is acted on by glacial acetic acid and sodium-amalgam, the ether-extract evaporated, treated with water and potassium carbonate, and then extracted with ether, a neutral oil is obtained boiling for the most part at 203—205°. It has not been obtained pure, the analytical results agreeing only approximately with the formula $C_5H_8O_2$; it has an odour like that of a lactone, dissolves in 5—6 parts water, and does not solidify in a freezing mixture of ice and salt. Boiled with barium hydroxide solution, it yields a gummy barium salt, which when dried at 100° has a composition agreeing with the formula $(C_5H_9O_3)_2Ba$.

The constitution of the chlorides which yield lactones may be assumed to be analogous to that of phthalic chloride. A. K. M.

Ethyl Dicarbontetracarboxylate. By M. CONRAD and M. GUTHZEIT (*Ber.*, **16**, 2631—2632).—This is best prepared by adding the calculated quantity of sodium to a mixture of ethyl chloromalonate (19·4 grams) and ether (free from water and alcohol). After about 20 hours, the ether is separated by distillation, the unaltered sodium removed, and the product mixed with water; the ethyl dicarbontetracarboxylate obtained is purified by crystallisation from alcohol. When it is heated in sealed tubes with alcohol and hydrochloric acid, first at 150° and subsequently at 190°, fumaric acid is formed according to the equation:—

$$(COOEt)_2C : C(COOEt)_2 + 4H_2O = 4EtOH + 2CO_2 + COOH.CH : CH.COOH.$$

By the action of zinc-dust and hydrochloric acid on an alcoholic solution of ethyl dicarbontetracarboxylate, ethyl acetylenetetracarboxylate melting at 76° is produced:—

$$(COOEt)_2C : C(COOEt)_2 + H_2 = (COOEt)_2CH.CH(COOEt)_2.$$

A. K. M.

Attempts to obtain Tartronic Acid from Glycerol, and Tartaric Acid from Erythrol by Electrolytic Oxidation. By D.

Bizzarri and G. Campani (*Gazzetta*, **13**, 490—492).—The experiments did not lead to the expected results. H. W.

Antimony Tartrates. By F. W. Clarke and C. S. Evans (*Ber.*, **16**, 2379—2387).—When antimony trioxide is dissolved in a considerable excess of tartaric acid, and the solution evaporated, it yields a well defined crystalline salt. It is not, however, always easy to obtain this compound, gummy amorphous masses being obtained in some cases. These crystals prove to be *antimony trihydric tartrate*,

$$Sb(C_4H_4O_6)_3H_3,4H_2O,$$

This salt crystallises in rosettes of white needles, easily soluble in water. It is strongly acid, decomposing carbonates with evolution of carbonic anhydride. The *normal antimony tartrate*, $Sb_2(C_4H_4O_6)_3,6H_2O$, is obtained by adding sodium carbonate to a solution of the trihydric tartrate, and then precipitating with alcohol; it forms a heavy white precipitate, easily soluble in water. In the cold, sodium carbonate has no action on it, but on boiling, a white precipitate is formed. Attempts to prepare double salts from antimony trihydric tartrate were unsuccessful.

By evaporating to dryness a saturated solution of antimony trioxide in tartaric acid, a non-crystalline residue was obtained having the composition $Sb(OH)H_2(C_4H_4O_6)_2$, which may also be represented as $Sb(C_4H_5O_6)_2OH$. Its aqueous solution when treated with alcohol yields a white precipitate of a compound $Sb_2(C_4H_4O_6)_2O.6H_2O$.

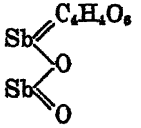
When the aqueous solution of this tartrate is allowed to evaporate, it yields a yellow scaly mass containing 16·39 per cent. of water, and when heated at 170° loses another molecule of water, and leaves a residue of two molecules of $Sb{\equiv}C_4H_3O_6$. These results indicate the existence of two salts, having the formulæ $SbC_4H_3O_6$ and $SbC_4H_5O_7$ respectively.

The results of this investigation indicate the existence of two series of antimony tartrates, one derived from ortho-antimonic acid, $Sb(OH)_3$, and the other from antimony trioxide, Sb_2O_3; the constitution of these salts is represented as follows:—

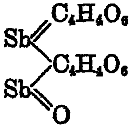
	I.	II.	III.
$Sb(OH)_3$ ..	$Sb(OH)_2C_4H_4O_6H$	$Sb(OH)(C_4H_4O_6H)_2$	$Sb(C_4H_4O_6H)_3$

Sb_2O_3 ....

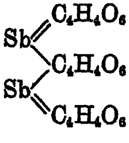
IV.



V.

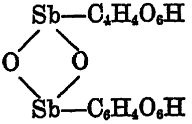


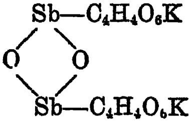
VI.



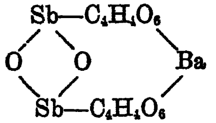
Of these, the antimony trihydric tritartrate (III), the antimony tritartrate (VI), and the antimony ditartrate, are described in the foregoing. The probable existence of II, antimony dihydric ditartrate, is also demonstrated. Attempts to prepare the compounds I and IV have not yielded altogether satisfactory results.

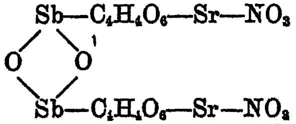
The authors consider that in its tartrates, antimony behaves just as any other trivalent metal, and the supposed existence in them of a radicle (SbO) is altogether unnecessary. There are cases, as for instance in tartar emetic, where the Sb atom and the oxygen atom are united, still the composition of these may be explained without presupposing the existence of the radicle (SbO). Tartar emetic may be represented as derived from a tartarantimonious acid, thus:—





a view by which the composition of barium antimony tartrate and of the double salt of strontium antimony tartrate and strontium nitrate can be easily explained, as shown in the following formulæ:—





P. P. B.

Oxidation of Benzene Derivatives with Potassium Ferricyanide. By W. A. Noyes (*Amer. Chem. J.*, 5, 97—105).—The presence of negative atoms or groups in many benzene derivatives exerts a powerful influence on the oxidation of hydrocarbon groups attached to the same benzene ring. Experiments, so far, seem to show that a hydrocarbon-group in the ortho-position relatively to the negative atom or group, is not oxidised at all, or only in small amount, by chromic acid; that nitric acid can oxidise a group in the ortho-position, but if there is a choice, will, in preference, oxidise groups in the meta- or para-position. Caustic potash, in the one class of compounds for which it has been used, oxidises groups in the ortho-position; potassium permanganate in alkaline solution oxidises groups in all three positions, but where there is a choice would seem to oxidise the group in the ortho-position by preference.

In order to ascertain if another alkaline oxidising agent would behave similarly to the two last mentioned, the author has investigated the action of potassium ferricyanide in alkaline solution on the nitro- and bromo-toluenes. Ortho-, nitro-, and paranitro-toluene are both readily oxidised to the corresponding nitrobenzoic acids, there being no indication as to which is oxidised more easily. Para-bromotoluene is only oxidised with great difficulty with alkaline ferricyanide, whilst orthobromotoluene appears to be scarcely attacked. For comparison, toluene was treated with alkaline ferricyanide, and found to be only slightly attacked by it. A. J. G.

Metaisopropylmethylbenzene. By H. E. Armstrong and A. K. Miller (*Ber.*, 16, 2748—2750).—When pure metaisocymene is dissolved in warm sulphuric acid, and the solution neutralised with barium carbonate, the barium salt of α metaisocymenesulphonic acid is deposited, and the mother-liquor contains a more soluble salt, which readily crystallises in prisms of the composition $(C_{10}H_{13}SO_3)_2Ba + 9H_2O$. According to Kelbe (*Annalen*, **210**, 30) the β barium salt is deposited from the concentrated syrupy solution in glistening plates containing 1 mol. H_2O. The calcium salt resembles the barium salt and crystallises with 5½ mols. H_2O. The potassium salt forms long prisms containing 2½ mols. H_2O. W. C. W.

Action of Chlorine on Boiling Cymene. (Preliminary Notice.) By G. Errera (*Gazzetta*, **13**, 421—422).—The action of chlorine on cymene vapour gives rise to a liquid resolvable by a few fractional distillations into three portions, the first passing over below 195°, and containing a considerable quantity of unaltered cymene, the second boiling at 225—229°, the third above 255°. This last portion is rapidly decomposed by boiling, but on distilling it with steam, a heavy oily liquid passes over, apparently consisting of a mixture of di- and mono-chlorocymene. The more abundant fraction, boiling at 225—229°, is a liquid heavier than water, decomposing on distillation, with evolution of hydrochloric acid, and consisting, as shown by analysis, of monochlorocymene or cymyl chloride, $C_{10}H_{13}Cl$, identical with that which Paternò and Spica obtained by the action of hydrochloric acid on cymyl alcohol* (Abstr., 1880, 106). Cymyl chloride, heated in a reflux apparatus with lead nitrate, is converted into cumic aldehyde, which in its turn is oxidised to terephthalic and cumic acids.

Cymyl chloride is decomposed by boiling, yielding hydrochloric acid and a fluorescent hydrocarbon, $C_{20}H_{24}$, of very high boiling point.

H. W.

Two Butyltoluenes Occurring in Rosin Spirit. By W. Kelbe and A. Baur (*Ber.*, **16**, 2559—2566).—Kelbe (Abstr., 1881, 809) obtained a hydrocarbon of the formula $C_{11}H_{16}$ from rosin spirit; this yielded isophthalic acid on oxidation, and he therefore assumed it to be either a methylbutylbenzene or an ethylpropylbenzene. The authors now find it to be *metaisobutyltoluene*, $C_6H_4Me.CH_2.CHMe_2$, and they have also obtained an isomeric hydrocarbon, namely, *parabutyltoluene*. Metaisobutyltoluene, obtained on heating its lead sulphonate at 150° with concentrated hydrochloric acid, is a colourless strongly refracting liquid of agreeable odour, boiling at 186—188°. Its sulphonic acid crystallises in small very deliquescent scales, melting at 75—76°. The *barium salt*, $(C_{11}H_{15}SO_3)_2Ba,H_2O$, forms small lustrous scales, sparingly soluble in cold, more readily in hot water, very sparingly in absolute alcohol; the *lead salt*, $(C_{11}H_{15}SO_3)_2Pb,3H_2O$, forms large nacreous plates, much more readily soluble in hot than in cold water; the *potassium salt*, $C_{11}H_{15}SO_3K,H_2O$, crystallises in large moderately soluble nacreous plates, and the *sodium salt*, $C_{11}H_{15}SO_3Na,H_2O$, in easily soluble lustrous needles; the *copper salt*, $(C_{11}H_{15}SO_3)_2Cu,4H_2O$, crystallises in large blue lustrous plates, readily soluble in water.

---

* Commonly, but incorrectly, called cumic alcohol or cumyl alcohol; the proper name of the radicle $C_{10}H_{13}$ is *cymyl*.—H. W.

Metaisobutyltoluenesulphonamide, $C_{11}H_{15}.SO_2.NH_2$, crystallises in small lustrous scales melting at 74—75°.

Parabutyltoluene, $C_6H_4Me.C_4H_9$, is separated from the crude metaisocymene by crystallising the barium sulphonates from 50 per cent. alcohol, in which barium parabutyltoluenesulphonate is much more readily soluble than the metaisocymene salt. Parabutyltoluene (b. p. 176—178°) is a colourless, highly refracting liquid of agreeable odour; dilute nitric acid oxidises it to paratoluic acid. The *barium sulphonate*, $(C_{11}H_{15}SO_3)_2Ba,H_2O$, forms small scales, sparingly soluble in water; the *lead salt*, $(C_{11}H_{15}SO_3)_2Pb,3H_2O$, crystallises in small lustrous scales, sparingly soluble in cold, readily in hot water; the *potassium salt*, $C_{11}H_{15}SO_3K,1\frac{1}{2}H_2O$, in small, lustrous, easily soluble scales; the *sodium salt*, $C_{11}H_{15}.SO_3Na,2H_2O$, in small wart-like crystals, readily soluble in water, and the *copper salt* in readily soluble bright blue wart-like crystals. *Parabutyltoluenesulphonamide*, $C_{11}H_{15}.SO_2NH_2$, forms large nacreous plates melting at 113°, and sparingly soluble in hot water. With potassium permanganate, it yields *paratolylsulphonaminic acid*, $COOH.C_6H_3Me.SO_2NH_2$, melting at 242°, sparingly soluble in water, almost insoluble in ether and in alcohol.

Metaisobutyltoluene, identical with the hydrocarbon contained in rosin-spirit, can be obtained synthetically from isobutyl bromide and toluene, in presence of aluminium bromide. A. K. M.

Reductions with Zinc and Ammonia. By W. G. MIXTER (*Amer. Chem. J.*, 5, 1—9).—Powdered zinc, with aqueous or alcoholic ammonia, and a small quantity of platinic chloride solution, forms a very gentle reducing agent, of which, so far, but little use seems to have been made. It was used for the reductions in the preparation of the bodies described below.

Parazoxyacetanilide,  $O<\begin{array}{l}N.C_6H_4.NH\overline{Ac}\\ |\\ N.C_6H_4.NH\overline{Ac}\end{array}$, obtained by the reduction of paranitracetanilide in alcoholic solution, forms minute hair-like particles of a light golden-yellow colour, melts at 275—278°, is sparingly soluble in boiling, nearly soluble in cold alcohol. The ammoniacal mother-liquor from the preparation of this substance contains *azo-acetanilide*, $C_{16}H_{16}N_4O_2$; it will be described in a future paper. By boiling parazoxyacetanilide with alcoholic potash, it yields *parazoxyaniline*,  $O<\begin{array}{l}N.C_6H_4.NH_2\\ |\\ N.C_6H_4.NH_2\end{array}$, as a fibrous mass which melts at 182—184°, and is readily soluble in alcohol. The hydrochloride crystallises well from water, and is sparingly soluble in alcohol. The sulphate separates on adding sulphuric acid to a dilute solution of the base. The platinochloride, $C_{12}H_{12}N_4O,H_2PtCl_6$, forms long brownish-red needles. By reduction with ammonium sulphide, or with tin and hydrochloric acid, azoxyaniline yields paraphenylenediamine, showing that the azoxy- and amido-groups occupy the [1 : 4] positions.

Metazoxybenzanilide,  $O<\begin{array}{l}N.C_6H_4.NH\overline{Bz}\\ |\\ N.C_6H_4.NH\overline{Bz}_2\end{array}$, obtained by the reduction

of metanitrobenzanilide, forms a light powder of pale yellow colour; it melts at 272°, and is insoluble or nearly insoluble in alcohol, ether, and benzene. The mother-liquor, after renewed digestion with zinc, yielded the substance $NHBz.C_6H_4.NH_2$, described by Bell (this Journal, 1874, 900).
A. J. G.

Action of Ethyl Acetoacetate on Phenylhydrazine. I. By L. KNORR (*Ber.*, 16, 2597—2599).—This reaction is similar to that between ethyl acetoacetate and aniline, yielding a new class of compounds, the properties of which closely resemble those of α-meth-γ-hydroxyquinoline (see p. 334). According to Fischer, phenylhydrazine and ethyl acetoacetate, at the ordinary temperature, yield an oily condensation-product with liberation of water; this compound must have the formula $PhN_2H : CMe.CH_2.COOEt$. When heated on a water-bath, it yields alcohol and a substance, $C_{10}H_{10}N_2O$, which resembles carbostyril in many of its properties. It melts at 127°, can be distilled unchanged, and shows both basic and acid properties; it is a stronger acid than carbostyril, dissolving in ammonia and in alkaline carbonates. To prepare it, 100 grams of phenylhydrazine are added to 125 grams of ethyl acetoacetate, the water which forms is separated, and the oily product is heated for about two hours on a water-bath, until a portion is found to solidify on cooling, or on the addition of ether. The warm mass is poured into and stirred with ether, which removes colouring matter, and the white crystalline product is then washed with ether and dried at 100°. The yield is quantitative and the product pure. It is almost insoluble in cold water, ether, and light petroleum, more readily soluble in hot water, and very readily in alcohol. It crystallises from hot water in hard prisms, and by the slow evaporation of its alcoholic solution can be obtained in crystals of diamond lustre. It yields crystalline precipitates with salts of most of the heavy metals, the ultramarine blue cobalt salt, and the orange-yellow uranium salt, being especially characteristic. Its constitution remains to be explained. An anhydride, $C_{20}H_{18}N_4O$, is formed, when it is heated with an excess of phenylhydrazine; this may be prepared as follows: ethyl acetoacetate (50 grams) is mixed with phenylhydrazine (60—70 grams), the water which forms separated, and the oily product heated to boiling in an oil-bath until a solid mass is obtained; on boiling this with alcohol, the anhydride is obtained pure. Heated to 250—260° it turns brown and decomposes before melting. It is insoluble in most of the usual solvents; is in many respects similar to carbostyril; dissolves in acids and bases, from which it is reprecipitated on neutralisation; it is insoluble in acetic acid and in ammonia, and is precipitated by carbonic anhydride from its alkaline solution, so that it apparently contains a hydroxyl-group.
A. K. M.

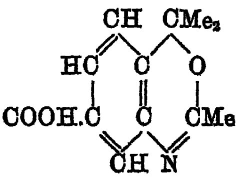
A New Group of Organic Bases. By O. WIDMANN (*Ber.*, 16, 2576—2587).—By the action of acetic anhydride on amidohydroxypropylbenzoic acid (the external application of heat being avoided), acetamidohydroxypropylbenzoic acid is formed (see p. 317), but if the amido-acid is boiled with an excess of acetic anhydride, and the latter then separated by repeated evaporation with alcohol, a reddish coloured oil is obtained crystallising from alcohol in rhombic plates, melting at 218°, and insoluble in water. Its hydrochloride is extremely soluble in water, sodium acetate reprecipitating the base $C_{12}H_{13}NO_3$ in white needles. The same compound is formed on boiling acetamidohydroxypropylbenzoic acid with hydrochloric acid, and also when acetamidopropenylbenzoic acid is boiled with hydrochloric acid. The author names it *methylcumazonic acid;* it dissolves readily in dilute acids, forming salts, and also in concentrated sulphuric acid. On distillation, it yields a tarry product having an odour like that of indole, but when cautiously heated, white needles sublime. By the action of potassium nitrite on a solution of the hydrochloride, nitrous acid is liberated, whilst needles of free methylcumazonic acid separate. When heated in a tube with ethyl iodide, it yields a syrupy substance which could not be obtained in a pure state. By evaporating a solution of the base in dilute sulphuric acid, the acid sulphate, $C_{12}H_{13}NO_3,H_2SO_4 + H_2O$, is obtained in slender, white, silky needles, very readily soluble in water; it loses its water of crystallisation at 100—140°. The hydrochloride crystallises in needles. The platinochloride, $(C_{12}H_{13}NO_3)_2,H_2PtCl_6$, forms lustrous four-sided plates or cubical crystals, very readily soluble in water. By the action of sodium-amalgam on a solution of methylcumazonic acid in sodium hydroxide, the compound $C_{12}H_{15}NO_3$ is produced; it is very sparingly soluble in ether and alcohol, crystallising from the latter in slender needles, which melt at 246° and sublime at higher temperatures. This substance is identical with *acetamidocumic acid,*

$$C_6H_3Pr(NH\overline{Ac}).COOH,$$

prepared by the author from nitrocumic acid. With the object of eliminating an acetyl-group from methylcumazonic acid, it was boiled with hydrochloric acid and with alcoholic potash, but with negative results. Judging from its formation from amidohydroxypropylbenzoic acid or its acetyl-derivative, methylcumazonic acid might be assumed to have the constitution  $COOH.C_6H_3\langle\begin{matrix}CMe_2\\ |\\ N\overline{Ac}\end{matrix}$, but this formula does not explain the basic character of the substance, nor the difficulty of displacing the acetyl-group: the formula

$$COOH.C_6H_3<\begin{matrix}CMe_2.CH_2\\ -NH.CO-\end{matrix}>$$

is equally unsatisfactory. Its reactions and properties can, however, be satisfactorily explained on the assumption that its constitution is—



i.e., that it is formed by the abstraction of the elements of a molecule of water from acetamidohydroxypropylbenzoic acid, the carbon-atom of the propyl residue uniting with the oxygen-atom of the acetyl-group. A substance of this constitution must be a tertiary base, contains no acetyl-group, and might yield acetamidocumic acid on reduction. Its formation from acetamidopropenylbenzoic acid is more difficult to explain, the yield in this case being also less satisfactory; the hydrochloric acid may perhaps first form an addition-compound with the propenyl-group, the chlorine then separating again, but in union with the amido-hydrogen. In support of the above constitution, the author mentions the analogous formation of Ladenburg's condensation-products from orthamidophenol, and the acid anhydrides (*Ber.*, 9, 1524) as, for example,  $C_6H_4<^{O}_{N}>CMe$.

The name "methylcumazonic acid" is intended to imply that this substance is derived from cumic acid, and that it contains both nitrogen and oxygen, "cumazone" being the hypothetical parent substance  $C_6H_4<^{CMe_2}_{N:CH}>O$.

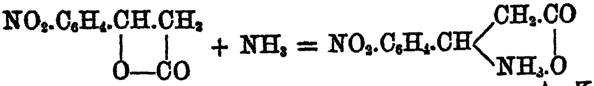
Ethylcumazonic acid,  $COOH.C_6H_3<^{CMe_2.O}_{N:CEt}>$, is obtained by boiling amidohydroxypropylbenzoic acid with an excess of propionic anhydride, and crystallises from alcohol in small lustrous well-formed pyramids, melting at 202°; it is readily soluble in alcohol, insoluble in water. The hydrochloride crystallises in white needles, extremely soluble in water. The acid sulphate, $C_{13}H_{15}NO_3,H_2SO_4$, also crystallises in extremely soluble white needles. The free base dissolves readily in very dilute sulphuric acid.

Phenylcumazonic acid, $C_{17}H_{15}NO_3$, is formed on heating amidohydroxypropylbenzoic acid with an excess of benzoic chloride at 100—120°, as long as hydrochloric acid is evolved, boiling the product with alcohol and subsequently with water. It melts at 219—220°, is insoluble in water, and separates from alcohol in transparent crystals of the formula $2C_{17}H_{15}NO_3 + EtOH$. The acid sulphate, $C_{17}H_{15}NO_3,H_2SO_4 + 2H_2O$, forms lustrous, colourless, elliptical plates, insoluble in water.

Compared with the methyl- and ethyl-derivatives, phenylcumazonic acid is a weak base. A. K. M.

Orthonitrophenyl-β-alanine. By A. Einhorn (*Ber.*, 16, 2645—2651).—In describing the lactone of orthonitrophenyl-β-lactic acid (this vol., p. 65), the author mentioned that it was converted into salts of the hydroxy-acid by warming it with alkaline hydrates or baryta. When heated with ammonia solution, it gradually dissolves, and on cooling white crystals separate; these, after recrystallisation, melt at 197°. The product, $C_9H_{10}N_2O_4$, has the composition of *orthonitrophenyl-β-alanine*, but it neither forms metallic salts, nor does it combine with acids. In order to be able to compare it with orthonitrophenyl-β-alanine, the author prepared the latter by dissolving orthonitrophenyl-β-bromopropionic acid in an excess of ammonia, and leaving the solution at rest. Crystalline scales gradually separate, and on recrystallisation from water or alcohol needles are obtained melting at 197°. The composition, $C_9H_{10}N_2O_4$, and mode of preparation of the product show it to be orthonitrophenyl-β-alanine; it dissolves readily in water, alcohol, acetone, and glacial acetic acid, more sparingly in ether, chloroform, light petroleum, and carbon bisulphide. It dissolves when heated with dilute sodium carbonate solution, but not more readily than in water, and separates unchanged on cooling. When boiled with sodium or barium hydroxide, it does not yield salts, a partial decomposition taking place with formation of ammonia; attempts to obtain copper and silver salts were also unsuccessful. Orthonitrophenyl-β-alanine crystallises unchanged from dilute or concentrated hydrochloric acid. Sulphuric acid (1 part acid and 1 part water) dissolves it in the cold, but decomposition sets in after a time. On warming it with concentrated sulphuric acid, a blue solution is obtained, and on pouring this into water a blue dye is precipitated agreeing in its reactions with indoïn. It is converted into the orthonitro-β-lactic acid by boiling with nitrous acid. The perfect coincidence of these properties with those of the compound obtained by the action of ammonia on the lactone, prove the identity of the two substances. The *acetyl-derivative*, $C_{11}H_{12}N_2O_5$, is prepared by dissolving orthonitrophenyl-β-alanine in boiling acetic anhydride; it crystallises from alcohol in splendid prisms melting at 141—142°; it crystallises unchanged from hot water, is insoluble in cold sodium carbonate and alkali solutions, but on boiling with the latter, is decomposed with formation of orthonitrophenyl-β-alanine. It does not yield salts when boiled with copper hydroxide or silver hydroxide, is insoluble in cold hydrochloric acid, but dissolves in hot concentrated sulphuric acid to a blue solution, which has a strong odour of acetic acid. When the alanine is boiled for about three hours with acetic anhydride, the latter separated by distillation, and the residue crystallised from alcohol, a substance, $C_{11}H_{10}N_2O_4$, is obtained crystallising in needles melting at 172°. It is assumed to be the *lactam of orthonitrophenyl-β-acetylalanine*,  $NO_2.C_6H_4.CH<{}^{CH_2}_{NAc}>CO$. It is decomposed by dilute soda solution, with evolution of ammonia and formation of orthonitrocinnamic acid. If equal quantities of the alanine and sodium acetate are boiled with acetic anhydride, and after removal of the latter the product is crystallised from alcohol, the above lactam separates, whilst the solution contains a small quantity of a second substance, which is probably the *lactam of orthonitrophenyl-β-alanine*,  $NO_2.C_6H_4.CH<{}^{CH_2}_{N.H}>CO$. It crystallises in transparent, strongly refracting, vitreous prisms, melting at about 80°, but it has not yet been obtained pure. It is moderately soluble in hot water, and is not altered by alkalis or acids.

From the chemical behaviour of orthonitrophenyl-β-alanine, and from its ready production from the lactone or orthonitrophenyl-β-lactic acid and ammonia, the author concludes that it is not an amido-acid, and he gives the following equation to express its formation:—



$$NO_2.C_6H_4.\underset{O\text{---}CO}{CH.CH_2} + NH_3 = NO_2.C_6H_4.CH\langle\begin{matrix}CH_2.CO\\NH_3.O\end{matrix}$$

A. K. M.

Synthesis of Methylene-blue. By R. MÖHLAU (*Ber.*, 16, 2728—2730).—When nitrosodimethylaniline acts on dimethylaniline in presence of strong hydrochloric acid, the hydrochloride of the base $C_{16}H_{19}N_3$ is obtained. The base crystallises in prisms which melt at 215°. Methylene-blue is produced by reducing the hydrochloride with sulphuretted hydrogen and oxidising the product with ferric chloride. The base $C_{16}H_{19}N_3$ is decomposed by reducing agents, such as zinc-dust, into paramidomethylaniline and dimethylaniline. By oxidising these products of reduction, dimethylaniline-green is formed.

Sulphuretted hydrogen converts dimethylaniline-green into leucodimethylaniline-green and methylene-white, and by alternate reduction with sulphuretted hydrogen and oxidation with ferric chloride, dimethylaniline-green is converted into methylene-white and methylene-blue. As methylene-white has the constitution

$$HS\,NH(C_6H_4NMe_2)_2,$$

the hydrochloride of methylene-blue is probably

$$NMe_2.C_6H_4.N\langle\begin{matrix}-S-\\C_6H_4\end{matrix}\rangle NMe_2Cl.$$

W. C. W.

Metanitrophenylthiocarbimide. By H. STEUDEMANN (*Ber.*, 16, 2331—2335).—The production of this compound by the action of hot glacial acetic acid on metanitrothiocarbamide has already been described (Abstr., 1883, 801). In this communication, the author gives an account of a detailed examination of the reaction taking place in its production, which may be represented by the following equations:—

I. $NHPh.CS.NH.C_6H_4.NO_2 + \overline{Ac}_2O = CSNPh_2 + NO_2.C_6H_4.NH\overline{Ac} + \overline{Ac}OH.$

II. $NHPh.CS.NH.C_6H_4.NO_2 + \overline{Ac}_2O = CSN.C_6H_4.NO_2 + NHPh\overline{Ac} + \overline{Ac}OH.$

The presence of phenylthiocarbimide, metanitroacetanilide, metanitrophenylthiocarbimide, and acetanilide was satisfactorily demonstrated amongst the products of the reaction. Two other substances are also produced, viz., metanitrodiphenylthiocarbamide melting at 160—161°, and a substance having the same composition as metanitrophenylthiocarbimide; the formation of the former resulting from the action of water on metanitrophenylthiocarbimide, thus:—

$$2(CSN.C_6H_4.NO_2) + 2H_2O = CS(NH.C_6H_4.NO_2)_2 + CO_2 + H_2S.$$

Phenylthiocarbimide undergoes a similar change when heated with water in sealed tubes at 100°, giving diphenylthiocarbamide, carbonic anhydride, and sulphuretted hydrogen.

These secondary reactions show that in the preparation of metanitrophenylthiocarbimide, distillation in a current of steam should be avoided, and the purification by crystallising from glacial acetic acid and carbon bisulphide is to be preferred.

Metanitrophenylthiocarbimide is also formed by the action of glacial acetic acid on dinitrophenylthiocarbamide. It crystallises in long flexible needles melting at 60·5°, and boiling at 275—280°; it is soluble in alcohol, ether, benzene, and carbon bisulphide. Attempts to reduce the "nitro-group" have failed; the alcoholic solution of this compound yields nitraniline when treated with sulphuretted hydrogen.

The following derivatives of metanitrophenylthiocarbimide have been prepared:—*Metanitrophenylparatolylthiocarbamide*,

$$NO_2.C_6H_4.NH.CS.NH.C_6H_4Me,$$

pale yellow needles melting at 173°, and sparingly soluble in water, benzene, and ether, easily soluble in alcohol and glacial acetic acid. *Metanitrophenylparaoxyphenylthiocarbamide*,

$$NO_2.C_6H_4.NH_2CS.NH.C_6H_4.OH,$$

crystallises in white needles melting at 152°. *Metanitrophenylorthonitroparatolylthiocarbamide*, $NO_2.C_6H_4$ $NH.CS.NH.C_6H_3Me.NO_2$ [1 : 2 : 4], crystallises in yellow needles melting at 188°. P. P. B.

Orthonitroparatolylthiocarbamide. By H. STEUDEMANN (*Ber.*, 16, 2336—2338).—Neither of the isomerides of metanitraniline appear to form isomerides of metanitrophenylthiocarbamide; and of its homologues, othonitroparatoluidine alone yields a thiocarbamide.

Orthonitroparatolylphenylthiocarbamide, $NO_2.MeC_6H_3.NH.CS.NHPh$, is obtained by acting on an alcoholic solution of orthonitroparatoluidine with phenylthiocarbimide; it melts at 143°, and is easily soluble in alcohol and glacial acetic acid. It is isomeric with the nitrophenylparatolylthiocarbamide melting at 173°, described in the preceding Abstract.

Orthonitroparatolylthiocarbimide, CSN $C_6H_3Me.NO_2$, obtained by boiling the solution of the above compound in acetic anhydride with water; phenylthiocarbimide, acetanilide, and nitro-acetotoluide are amongst the products of this reaction. It crystallises in broad needles, which melt at 56—57°, and resemble metanitrophenylthiocarbimide in its properties. When heated with water, it forms hydric sulphide, carbonic anhydride, and *dinitrodiparatolylthiocarbamide*, $CS.[NH.C_6H_2Me(NO_2)_2]_2$, which is also obtained by acting on nitrotoluidine with nitrotolylthiocarbimide. It melts at 207°, is soluble in glacial acetic acid, and when heated with acetic anhydride is resolved into orthonitroparatolylthiocarbimide and nitroacetotoluide.

Orthonitroparatolylethylthiourethane, $EtO.CS.NH.C_6H_3Me.NO_2$, formed by slow decomposition of the alcoholic solution of orthonitroparatolylthiocarbimide, melts at 95 5°.

Orthonitromonoparatolylthiocarbamide, $NH_2.CS.NHC_6H_3Me.NO_2$, obtained by dissolving the thiocarbimide in ammonia, forms a citron-yellow powder melting at 176°.

Orthonitrodiparatolylthiocarbamide,

$$NO_2.MeC_6H_3.NH.CS.NH.C_6H_4Me,$$

formed by mixing alcoholic solution of paratoluidine and nitrotolylthiocarbimide, crystallises from alcohol in needle-shaped crystals melting at 169°. P. P. B.

An Isopicramic Acid. By C. W. Dabney (*Amer. Chem. J.*, 5, 20—30).—*α-Benzoylamidosalicylic acid*, $C_6H_3(NH\overline{Bz})(OH).COOH$, is obtained, together with two other substances not yet fully investigated, by the action of benzoic chloride on *α*-metamidosalicylic acid. It forms a white powder, melts at 252°, is readily soluble in acetic acid, sparingly in hot water, insoluble in chloroform, benzene, and light petroleum. The barium salt, $(C_{14}H_{10}O_4N)_2Ba + 6H_2O$, forms small colourless needles readily soluble in water. The calcium salt, $(C_{14}H_{10}O_4N)_2Ca$, forms little blunt needles of satiny lustre. The nitration of the acid was accompanied with some difficulty, pure nitric acid acting on it with ungovernable violence; finally, by dissolving the substance in 20—30 times its weight of acetic acid, adding five drops of nitric acid to each 100 c.c. of liquid, and heating to 80°, the nitration was effected. The resulting compound was, however, not the nitro-acid expected, but *benzoylparamidodinitrophenol*,

$$C_6H_2(NO_2)_2(NH\overline{Bz}).OH,$$

small quantities of benzoic acid and picric acid being also formed. It crystallises in glistening yellow plates, gives off red vapours at 150°, and then melts at 250°. It is readily soluble in glacial acetic acid, somewhat less in alcohol, benzene, and naphtha, sparingly soluble in water. It acts as a strong acid, forming salts which crystallise well, and yield deep bluish-red solutions. The *potassium* salt,

$$C_6H_2(NO_2)_2(NH\overline{Bz}).OK + H_2O,$$

forms light red needles with a splendid golden-yellow lustre; the anhydrous salt is of a dark brick-red colour. The *barium* salt, $(C_{13}H_8N_4O_8)_2Ba + 3H_2O$, crystallises in slender bright red needles. The *calcium* salt, $(C_{13}H_8N_4O_8).Ca + 4\frac{1}{2}H_2O$, crystallises in glistening yellowish-red scales or plates. The *lead* salt, $(C_{13}H_8N_4O_8)_2Pb$, is obtained by precipitation as a dark red crystalline mass. When heated with moderately dilute hydrochloric acid at 130° for 12 hours, benzoylparamidodinitrophenol is resolved into benzoic acid and *diorthonitroparamidophenol* or *isopicramic acid*,

$$C_6H_2(NO_2)_2(NH_2).OH \quad [OH:NO_2:NH_2:NO_2 = 1:2:4:6].$$

This crystallises in dark brown plates or needles, melts apparently with some decomposition at 170°, is sparingly soluble in cold water, soluble in benzene and naphtha, readily soluble in hot water or in alcohol; the solutions have a cherry-red colour. It appears to combine with acids, dissolving in them to form yellow solutions, but the compounds so formed could not be isolated. It unites with alkalis, forming crystalline salts, whose solutions are of a deep bluish-red colour. The *potassium salt*, $C_6H_2(NO_2)_2(NH_2).OK$, crystallises in bluish-black needles, and is very soluble in water. Both acid and salts explode when heated. The properties of isopicramic acid and its derivatives are compared with those of picramic acid in the following table:—

Picramic Acid [OH : NH_2 : NO_2 : NO_2 = 1 : 2 : 4 : 6], m. p. 165°.—Crystallises from water in orange-red needles, from chloroform in blood-red scales. Soluble in alcohol. 100 parts water at 22° dissolve 0·14 part acid; solubility in hot water about the same. Solutions orange-red in colour.	*Isopicramic Acid* [OH : NO_2 : NH_2 : NO_2 = 1 : 2 : 4 : 6], m. p. 170°.—Crystallises in bundles of fine brownish-yellow needles, having a golden lustre when moist, very readily soluble in alcohol. 100 parts water at 22° dissolve 0·082 of acid : at just below the boiling point 0·812 part of acid. Solutions bluish red.
Potassium Salt.—Red translucent rhombic tables.	*Potassium Salt.*—Bluish-black needles.
Benzoylpicramic Acid, m. p. 220°.—Greenish-yellow needles sparingly soluble in alcohol.	*Benzoylisopicramic Acid*, m. p. 250°.—Reddish plates of golden lustre, soluble in alcohol.

A. J. G.

Note.—Another isomeride of picramic acid, *β-dinitroamidophenol*, of unknown constitution, has been prepared by Henriques (Abstr., 1883, 328) by the action of ammonia on the trinitrophenols from δ-dinitrophenol. It crystallises in brilliant red needles, melts at 202°, is nearly insoluble in water, sparingly soluble in alcohol, and yields a potassium salt crystallising in yellow needles.—A. J. G.

Triamidophenol. By E. BAMBERGER (*Ber.*, **16**, 2400—2403).—Triamidophenol hydrochloride was prepared by reducing picric acid with tin and hydrochloric acid and precipitating the tin from the product with zinc. The hydrochloride so prepared was next converted into the *triacetyl-triamidophenol*, $C_6H_2(NH\overline{Ac})_3.OH$, by heating it with acetic anhydride and sodium acetate. This compound crystallises from water in white leaflets melting at 263°. It is sparingly soluble in benzene and acetone, but more easily in alcohol, water, or glacial acetic acid. It is easily soluble in alkalis and ammonia, and is precipitated from these solutions by acids.

It was next attempted to nitrate this acetyl compound, with the result, however, of producing the quinone,

$$C_{20}H_{20}N_4O_8, \text{ or } <\begin{matrix}C_6H(OH)(NH\overline{Ac})_2O\\C_6H(OH)(NH\overline{Ac})_2O\end{matrix}>,$$

which is also produced when the acetyl compound is treated with weak oxidising agents such as dilute nitric acid or ferric chloride. This quinone crystallises from glacial acetic acid in golden-yellow leaflets melting at 268°, sparingly soluble in alcohol and water.

The corresponding quinol, viz., tetracetamidodihydroxyphenyl quinol, $[C_6H(OH)_2(NH\overline{Ac})_2]_2$, is obtained by treating the quinone suspended in water with hydrogen sulphide. It crystallises from alcohol in colourless needles. P. P. B.

Condensation Products of Paranitrobenzyl Alcohol. By A. Basler (*Ber.*, 16, 2714—2720).—The nitrobenzyl alcohol used in these experiments was prepared from paranitrocinnamic acid. The best results are obtained by dissolving 103·5 grams of methyl nitrocinnamate in 1400 grams of sulphuric acid, and gradually adding 135·5 grams of potassium nitrate to the solution, which must be kept at a temperature between 60° and 70°. When the reaction is complete, the mixture is left at rest for six hours, and afterwards poured into 10 times its volume of ice water. The precipitate is treated with a 3 per cent. solution of sodium carbonate, washed, and recrystallised from hot water. To convert the nitrobenzaldehyde into the alcohol, one part of the powdered aldehyde is dissolved in 5—6 parts of 15 per cent. soda solution. After 12 hours, the solid product is dissolved in a small quantity of water and extracted with ether. The alcohol is deposited from the ethereal solution in crystals melting at 92°. From 80 to 90 per cent. of the aldehyde is converted into alcohol. Nitrobenzyl alcohol was also prepared from the acetate. The yield is about 75 per cent. of the theoretical.

When a solution of nitrobenzyl alcohol in benzene is treated with strong sulphuric acid, two condensation products are formed. The one, *dinitrodibenzylbenzene* $[C_6H_4(NO_2)_2CH_2]_2C_6H_4$, is sparingly soluble in the usual solvents with the exception of benzene, in which it is tolerably soluble. It forms needle-shaped crystals which soften at 140° and melt at 146°. The other, *para mononitro diphenylmethane*, $C_6H_4(NO_2).CH_2Ph$, melting at 31°, is freely soluble in benzene, ether, and alcohol. It is deposited from the alcoholic solution in prisms. Chromic acid converts monodiphenylmethane, in acetic acid solution, into *para-mononitrobenzophenone*, $C_6H_4(NO_2)CO.Ph$, melting at 138°. It is freely soluble in benzene, in hot water, and in boiling alcohol. On reduction with tin and hydrochloric acid, mononitrodiphenylmethane is converted into *monamidodiphenylmethane*. This base forms white crystals melting at 34°, which rapidly change on exposure to the air. The sulphate, hydrochloride, and zinc chloride are crystalline salts. By means of the diazo-reaction it can be converted into para-monhydroxydiphenylmethane, $C_6H_4(OH).CH_2Ph$, which is identical with the compound Paternò obtained by the action of zinc-dust on phenol and benzyl chloride (*Ber.*, 5, 288, 435; 15, 153).

By dissolving para-mononitrodiphenylmethane in fuming nitric acid, a *dinitrodiphenylmethane* is obtained which melts at 175°. It has a musk-like odour, and is perhaps identical with Doer's isodinitrodiphenylmethane (*Ber.*, 5, 795). W. C. W.

Action of Aromatic Hydroxy-acids on Phenols. By A. Michael (*Amer. Chem. J.*, 5, 81—97).—Phenol and salicylic acid do not react on each other when heated either in open vessels or sealed tubes, but on addition of dehydrating agents, best stannic chloride, a reaction is readily effected, the products being paradihydroxybenzophenone and a new substance, salicylphenol, the former appearing to owe its formation to parahydroxybenzoic acid contained in the salicylic acid used.

Salicylphenol, $C_6H_4(\overset{2}{OH}).CO.C_6H_4.\overset{4}{OH}$, crystallises from hot water or alcohol in pale yellow plates, from benzene in pyramids with symmetrically truncated end-faces. It melts at 143—144°, is nearly insoluble in cold, moderately soluble in hot water, readily soluble in alcohol and benzene. It dissolves readily in alkalis, yielding metallic derivatives. The *sodium* compound, $C_{13}H_8O(ONa)_2$, forms stellate groups of needles, very soluble in water and alcohol; the *silver* compound, $C_{13}H_8O(OAg)_2 + H_2O$, is obtained as a bright yellow precipitate, sparingly soluble in water. The mercury compound forms reddish-yellow needles, the ferric salt is obtained in brown fern-shaped crystals, the copper salt crystallises in groups of greenish-yellow rhombic plates, the lead salt was obtained as an amorphous yellow precipitate which melts in boiling water. *Diacetylsalicylphenol*, $C_{13}H_8O(O\bar{Ac})_2$, prepared by heating a mixture of salicylphenol, acetic anhydride, and sodium acetate, crystallises in long concentrically grouped white needles, melts at 84—85°, is sparingly soluble in cold, moderately soluble in hot water, readily soluble in hot alcohol or benzene. From its formation from salicylic acid, one hydroxyl-group in salicylphenol must be in the ortho-position to the carbonyl-group, and as parahydroxybenzoic acid occurs largely amongst the products of its decomposition by fusion with sodium or potassium hydroxides, it is most probable that the second hydroxyl-group is in the para-position.

Ortho-para-dihydroxydiphenylcarbinol, $C_6H_4(OH).CH(OH).C_6H_4.OH$, is obtained by the action of sodium-amalgam on an alkaline solution of salicylphenol, and is precipitated on saturating the liquid with carbonic anhydride, as a white amorphous powder which could not be crystallised. It becomes strongly electric on rubbing, is insoluble in cold, sparingly soluble in hot water, readily soluble in cold alcohol, the solution, on evaporation, yielding an oil that does not solidify on standing. It dissolves readily in alkalis, yielding metallic derivatives. Like the corresponding dipara-compound (*Annalen*, **202**, 132) it gives an intense violet-blue coloration when heated with mineral acids.

Salicylresorcinol, $C_6H_4(OH).CO.C_6H_3(OH)_2$, is obtained in small quantity, by heating a mixture of salicylic acid and resorcinol at 195—200° for 15 hours. It crystallises from alcohol in glittering yellow scales, melts at 133—134°, and resolidifies at 116—117°; it volatilises slowly in a current of steam. It is insoluble in cold, sparingly soluble in hot water, readily soluble in alcohol, benzene, or in alkalis. Acetic anhydride converts it into an acetyl-derivative; an oil which solidifies partially on long standing. Reduction with sodium-amalgam gives a substance resembling the dihydroxydiphenylcarbinols. In presence of dehydrating agents (best zinc chloride) the reaction between salicylic acid and resorcinol takes rather a different course, the product of the action being *salicylresorcinol ether*,

$$C_6H_4{<}\genfrac{}{}{0pt}{}{CO}{-O-}{>}C_6H_3.OH.$$

This compound crystallises in long bright yellow needles, melts at

146—147°, is insoluble in cold, sparingly soluble in hot water. It is also formed by the action of zinc chloride on salicylresorcinol. Fused with alkalis, it yields salicylic acid and resorcinol. Its metallic derivatives are characterised by their insolubility in water. A *sodium compound*, $C_{13}H_7O_3Na,NaOH$, is obtained by the action of sodium methylate on the ether. It crystallises in long lemon-yellow needles, and on long washing with cold water is completely decomposed into sodium hydroxide and salicylresorcinol ether. A mono-sodium-derivative could not be obtained in a state of purity. The author considers it very probable that the disodium-derivative has the composition

$$C_6H_4<\substack{C(ONa)OH\\ \text{——}O\text{——}}>C_6H_3.ONa,$$

as from its behaviour with water it must be regarded as a derivative of the ether and not of salicylresorcinol. *Acetylsalicylresorcinol ether*, $C_6H_4<\substack{CO\\ -O-}>C_6H_3.O\overline{Ac}$, crystallises in white prismatic needles, melts at 167—168°, is sparingly soluble in water, readily soluble in hot alcohol.

Salicylorcinol ether, $C_6H_4<\substack{-O-\\ CO}>C_6H_2Me.OH$, is prepared by heating a mixture of salicylic acid, orcinol, and zinc chloride. It crystallises in straw-coloured silky needles, melts at 140°, is insoluble in water, soluble in hot alcohol. Fused with alkalis, it yields salicylic acid and orcinol. The *sodium* derivative, $C_{14}O_3H_9Na + 1\frac{1}{2}H_2O$, crystallises in long yellow needles; a disodium-compound could not be obtained. *Acetylsalicylorcinol ether*, $C_{14}H_9O_3\overline{Ac}$, crystallises in long needles, and melts at 151—152°.
A. J. G.

Conversion of Hydrocarbons into Aldehydes by the Action of Chromyl Dichloride. By A. ÉTARD (*Compt. rend.*, **97**, 909—911).—The author repeats, in reply to Paternò and Scichilone, that pure cumene yields cumaldehyde when the compound which it forms with chromyl dichloride is decomposed by water.

When a 10 per cent. solution of mesitylene in carbon bisulphide is mixed with a similar solution of chromyl dichloride, a precipitate is obtained of the composition $C_6H_3Me_2.CH(OCrCl_2.OH)_2$, and when this is decomposed by water it yields mesitylaldehyde in almost theoretical quantity. It boils at 220—222°, and oxidises rapidly on exposure to air, yielding mesitylenic acid.

Amyl-toluene, boiling at 213—218°, when treated in a similar manner at 45°, yields a precipitate of the composition

$$C_6H_4Me.C_5H_9(OCrCl_2.OH)_2,$$

and when this is decomposed by water, a mixture of two isomeric aldehydes of the composition $C_{12}H_{16}O$ is obtained.

Phenetoïl, in the same manner, yields a substance $C_8H_8O_4$; orthocresol yields $C_7H_6O_3$; and paracresol, $C_{14}H_{10}O_3$. These substances apparently resemble the quinones in character. They dissolve in alkalis, but are insoluble in acids. Styrolene also forms a definite compound with chromyl dichloride, but it has not yet been examined.
C. H. B.

Action of Benzaldehyde on the Mononitro-derivatives of the Paraffins. By B. PRIEBS (*Ber.*, **16**, 2591).—When nitromethane and benzaldehyde in molecular proportions are heated with zinc chloride in a sealed tube at 160°, phenylnitroethylene, $CHPh : CH.NO_2$, melting at 56·5—57°, is produced: $Ph.COH + CH_3.NO_2 = H_2O + CHPh : CH.NO_2$. In the same way nitroethane and benzaldehyde yield a phenylnitropropylene, $CHPh : CMe\,NO_2$, melting at 64°.

A. K. M.

Ammonia-derivatives of Benzil. (Preliminary Notice.) By F. R. JAPP (*Ber.*, **16**, 2636—2640).—According to Zincke and Henius, (*Ber.*, **16**, 889) the compounds *imabenzil*, *benzilimide*, and *benzilam*, obtained by Laurent, have the formulæ $C_{42}H_{32}N_2O_4$, $C_{42}H_{32}N_2O_4$, and $C_{42}H_{32}N_2O_2$ respectively. The author refers to previous communications (this Journal, Trans., 1883, p. 12, and *Ber.*, **15**, 2413), in which he has shown that the formula of azobenzil (benzilam) is $C_{21}H_{15}NO$, and not $C_{42}H_{30}N_2O_2$, as Zinin assumed (*Annalen*, **34**, 190). Its vapour-density also excludes the formula proposed by Zincke and Henius. When heated with concentrated hydrochloric acid at 250°, it yields benzoic acid, ammonium chloride, and a resinous mass. If oxidised by chromic mixture, benzoic acid is obtained in almost the theoretical amount required by the equation $C_{21}H_{15}NO + O_2 + 3H_2O = 3C_7H_6O_2 + NH_3$, showing that three benzenyl groups must be present in the compound. Moreover, azobenzil is closely analogous in its behaviour to benzenylamidophenanthrol, the constitution of which is known. These facts leave little doubt as to the correctness of the constitutional formula previously assumed by the author (*loc. cit.*). According to Zincke, the conversion of *benzilimide* into azobenzil by cold concentrated sulphuric acid, consists in the removal of oxygen, and as the latter does not appear in the free state it must be assumed to oxidise a part of the substance. This, however, is not in accordance with the fact that the change is very complete, and the author thinks it far more probable that water is eliminated, which might occur in the following manner, if benzilimide be assumed to have the formula $C_{21}H_{17}NO_2$, thus: $C_{21}H_{17}NO_2 - H_2O = C_{21}H_{15}NO$. This formula also agrees better with the results of analysis than that given by Zincke. The constitution,  $\begin{matrix} PhC-O \\ \| \\ PhC.NH \end{matrix}\!\!>C(OH)Ph$, is suggested, according to which benzilimide would also be a condensation-product of benzaldehyde and benzil with ammonia. The author agrees with Zincke that *imabenzil* has the formula $C_{42}H_{32}N_2O_4$; the halved formula would require that half the benzil taking part in the reaction should be decomposed, but the yield of imabenzil is too great for this. Moreover, on boiling it with dilute sulphuric acid, almost exactly the same weight of benzil is obtained: $C_{42}H_{32}N_2O_4 + 2H_2O = 3C_{14}H_{10}O_2 + 2NH_3$, this being the reverse of Zincke's method of forming it. Imabenzil contains therefore neither benzoic acid nor benzaldehyde radicals, and must be derived from 3 mols. of benzil.

A. K. M.

Action of Nitriles on Benzil. By F. R. JAPP and R. C. TRESIDDER (*Ber.*, **16**, 2652 - 2654).—On adding acetaldehyde and benzonitrile to well cooled concentrated sulphuric acid, Hepp and Spiess obtained a compound of the formula $C_{16}H_{16}N_2O_2$; $C_2H_4O + 2C_7H_5N + H_2O = C_{16}H_{16}N_2O_2$. The authors find that a similar reaction takes place with benzil and propionitrile. Finely powdered benzil is suspended in four times its weight of concentrated sulphuric acid, and propionitril gradually added, the mixture being agitated and cooled. After remaining at rest for some hours, it is poured into water and the white product washed with ether and crystallised from boiling alcohol. It forms lustrous colourless needles of the formula $C_{20}H_{22}N_2O_3$, melting at 197°: $C_{14}H_{10}O_2 + 2C_3H_5N + H_2O = C_{20}H_{22}N_2O_3$. On boiling it with dilute sulphuric acid, it yields benzil, propionic acid, and ammonia: $C_{20}H_{22}N_2O_3 + 3H_2O = C_{14}H_{10}O_2 + 2C_2H_5.COOH + 2NH_3$. When benzil and benzonitril are treated as above described, the product consists of two compounds, which can be separated by crystallisation from alcohol. The more soluble compound forms colourless prisms melting at 168°, which crystallise with half a molecule of alcohol, $2C_{28}H_{22}N_2O_3 + C_2H_6O$; $C_{14}H_{10}O_2 + 2C_7H_5N + H_2O = C_{28}H_{22}N_2O_3$. The second substance, $C_{28}H_{21}NO_3$, is nearly insoluble in alcohol and in most of the usual solvents, but can be purified by crystallisation from boiling benzene, when it is obtained in microscopic prisms melting at 225°. Its formation probably takes place thus: $2C_{14}H_{10}O_2 + C_7H_5N + H_2O = C_{28}H_{21}NO_3 + PhCOOH$. When it is heated with concentrated hydrochloric acid at 150°, it is decomposed, benzil, benzoic acid, and ammonia being formed, probably according to the equation $C_{28}H_{21}NO_3 + 2H_2O = C_{14}H_{10}O_2 + C_7H_6O_2 + C_7H_6O + NH_3$; the authors did not succeed in confirming the formation of benzaldehyde. Acetic anhydride, at 150°, has no action on the substance. A. K. M.

Substituted Benzoic Acids, and the Nature of the Hydrogen Atoms in Benzene. Part I. By H. Hübner (*Annalen*, **222**, 67—115).—I. Metanitrobenzoic acid melting at 142° is prepared by adding finely powdered benzoic acid to nitric acid (sp. gr. 1·5), and then boiling for 24 hours. It is separated from the orthonitrobenzoic acid simultaneously formed, by means of the sodium salt, which is more soluble in the case of the ortho-acid. The preparation of dimetanitrobenzoic acid melting at 205°, by the action of a mixture of strong sulphuric and fuming nitric acids on benzoic acids, has been already described (Abstr., 1878, 148). The same acid may also be obtained from the above metanitrobenzoic acid by the action of a mixture of strong sulphuric and nitric acids. The preparation of the same dinitro-acid from paratoluidine was made known by W. Staedel (Abstr., 1881, 724). Paraorthonitrobenzoic acid,

$$C_6H_3(COOH)(NO_2)_2\ [1 : 2 : 4],$$

is prepared by heating paranitrobenzoic acid with a mixture of equal volumes of the strongest nitric and commercial sulphuric acids at 170°. The acid is purified by means of its barium and lead salts: it melts at 179°. This nitration has since been studied by Claus and Halberstadt (Abstr., 1880, 647), who find that a second dinitrobenzoic acid is simultaneously formed. From the above it appears that the NO_2-group in entering into mononitrobenzene-derivatives principally replaces those hydrogen atoms which are in the meta-position, irrespectively of any oxatyl-, methyl-, or amido-groups, which may be already present in the molecule.

II. The preparation of metanitrometamidobenzoic acid melting at 208° has been already described (Abstr., 1878, 148). Metamidobenzoic acid is prepared by passing sulphuretted hydrogen through an ammoniacal solution of metadinitrobenzoic acid until the solution yields no precipitate with hydrochloric acid. The acid crystallises with 1 mol. H_2O, and melts at 228°. By heating the dry hydrochloride of this acid with barium hydroxide, dimetamidobenzene melting at 60° is obtained. This shows that the dinitrobenzoic acid melting at 204°, which is the chief product of the nitration of monometanitrobenzoic acid, has the two nitro-groups in the meta-position relatively to each other.

The nitramidobenzoic acid melting at 208° was converted by means of the diazo-compound into metanitrobenzoic acid melting at 142°, and this again, by means of tin and hydrochloric acid, into metamidobenzoic acid melting at 172·5°. The same metanitramidobenzoic acid melting at 208° was converted by means of the diazo-compound into metanitrochlorobenzoic acid melting at 147°; then, by means of zinc and hydrochloric acid, the latter was converted into metamidochlorobenzoic acid melting at 216°, and this again, through the diazo-compound, into metachlorobenzoic acid melting at 153°. Thus both the nitro-groups in the dinitrobenzoic acid are shown to be in the meta-position. These experiments and results may be thus briefly tabulated:—

		[1 :	3 :	5.]
Dimetanitrobenzoic	acid....	COOH	αNO_2	βNO_2
Metranitramidobenzoic	,, ...	COOH	αNO_2	βNH_2
Metanitrobenzoic	,, ...	COOH	αNO_2	H
α-Metachlorobenzoic	,, ...	COOH	αCl	H
Metanitrochlorobenzoic	,, ...	COOH	αNO_2	βCl
Metamidochlorobenzoic	,, ...	COOH	αNH_2	βCl
αβ-Metachlorobenzoic	,, ...	COOH	H	βCl

III. When metachlorobenzoic acid is acted on by fuming nitric acid, two nitrochlorobenzoic acids are produced. As it may be assumed that the nitric acid acts in the same way as on metabromobenzoic acid, the two acids must be metachlororthonitrobenzoic acids. The two acids are separated by repeatedly boiling them with small quantities of water until the undissolved portion (α-metachloronitrobenzoic acid melting at 235°) no longer melts under water. The solution contains the β-metachloronitrobenzoic acid melting at 137°. The properties, both of the acids themselves and of their respective salts, are quite distinct, thus demonstrating that in monosubstituted benzenes there are two atoms of hydrogen in the ortho-position.

IV. Hitherto for the preparation of α- and β-orthonitrometabromobenzoic acid, purified bromobenzoic acid from bromine and benzoic acid has been employed (*Ber.*, 8, 558; Abstr., 1878, 148).

Owing to the difficulty of separating the products of such an action as that of bromine on benzoic acid, the suspicion might arise that these isomeric bromonitrobenzoic acids had been formed from different bromobenzoic acids. In order to obviate this objection, pure metanitrobenzoic acid was converted into metamido-, and then into metabromobenzoic acid, and this on treatment with nitric acid yielded the α- and β-orthonitrometabromobenzoic acids as with the ordinary bromobenzoic acid. To prepare the α-orthobromometabromobenzoic acid, the above α-orthonitro-acid was converted into the diazo-compound, or rather into the diazoimido-compound,  $\begin{array}{l}COOH.C_6H_3Br.N{=}\\COOH.C_6H_3Br.NH\end{array}\!\!>\!N$, as it proved to be, and the latter into the dibromobenzoic acid, which melts at 147°.

To prepare the metabromo-β-orthobromobenzoic acid, the above β-orthonitro-acid was first converted into the metabromo-β orthamidobenzoic acid. The further conversion of the latter, by means of the diazo-compound, into dibromobenzoic acid, is attended with much difficulty. The hydrobromide of the amido-acid is first prepared, treated with nitrous anhydride in the cold, and finally boiled. The metabromo-β-orthobromobenzoic acid melts at 153°.

The two isomeric bromamidobenzoic acids were also converted into amidobenzoic acid by means of sodium-amalgam. In both cases, the same amidobenzoic acid melting at 144°, and identical with anthranilic acid or orthamidobenzoic acid was obtained, thus confirming the already demonstrated existence of two ortho-hydrogen atoms in mono-substituted benzene.

That the existence of two isomeric metabromorthonitrobenzoic acids depends on the different relationship between the bromine- and nitro-groups, was shown by converting these acids into dibromobenzene. The β-compound was found to yield paradibromo-, and the α-compound orthodibromobenzene, thus:—

Metabromo-β-orthonitrobenzoic acid. [$COOH : NO_2 : Br = 1 : 2 : 5$].	Metabromo-α-orthonitrobenzoic acid. [$COOH : NO_2 : Br = 1 : 2 : 3$].
Metabromo-β-orthobromobenzoic acid. [$COOH : Br : Br = 1 : 2 : 5$].	Metabromo-α-orthobromobenzoic acid. [$COOH : Br : Br = 1 : 2 : 3$].
Paradibromobenzene. [$Br : Br = 2 : 5$].	Orthodibromobenzene. [$Br : Br = 2 : 3$].

P. F. F.

Nitrohydroxypropylbenzoic Acid and its Derivatives. By O. Widmann (*Ber.*, 16, 2567—2575).—This acid, together with some of its derivatives, have been already described by the author (Abstr., 1883, 330). The *ammonium salt*, $C_{10}H_{10}NO_5.NH_4 + 2H_2O$, forms lustrous needles extremely soluble in water; the *silver salt*,

$$C_{10}H_{10}NO_5Ag + \tfrac{1}{2}H_2O,$$

separates from a warm solution in needles, and from a cold solution in well-formed prisms or rhombic plates, sparingly soluble in cold, more readily in warm water; the *calcium salt*, $(C_{10}H_{10}NO_5)_2Ca$, crystallises in sparingly soluble white needles, the *barium salt*, $(C_{10}H_{10}NO_5)_2Ba + 6H_2O$, in highly lustrous needles, 1 part of the latter salt (anhydrous) dissolving in 11 parts water at 13°. The *lead salt*,

$$(C_{10}H_{10}NO_5)_2Pb + 5H_2O,$$

forms short lustrous prisms very sparingly soluble in water, and the *copper salt*, $(C_{10}H_{10}NO_5)_2Cu + 1\frac{1}{2}H_2O$, bluish-green prismatic or cubical crystals, also very sparingly soluble in water, although readily in alcohol, from which it crystallises in small green slender needles. *Nitroacetoxypropylbenzoic acid*, $C_6H_3(NO_2)(CMe_2.O\overline{Ac}).COOH$, is obtained when nitrohydroxypropylbenzoic acid is heated with an excess of acetic anhydride in sealed tubes at 100°, the solution repeatedly evaporated with alcohol, and the oily product crystallised from a mixture of ether with a little alcohol. It forms colourless rhomboidal pyramids melting at 131—133°, and extremely readily soluble in alcohol, ether, and the usual solvents, almost insoluble in water.

Salts of Nitropropenylbenzoic Acid.—The *ammonium salt* is extremely soluble in water, and crystallises at ordinary temperatures in white needles, $C_{10}H_8NO_4.NH_4$; the *silver salt*, $C_{10}H_8NO_4Ag$, forms clusters of white needles, or on rapidly cooling its hot solution, slender white feathery needles, very sparingly soluble in cold, more readily in warm water; the *calcium salt*, $(C_{10}H_8NO_4)_2Ca + 2H_2O$, separates in clusters of slender white needles, very sparingly soluble in water; the *barium salt*, $(C_{10}H_8NO_4)_2Ba + 3\frac{1}{2}H_2O$, crystallises in small white concentrically grouped needles, very sparingly soluble in cold, much more readily in warm water; the *copper salt*, $(C_{10}H_8NO_4)_2Cu + H_2O$, obtained by precipitating the ammonium salt with copper sulphate, forms a bluish-green precipitate; it begins to decompose above 100°, whilst long white needles sublime, insoluble in water, readily soluble in potash, and melting at about 150°. *Amidohydroxypropylbenzoic acid*, $C_6H_3(NH_2)(CMe_2.OH).COOH$, is prepared by dissolving the nitro-acid (5 grams) in an excess of ammonia, and gradually adding a solution of ferrous sulphate (40 grams). The mixture is supersaturated with ammonia, warmed on a water-bath, and the nearly colourless filtrate treated with acetic acid and repeatedly extracted with ether, from which, after purification, the amido-acid crystallises in colourless lustrous prisms, which do not melt at 270°. It is almost insoluble in benzene, readily soluble in alcohol, very sparingly in ether, and moderately soluble in water; it possesses very feeble acid as well as basic properties; it yields amidopropenylbenzoic acid when boiled with hydrochloric acid.

Acetamidohydroxypropylbenzoic acid, $N\overline{Ac}H.C_6H_3(CMe_2.OH).COOH$, is obtained by the action of acetic anhydride (1 mol.) on amidohydroxypropylbenzoic acid (1 mol.), the two substances reacting violently with great evolution of heat, the product soon solidifying to a hard brittle mass. It is very sparingly soluble in boiling alcohol, from which it separates as a white crystalline powder, which does not melt at 280°. *Amidopropenylbenzoic acid*, $NH_2.C_6H_3(C_3H_5).COOH$, is prepared from the corresponding nitro-compound by reduction with ammonia and ferrous sulphate. It crystallises in long white lustrous needles melting at 93—94°, and is readily soluble in ether, alcohol, chloroform, and benzene, sparingly in light petroleum and in water. It may also be obtained by boiling amidohydroxypropylbenzoic acid with hydrochloric acid. On evaporating the solution. the hydrochloride is obtained, and may be decomposed by sodium hydroxide, and the acid separated by the addition of acetic acid. The *hydrochloride*, $COOH.C_6H_3(C_3H_5).NH_2Cl$, crystallises in long colourless prisms, very readily soluble in water, and yields a readily soluble platinochloride. The *acetate*, $COOH.C_6H_3(C_3H_5).NH_2,\overline{Ac}OH$, crystallises in short colourless well-formed prisms, melting at about 160°, with evolution of gas and formation of a substance of very high melting point: this behaviour is due to the presence of water of crystallisation. Considerable evolution of heat takes place when acetic anhydride (1 mol.) acts on amidopropenylbenzoic acid, and *acetamidopropenylbenzoic acid*, $N\overline{Ac}H.C_6H_3(C_3H_5).COOH$, is formed. It crystallises from dilute alcohol in white flat needles melting at 210—212°. If an excess of acetic anhydride is used, the second amido-hydrogen seems to be replaced, the product melting at 215—216°. Acetamidopropenylbenzoic acid is sparingly soluble in boiling water, from which it crystallises in long needles; it is insoluble in cold, but soluble in boiling dilute sulphuric acid, from which it crystallises unchanged; it is also insoluble in cold hydrochloric acid, and on boiling dissolves with difficulty and with partial saponification and formation of the hydrochloride of a new compound (see p. 303).

Conversion of Active Mandelic Acid into Inactive. By J. LEWKOWITSCH (*Ber.*, 16, 2721—2722).—When lævomandelic acid is heated at 160° in a sealed tube for 30 hours, it is converted into benzaldehyde and inactive mandelic acid. By means of the cinchonine salt, the inactive acid can be split up into the two optically active varieties. When paramandelic acid is exposed to the action of *schizomycetes*, the dextromandelic acid is decomposed, but the lævo-acid remains.

W. C. W.

Dipyrogallopropionic Acid. By C. BÖTTINGER (*Ber.*, 16, 2404—2412).—By treating pyroracemic acid and pyrogallol with concentrated sulphuric acid, a mixture of this acid and its anhydride was obtained from which the former was separated by its greater solubility in water. The aqueous solutions, on spontaneous evaporation, leave a red resinous mass, which is easily soluble in glacial acetic acid, acetone, and alcohol. It is decomposed by heat, leaving the anhydride, and melts at 162°. The composition of this acid is expressed by the formula $C_{15}H_{14}O_8$. It dissolves in ammonia and alkalis, forming blue solutions, in which barium chloride, calcium chloride, and copper sulphate produce dark-blue precipitates.

Methyldipyrogallopropionate is obtained by heating the acid with potash, methyl iodide, and methyl alcohol at 120°. It is a dark-brown powder melting below 100°.

Dipyrogallopropionic acid with acetic anhydride, yields a diacetyl-derivative, $C_{15}H_{10}\overline{Ac}_2O_7$; this when treated with bromine yields a pentabromo-derivative, $C_{15}H_7Br_5\overline{Ac}_2O_7$.

Dipyrogallopropionic acid treated with bromine in glacial acetic acid solution, yields a mixture of a tribromo- and pentabromo-derivative.

Anhydrodipyrogallopropionic acid, $C_{15}H_{12}O_7$, is obtained by heating the acid at 100°. It forms a reddish-brown powder soluble in hot water and dissolving in ammonia to a violet-coloured solution. When heated with acetic anhydride, it yields a diacetyl-derivative. Bromine reacts with a solution in glacial acetic acid or chloroform, forming a tribromo- and pentabromo-anhydropyrogallopropionic acid.

P. P. B.

Properties of Ethylic Phenylsulphonacetates. By A. MICHAEL and A. M. COMEY (*Amer. Chem. J.*, 5, 116—119).—*Ethylic phenylsulphonacetate*, $PhSO_2.CH_2.COOEt$, is obtained by the action of ethyl chloracetate on an alcoholic solution of sodium phenylsulphonate, the mixture being heated for 4—5 hours on the water-bath, the alcohol distilled off, the residue extracted with water, and the insoluble oil allowed to stand for some time, when it crystallises, and is purified by crystallisation from alcohol. Ethylic phenylsulphonacetate crystallises in clusters of long prisms, melts at 45°, is insoluble in water, sparingly soluble in cold, soluble in hot alcohol. Boiled with alkalis, it yields the metallic salts, which, on treatment with acids, give the free acid.

Sodium has little action on the ethyl salt; sodium ethylate, on the contrary, readily reacts, a mixture of the substances in molecular proportion dissolved in absolute alcohol soon solidifying to a mass of white needles of *ethyl sodium phenylsulphonacetate*,

$$PhSO_2.CHNa.COOEt.$$

This is sparingly soluble in cold, moderately soluble in hot alcohol, readily soluble in water; on acidifying, the original ether is precipitated.

Ethylic benzylphenylsulphonacetate, $PhSO_2.CH(CH_2Ph).COOEt$, is prepared by the action of benzyl chloride on the preceding compound; it forms short white prisms, melts at 95—96°, is insoluble in water, readily soluble in hot alcohol. Heated with alcoholic sodium ethylate, it yields a sodium derivative which when treated with benzyl chloride gives the *dibenzyl derivative* melting at 118°. On heating the monobenzyl derivative with excess of alcoholic caustic soda in a closed tube at 100° for several hours, it yields cinnamic acid, according to the equation, $C_6H_5.CH_2.CH(SO_2Ph).COOEt + 2KOH = C_6H_5.CH:CH.COOK + PhSO_2K + EtOH + OH_2$.

These results show clearly that an acid radical such as $PhSO_2$, has as decided an effect as an acetyl-group in rendering the hydrogen of the CH_2-group to which it is attached sufficiently negative to be replaceable by metals.

A. J. G.

Oxidation of Substitution-products of Aromatic Hydrocarbons. Experiments with Derivatives of Naphthalene. By I. REMSEN and W. J. COMSTOCK (*Amer. Chem. J.*, 5, 106—111).—The lead salts of α- and β-naphthalenesulphonic acids were treated directly with phosphorous pentachloride and ammonia, and the amides so obtained submitted to oxidation. Satisfactory results were obtained only when potassium permanganate was employed as the oxidising agent. In neutral solution, or in alkaline solution with excess of permanganate, phthalic acid and sulphophthalic acid are obtained, whilst in alkaline solution with the permanganate not in excess of the amount theoretically required, sulphaminephthalic acids are obtained, together with a small quantity of phthalic acid.

α-Sulphophthalic acid could not be obtained pure in the free state; the *barium salt*, $\left(C_6H_3\genfrac{}{}{0pt}{}{\diagup SO_3}{\diagdown (COO)_2}\right)_2Ba_3 + 8H_2O$, crystallises in aggregates of small clear and transparent plates. It loses 7 mols. H_2O below 150°. It is sparingly soluble in boiling water. The *hydrogen lead salt*, $C_6H_3(COOH)<\genfrac{}{}{0pt}{}{SO_2O}{COO}>Pb + 1\frac{1}{2}H_2O$, crystallises in small prisms.

α-Sulphaminephthalic acid was not obtained free. *Potassium α-anhydrosulphaminephthalate*, $C_6H_3(COOK)<\genfrac{}{}{0pt}{}{SO_2}{CO}>NH + H_2O$, crystallises in needles, is soluble in alcohol and water, insoluble in ether. *Silver sulphaminephthalate*, $C_6H_3(COOH)(SO_2NH_2).COOAg$, forms colourless needles, is soluble in hot water, does not lose in weight at 180°, but appears to suffer decomposition when heated much at that temperature.

Dipotassium β sulphophthalate, $C_6H_3(SO_3K)(COOK).COOH + 2H_2O$, forms small prismatic crystals, readily soluble in water, nearly insoluble in alcohol. *Potassium β-sulphaminephthalate*,

$$C_6H_3(SO_2NH_2)(COOK).COOH + 2\frac{1}{2}H_2O,$$

crystallises in radiating groups of silky needles of a light straw colour, and is readily soluble in water. A. J. G.

Aniluvitonic Acid. By C. Böttinger (*Ber.*, **16**, 2357—2359).—The hydrochloride of this acid suspended in chloroform and treated with bromine, forms a red oily liquid which, after being washed with chloroform and then with water, forms a reddish-yellow powder, losing bromine on exposure to the air. This same oily bromine addition-product is obtained by heating the hydrochloride with bromine in sealed tubes at 120°, but substitution-products are formed at the same time.

Aniluvitonic acid hydrobromide is obtained by spontaneous evaporation of its aqueous solutions in beautifully iridescent large prismatic tabular crystals, containing 2 mols. H_2O, whilst from hot saturated solutions it crystallises in long spikes containing $\frac{1}{2}$ a mol. H_2O. Its aqueous solutions when not too dilute give a yellow precipitate with platinum chloride. When the hydrobromide is mixed with lime and distilled, it yields methylquinoline.

When the hydrochloride of aniluvitonic acid is heated with phthalic anhydride and zinc chloride, it gives a brownish-yellow colouring matter of a basic character, the hydrochloride of which reacts with methyl iodide, yielding a brownish-red powder, which crystallises from alcohol and ether in yellow needles, and is probably a methylated derivative of aniluvitonic acid. P. P. B.

Cymenesulphonic Acids. By E. PATERNÒ (*Ber.*, 16, 2713).—A reply to Claus (*Ber.*, 16, 1297).

"Oakbark Tannic Acid." By C. BÖTTINGER (*Ber.*, 16, 2710—2713).—In reply to Etti (Abstr., 1883, 995), the author maintains that the tannic acid contained in oakbark must have the composition $C_{19}H_{16}O_{10}$, as it forms a bromine substitution-product, $C_{19}H_{14}Br_2O_{10}$, which yields a *pentacetic* derivative. Strong hydrochloric acid at 200° decomposes the dibromo-derivative into carbonic acid, water, and the compound $C_{38}H_{18}O_{13}$, from which a tetrabrominated derivative was obtained. The tannic acid contains 1 ketone oxygen-atom. When dibromotannic acid is acted on by bromine, 4 hydrogen-atoms are eliminated, but only two of them are replaced by bromine, and $C_{19}H_{10}Br_4O_{10}$ is produced. This body also yields a pentacetic derivative.

Phlobaphen and "oak-red" have the composition $C_{38}H_{26}O_{17}$, five of the hydrogen-atoms being replaceable by acetyl. No methyl chloride is formed when the compound is converted into $C_{36}H_{22}O_{11}$ by the action of hydrochloric acid at a high temperature. Phlobaphen yields two bromine derivatives, $C_{38}H_{20}Br_6O_{17}$ sparingly soluble in alcohol, and $C_{38}H_{16}Br_{10}O_{17}$ freely soluble in alcohol. Seven hydrogen-atoms in the first body can be replaced by acetyl.

Phlobaphen does not contain a ketone oxygen-atom. It is reduced by hydriodic acid, and yields ethers when treated with alcoholic iodides and potash. On oxidation with potassium permanganate, the ether is converted into carbonic, oxalic, and acetic acids, and a solid compound which is decomposed by hydrochloric acid at 190° into ethyl chloride and pyrogallol.

From these facts, the author concludes that the tannic acid from oakbark is a condensation-product of an aldehyde, $C_6H_5.CO.CH_2.CHO$, with tannin. W. C. W.

Diphenylparaxylylmethane and its Products of Oxidation. By W. HEMILIAN (*Ber.*, 16, 2360—2379).—*Diphenylparaxylylmethane*, $CHPh_2.C_6H_3Me_2$, is obtained by heating together benzhydrol, paraxylene, and phosphoric anhydride. It is a solid, crystallising from ether in large shining transparent prismatic crystals, which melt at 92°, and are easily soluble in alcohol, ether, benzene, and glacial acetic acid. Like triphenylmethane, it yields colouring matters similar to rosaniline, by successive nitration, oxidation, and reduction. On careful oxidation with chromic mixture, it yields a resinous mass, which is partly soluble in concentrated soda solution; the residue, when extracted with boiling alcohol, yields methyldiphenylphthalide, the first homologue of diphenylphthalide described by Baeyer (Abstr., 1880, 650).

Methyldiphenylphthalide, $Ph_2C<\overset{C_6H_3Me}{\underset{O}{——}}>CO$, crystallises from

alcohol in large shining prismatic crystals, is sparingly soluble in cold, more easily in hot alcohol. It melts at 179°, and sublimes without decomposition at 360°.

Tolyldiphenylmethanecarboxylic acid, $CPh_2(OH).C_6H_5Me.COOH$, is obtained by first heating methyldiphenylphthalide with alcoholic soda, and then reducing the resulting sodium tolyldiphenylcarbinolorthocarboxylate, $CPh_2(OH).C_6H_3Me.COONa$, with zinc-dust; the solution so obtained is decomposed by an acid, when the tolyldiphenylmethanecarboxylic acid separates out as a white curdy precipitate. It crystallises from a mixture of alcohol and ether in large transparent tables, insoluble in water, but soluble in alcohol, ether, &c.; it melts at 217° and distils without decomposition. It is a strong monobasic acid, forming well-defined salts, which are mostly insoluble in water, but soluble in alcohol. By careful oxidation, it is easily reconverted into methyldiphenylphthalide.

Methylphenylanthranol,  $C_6H_3Me\left<\begin{matrix}CPh—\\ |\\ C(OH)\end{matrix}\right>C_6H_4$, is obtained by the action of concentrated sulphuric acid on tolyldiphenylmethanecarboxylic acid, a formation exactly analogous to that of phenylanthranol (Baeyer, *loc. cit.*). It crystallises from alcohol in light yellow shining tables which melt at 156°. It is soluble in ether, hot alcohol, and glacial acetic acid, insoluble in solutions of caustic alkalis, and of the carbonates of the alkali metals, but soluble in boiling alkalis.

Methylphenyloxanthranol,  $C_6H_3Me\left<\begin{matrix}CPh(OH)\\ CO\end{matrix}\right>C_6H_4$, formed by oxidising methylphenylanthranol with chromic acid. By crystallisation first from glacial acetic acid, and then from alcohol, it is obtained in colourless rhombic tables melting at 195°, and soluble in alcohol, ether, and glacial acetic acid, but insoluble in caustic alkalis. Like phenyloxanthranol (Baeyer, *loc. cit.*), it dissolves in concentrated sulphuric acid, forming a purple solution, which becomes dark violet on warming. By reducing agents, it is converted into methylphenylanthranol.

Methylphenylanthracene,  $C_6H_3Me\left<\begin{matrix}CPh\\ CH\end{matrix}\right>C_6H_4$, is obtained by heating methylphenylanthranol with zinc-dust. When crystallised from alcohol or glacial acetic acid, it forms tufts of yellow crystals which melt at 119°; its ethereal and alcoholic solutions exhibit distinct greenish-blue fluorescence. It forms a compound with picric acid, and when treated with sulphuric acid, is converted into a soluble sulphonic acid. Chromic acid converts it into the oxanthranol.

Tolyldiphenylmethane, $CHPh_2.C_6H_4Me$, is formed by distilling barium tolyldiphenylmethanecarboxylate with baryta. It crystallises in long thin needles, united in globular masses, melting at 62°, and volatile without decomposition at temperatures above 360°. It is easily soluble in alcohol, ether, benzene, and glacial acetic acid; its solutions exhibit well-defined blue fluorescence, which is observable in the crystals also. The crystals of this hydrocarbon exhibit the remarkable property of giving out an intensely blue light when rubbed. In its chemical behaviour the hydrocarbon resembles triphenylmethane and diphenylparaxylylmethane. On oxidation with chromic mixture, it yields a *triphenylcarbinolcarboxylic acid*, $CPh_2(OH).C_6H_4.COOH$, melting at 160—162°.

This hydrocarbon is the third known, having the formula

$$CHPh_2.C_6H_4Me.$$

E. and O. Fischer obtained one containing the methyl-group, symmetrically disposed as regards the methane residue, viz., in the position [1 : 4] (*Annalen*, **194**, 242). A second one has also been obtained by these chemists from leucaniline; it melts at 59—59·5°, and on oxidation yields a carbinol melting at 150°. In this hydrocarbon the position of the methyl-group to the methane residue is supposed to be the unsymmetrical one, viz., [1 : 3]. The author contends that this hydrocarbon is an ortho-compound, and that the tolyldiphenylmethane described by him is in reality the meta-compound, inasmuch as the acid from which it is formed can only have the constitution

$$[CHPh_2 : Me : COOH = 1 : 3 : 6],$$

and consequently the tolyldiphenylmethane formed from it must have the constitutional formula [$CHPh_2 : Me = 1 : 3$]. The portion of the products of oxidation of methyldiphenylphthalide, which is soluble in soda, contains the sodium salts of tolyldiphenylcarbinolmetacarboxylic acid and triphenylmethaneanhydrocarboxylic acid.

Tolyldiphenylcarbinolmetacarboxylic acid,

$$CPh_2(OH).C_6H_3Me.COOH,$$

crystallises from hot glacial acetic acid in small leaflets; it is sparingly soluble even in hot alcohol and glacial acetic acid, and insoluble in the cold; it melts at 250—255°, and is at the same time resolved into water and a yellow non-crystalline product. It forms well-defined crystalline salts, most of which are insoluble in water. Heated with acetic anhydride, it is partially converted into an acetic compound, $C_{21}H_{17}(\overline{Ac})O_3$.

Triphenylmethane-anhydrocarboxylic acid, $CPh_2{<}\genfrac{}{}{0pt}{}{C_6H_3(COOH)}{\text{——}O\text{——}}{>}CO$, is obtained from the mother-liquors obtained in the purification of the tolyldiphenylcarbinolmetacarboxylic acid, from which it differs by being much more easily soluble in alcohol and glacial acetic acid: it crystallises in two distinct forms from its solutions in the latter solvent; by quickly cooling the hot saturated solution, it is obtained in silky needles, and by slow evaporation in transparent tablets; both forms melt at 244—246°, and distil at higher temperatures without decomposition. It is a monobasic acid, forming salts which as a rule are easily soluble in water. When distilled with excess of caustic alkalis, it yields benzophenone and benzene, the latter being a secondary product of the decomposition of terephthalic acid and benzoic acid. This decomposition is exactly analogous to that which phenolphthaleïn undergoes under similar conditions.

Triphenylmethanedicarboxylic acid, $CHPh_2.C_6H_3(COOH)_2$. — This acid is obtained by treating the solution of triphenylmethaneanhydrocarboxylic acid in caustic soda with zinc-dust, and filtering from excess of zinc, then decomposing the solution with hydrochloric acid. The white curdy precipitate so obtained is next crystallised from glacial acetic acid, when it forms slender needle-shaped crystals melting at 278—280°, and easily soluble in alcohol, ether, and glacial acetic acid. It is a dibasic acid, forming salts which are generally soluble in water; the silver salt is insoluble in water and alcohol. When distilled with an excess of an alkali, it yields triphenylmethane. On oxidation, it is converted into triphenylmethane-anhydrocarboxylic acid. It dissolves in cold concentrated sulphuric acid, forming a greenish-yellow solution, which on warming changes first to green, then indigo-blue, violet, and finally assumes an intense purple. P. P. B.

Carbonyldiphenyl Oxide and Hydroxyphenylene Ketone. By R. Richter (*J. pr. Chem.* [2], **28**, 273—309).—In this paper a more detailed account (Abstr., 1882, 618) is given of the ketones obtained originally by Kolbe and Lautemann (*Annalen*, **115**, 197) by the action of phosphorus oxychloride on the basic and neutral sodium salts of salicylic acid.

Carbonyldiphenyl oxide, $CO(C_6H_4)_2O$, is best prepared by the action of phenyl phosphate on sodium salicylate:

$$Ph_3PO_4 + 3C_6H_4(OH)COONa = 3CO(C_6H_4)_2O + Na_3PO_4 + 3H_2O.$$

It is obtained from alcoholic solution in white crystals, which melt at 173—174°, and sublime readily. It is soluble in hot alcohol, benzene, and chloroform, less soluble in cold alcohol and ether, and quite insoluble in water. This ketone is also formed by distilling phenyl phosphate with sodium meta- or para-hydroxybenzoate (with phosphorus oxychloride the reaction is quite different); by acting on potassium methyl salicylate with phenyl phosphate; by distillation of neutral or basic sodium salicylate with phosphorus pentoxide; by dry distillation of sodium chloro-salicylate; by the action of chlorosalicylic chloride on basic sodium salicylate, $C_6H_4Cl.COCl + C_6H_4(ONa).COONa = NaCl + CO_2 + CO(C_6H_4)_2O$; and lastly by the action of phosphorus oxychloride on sodium ortho-phenylbenzoate. The ketone character of the compound was demonstrated by the action of hydriodic acid and of zinc-dust; and also by fusion with potash, when it is decomposed into salicylic acid and phenol.

Methylenediphenyl oxide, $CH_2(C_6H_4)_2:O$, is prepared by the action of hydriodic acid on the ketone, and forms white crystals, soluble in alcohol and ether, sublimable, and melting at 98·5°. It is easily oxidised again to the ketone by dilute nitric acid. By the action of phosphorus pentachloride, a bibasic acid of the formula $(C_{13}H_9O)PO_3$ is formed, crystallising in needles, and melting at 255—260°. The ammonium and silver salts were prepared; the latter is insoluble in water. Dilute nitric acid decomposes it into phosphoric acid and the original ketone. Bromine gives a substitution-product with methylenediphenyl oxide, and fuming nitric acid a dinitro-derivative of the ketone.

Carbonyldihydroxydiphenyl, $CO(C_6H_4.OH)_2$, is formed as an intermediate compound on fusing carbonyldiphenyl oxide with potash. With strong bases, it forms salts in which one atom of hydrogen is replaced by the metal, but with alcohol and acid radicals, at high temperatures, it forms compounds in which two hydrogen atoms are replaced. The author has prepared the barium and ammonium salts, and also a mono- and a di-methyl ether, an acetyl-compound, $C_{13}H_3O_3\overline{Ac}_2$, and a benzoyl compound. In his opinion this substance is not an acid containing the group COOH, as Merz and Werth have supposed (*Ber.*, **14**, 192), since no ether could be obtained by long action of hydrochloric acid on the substance dissolved in absolute alcohol, and from the nature of the above-mentioned salts and ether, the two hydroxyls are not of the same kind, but are similar in character to those in the glycols. Dilute nitric acid converts this substance into the original ketone. On heating it with fuming hydriodic acid and amorphous phosphorus, methylenediphenyl oxide is first formed by reduction, and finally the phosphoric acid compound, $C_{13}H_9O.PO(OH)_2$. It differs from the ketone in being completely decomposed by fuming hydrochloric acid at 200° into phenol and carbonic anhydride. By reduction with sodium-amalgam, a crystalline substance, $C_{26}H_{18}O_3$, is formed. Since acetic anhydride decomposes it into the ketone and methylenediphenyl oxide, its formula may be represented as $\left.\begin{matrix}(C_{12}H_8O)''CO\\(C_{12}H_8O)''CH_2\end{matrix}\right\}$.

By oxidation with chromic acid in glacial acetic acid or by permanganate of potash, the ketone is slowly but completely decomposed. It forms a dibromo-substitution product with bromine, and with nitric acid, α-carbonyldinitrodiphenyl oxide, melting at 145—150°, and β-carbonyldinitrodiphenyl oxide, melting at 260°.

Hydroxydiphenylene ketone, $CO\left<\begin{matrix}C_6H_3.(OH)\\—C_6H_4—\end{matrix}\right>$.—This ketone is formed by the action of phosphorus oxychloride on neutral sodium salicylate, and differs in being easily soluble in alcohol, ether, and alkaline carbonates. It forms colourless needles melting at 91°. It can also be obtained by the action of phosphorus oxychloride on methyl or ethyl salicylate. By treating a mixture of basic sodium salicylate and ethyl salicylate with phosphorus oxychloride, a mixture of the two ketones is obtained. Distilled over red-hot calcium oxide, it is decomposed into diphenylene oxide and diphenyl ketone. Over red-hot zinc-dust, it yields a substance smelling of diphenyl, soluble in caustic soda and reprecipitated by acids, and crystallising in beautiful colourless plates. The melting point of this substance is 51°; diphenyl, melting at 71°, was also obtained. This ketone is not reduced by zinc or sulphuric acid, or by fuming hydriodic acid and phosphorus. Chromic acid completely oxidises it. The author has prepared a mono- and a di-nitro-derivative, also a disulpho- and a monobromo-substitution compound.

Action of Phosphorus Oxychloride on Neutral Potassium Salicylate and Sodium Meta- and Para-hydroxybenzoates.—The action on potassium salicylate is the same as on the sodium salt. Sodium metahydroxybenzoate gives a yellow crystalline acid, melting and decomposing at 285°. The para-salt gives a chlorinated sublimable or crystalline compound, melting and distilling at 105°. These reactions will form the subject of future research.

Amongst the products of the action of phenyl phosphate on sodium salicylate were found phenylbenzoïc acid melting at 110—111°, diphenyloxide melting at 27—28°, and a substance which the author supposes may be phenylene oxide (C_6H_4O). A. B.

Unsymmetrical Tetraphenylethane. By R. ANSCHÜTZ (*Ber.*, 16, 2377—2379).—By the action of aluminium chloride on a solution of stilbene bromide in benzene, a tetraphenylethane is formed, which is found to be identical with that obtained from unsymmetrical tetrabromethane, benzene, and aluminium chloride (*Ber.*, 16, 1435), and also with that obtained by the reduction of β-benzopinacoline. The formation of this compound by these three reactions is represented by the following equations:—

$$CH_2Br.CBr_3 + 4C_6H_6 = CH_2Ph + CPh_3 + 4HBr.$$
$$CPh_3.COPh + 2H_2 = CPh_3.CH_2Ph + H_2O.$$
$$CHPhBr.CHPhBr + 2C_6H_6 = CPh_3.CH_2Ph + 2HBr.$$

The formation of an unsymmetrical tetraphenylethane from symmetrical stilbene bromide is apparently due to an intermolecular change taking place in the stilbene bromide, and brought about by the action of the aluminium chloride on this substance.

P. P. B.

Bromine-derivatives of β-Naphtholazobenzene. By L. MARGARY (*Gazzetta*, 13, 438—440).—The author prepared β-naphtholazobenzene by the action of diazobenzene chloride on an alkaline solution of β-naphthol, whereby a brown crystalline mass was formed, having a green metallic reflex, and after a few hours the whole of the colouring matter separated at the surface of the liquid. β-Naphtholazobenzene forms red-brown needle-shaped crystals, soluble in acetic acid, light petroleum, alcohol, and benzene, and melting at 125—126°, differing thereby from Typke's α-naphtholazobenzene (*Ber.*, 1877, p. 1550), one modification of which melts at 166°, and the other at 175°.

With the view of determining whether the action of bromine on β-naphtholazobenzene gives rise to a monobrominated derivative, and whether the substitution takes place in the benzene- or in the naphthol-group, the author treated that compound dissolved in acetic acid with bromine in the proportion required to form a monobromo-derivative, whereupon a brown crystalline mass separated, which after two crystallisations from alcohol yielded orange-red silky needles melting at 160—161°, and having the composition $C_6H_4BrN : NC_{10}H_6.OH$ or $C_6H_5N : NC_{10}H_5Br.OH$. In this respect β-naphtholazobenzene differs from the α compound, which, according to Typke, does not yield a monobromo-derivative when similarly treated.

This being established, the position of the bromine in the molecule may be determined by subjecting the monobromo-compound to Nietzki's reaction for the preparation of the amidonaphthols: for if the bromine replaces an atom of hydrogen in the naphthol-group, the product will be a bromamid naphthol, whereas if the substitution takes place in the benzene-group, the result will be the formation of bromanilines. Experiment showed that the reaction took place in the manner last mentioned, the products being parabromaniline and amidonaphthol, the presence of which latter was demonstrated by converting it, according to Liebermann and Jacobsen's method, into naphthaquinone. As a confirmation of this result, the author diazotised parabromaniline, and treated β-naphthol with the product, obtaining thereby a body agreeing in crystalline form and melting point with the above-described product formed by direct bromination.

H. W

Products of the Decomposition of Santonous Acid. By S. Cannizzaro (*Gazzetta*, **13**, 385—395).—This acid heated in a stream of carbonic anhydride at 330—320°, gives off a few gas-bubbles, and yields a liquid distillate together with a crystalline substance saturated with oil, which condenses in the neck of the retort. At 360° a fresh portion of liquid acid is obtained, together with a crystalline matter and a considerable quantity of viscid yellowish oil; and on continuing the heating at a temperature above 360° till nothing is left but a small carbonaceous residue, an oil distils over similar to that above mentioned, and bubbles of combustible gas are given off.

The portion which distils up to 360° contains water, santonous acid, propionic acid, dimethylnaphthol dihydride, $C_{12}H_{14}O$, dimethylnaphthol, $C_{12}H_{12}O$, and an oil resolvable by potash into propionic acid and dimethylnaphthol dihydride, consisting therefore of the propionic ether of the latter. The portions which distil above 360° consist chiefly of this ether, together with a small quantity of dimethylnaphthalene, $C_{12}H_{12}$. The residue left in the retort when the heat has not been raised above 300°, and has been discontinued after water, santonous acid, and traces of other products have passed over, is an anhydride of santonous acid, which solidifies to a transparent brittle resin not perceptibly soluble in alcohol or ether: it dissolves, however, when heated for some time with alcoholic potash, and on evaporating the alcohol and replacing it by water, an alkaline solution is obtained, from which carbonic acid does not separate any phenol, and hydrochloric acid throws down santonous acid. This acid is also found in the residue left after heating to 360°. If the temperature has been raised from that point to 400°, the residue consists of a mixture of $C_{12}H_{12}O$ and $C_{12}H_{14}O$; but if it has been raised above 400°, the residue is small in quantity, and does not contain any determinable product.

The formation of these products appears to take place as follows: 1. Part of the santonous acid $C_{15}H_{20}O_3$, is resolved into water and the anhydride $C_{15}H_{18}O_2$. 2. A small portion of the santonous acid is carried over unaltered by the aqueous vapour, and another portion is split up into propionic acid and dimethylnaphthol dihydride, $C_{15}H_{20}O_3 = C_3H_6O_2 + C_{12}H_{14}O$. 3. When all the water that can form has been given off, the anhydride, $C_{15}H_{18}O_2$, is transformed by the action of heat into the propionic ether of dimethylnaphthol dihydride,

$$C_{12}H_{13}O.C_3H_5O.$$

4. The dimethylnaphthol which is formed in variable quantity, and the small quantity of dimethylnaphthalene obtained towards the end of the process, are secondary products of the decomposition of the methylnaphthol dihydride.

Dimethylnaphthol dihydride, $C_{12}H_{14}O = H_2,C_{10}H_5Me_2.OH$, is prepared by decomposing its propionic ether with alcoholic potash, evaporating the alcohol, saturating with carbonic anhydride, and distilling in a current of steam. When purified by solution in alcohol and precipitation with water, it crystallises on cooling in very slender silky needles, which after two or three recrystallisations melt constantly at 113°. It is very soluble in ether, alcohol, benzene, and petroleum, especially when hot, nearly insoluble in cold water. It is volatile, and distils unaltered with vapour of water. When treated with phosphorus pentasulphide, it gives up 1 mol. H_2O, and is converted into dimethylnaphthalene, $C_{12}H_{12}$, identical with that which is obtained from dimethylnaphthol, and therefore analogous in constitution to Glaser's dibromonaphthalene melting at 81°. When heated with sulphur in a test-tube, it is partly decomposed, with evolution of hydrogen sulphide and formation of dimethylnaphthol, $C_{10}H_5Me_2.OH$, melting at 134°.

The results above described, and those previously observed by Cannizzaro and Carnelutti (Abstr., 1883, 77), may be explained by regarding santonous acid as a tetra-substituted derivative of naphthalene tetrahydride, $H_4C_{10}H_8$, represented by the formula

$$H_4,C_{10}H_4Me_2(OH).CH_2.CH_2.COOH,$$

which is that of a tetrahydride of dimethylhydroxynaphthylpropionic acid. On heating it, two out of the four additive hydrogen-atoms are detached, and employed in separating the propionic acid residue, the products thereby formed being dimethylnaphthol dihydride and propionic acid, thus—

$$H_4,C_{10}H_4Me_2(OH).CH_2.CH_2.COOH = H_2,C_{10}H_4Me_2(OH)H + CH_3.CH_2.COOH.$$

The resinous substance formed by elimination of a molecule of water from santonous acid may be regarded as an inner anhydride, in which the propionic residue, having lost its acid hydroxyl, has attached itself to the phenolic oxygen, as in the phenolic ethers, a change which may be represented by the following equation:—

$$H_4,C_{10}H_4Me_2(OH).CH_2.CH_2.COOH = H_2O +$$

$$H_4,C_{10}H_4Me_2{<}\begin{matrix}-O.CO-\\CH_2.CH_2\end{matrix}{>}$$

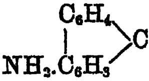
When this anhydride is heated, two out of the four additive hydrogen-atoms may be supposed to separate the propionic residue from the naphtholic nucleus, leaving it attached by the oxygen as an acid radicle, and thereby forming the propionic ether of dimethylnaphthol dihydride, $CH_3.CH_2.COO.C_{10}H_4Me_2,H_2$. H. W.

Derivatives of Phenanthraquinone. By J. STRASBURGER (*Ber.*, 16, 2346—2348).—Mononitrophenanthraquinone, obtained by nitrating phenanthraquinone (Anschütz and Schultz, *Ber.*, **9**, 1404), yields on nitration a dinitrophenanthraquinone, which is converted by oxidising agents into the α-dinitrophenic acid melting at 253°, and in which Schultz has shown that both nitro-groups occupy the para-position (*Annalen*, **196**, 29). Hence mononitrophenanthraquinone must have the constitutional formula $C_6H_4<^{CO}_{CO}>C_6H_3.NO_2$ [4].

Paramononitrodiphenic acid,

$$COOH.C_6H_4.C_6H_3(NO_2).COOH\ [2:1:4:2],$$

is obtained by oxidising the above mononitrophenanthraquinone. It forms yellow prismatic needles melting at 217°. On reduction with tin and hydrochloric acid, it yields an amido-derivative; the hydrochloride of this, when distilled with lime, yields *para-amidofluorene*,



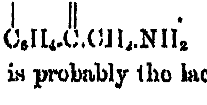
$$\begin{array}{l} C_6H_4 \\ \mid \quad\ \ >CH_2 \\ NH_2.C_6H_3 \end{array}$$

which crystallises from alcohol in pale-brown needles melting at 123°. P. P. B.

Hydrocyanides of the Diketones, and their Saponification.

(Preliminary Notice.) By F. R. Japp and N. H. J. Miller (*Ber.*, **16**, 2416—2418).—When *benzil hydrocyanide*, prepared according to Zinin's method, is treated with hydrochloric acid gas, it yields a substance crystallising from benzene in pale yellow needles melting at 196°, and having the formula $C_{16}H_{12}N_2O$, also an acid containing nitrogen, which crystallises from water in prisms melting at 185°.

Phenanthraquinone Hydrocyanide, $C_{14}H_8O_2(HCN)_2$.—Phenanthraquinone is treated with aqueous hydrocyanic acid (30 per cent. HCN), and the solution filtered from unaltered phenanthraquinone. The new compound separates in slender needles which easily decompose when moist. It is freed from phenanthraquinone by washing with chloroform, and then dried over concentrated sulphuric acid. When saponified with hydrochloric acid, it yields a compound crystallising from benzene in colourless silky needles, which melt at 241°, and have the composition $C_{16}H_{11}NO$. At the same time an acid of the formula $C_{16}H_{13}NO_3$ is formed; this melts at 183°, and its constitution is probably—



$$\begin{array}{l} C_6H_4.C.COOH \\ \mid \qquad \ \| \\ C_6H_4.C.CH_2.NH_2 \end{array}.$$

The compound $C_{16}H_{11}NO$ is probably the lactame or lactime of this acid. P. P. B.

Anthracene-carboxylic Acid from Methylanthraquinone.

By E. Börnstein (*Ber.*, **16**, 2609—2613).—One part of the crude methylanthraquinone (Abstr., 1883, 70) crystallised from alcohol is mixed with concentrated sulphuric acid (6 parts), water (1 part) added, and then powdered potassium dichromate (2½ parts) in small quantities at a time. The mass must be continually stirred during the reaction, which is very violent, and after all the chromate has been introduced the product is heated for some time at about 110—

120°, water being added if necessary. When cold, the product is washed, boiled with dilute ammonia until the ammoniacal odour disappears and the filtrate acidulated, when the anthraquinonecarboxylic acid is precipitated. The residue insoluble in ammonia is a mixture of anthraquinone and methylanthraquinone. The anthraquinonecarboxylic acid is warmed with an excess of dilute ammonia and twice its weight of zinc-dust gradually added; the filtrate is dark yellow by transmitted light, and exhibits a strong blue fluorescence. On the addition of a mineral acid, anthracenecarboxylic acid is thrown down as a voluminous yellow precipitate; it is sparingly soluble in cold, more readily in hot alcohol, the solution showing an intense blue fluorescence. It crystallises from alcohol in small yellow scales, soluble in glacial acetic acid, sparingly in chloroform, and almost insoluble in benzene and carbon bisulphide; it melts at about 280°, and sublimes, forming small scales and needles. The alkali salts are readily soluble in water, the barium salt almost insoluble. The ethyl derivative crystallises in white scales melting at 134—135°, showing that the acid is identical with the anthracenecarboxylic acid obtained by Liebermann and Bischof (Abstr., 1880, 399), in which the carboxyl-group has the same position as the hydroxyl-group in hydroxyanthraquinone. The *chloride*, $C_{15}H_9OCl$, forms a yellow solution with benzene, showing an intense green fluorescence, and yielding the chloride in nodules on evaporation; it also dissolves readily in chloroform, carbon bisulphide, ether and alcohol, and is readily decomposed by boiling with water. The *amide*, $C_{15}H_{11}NO$, crystallises from glacial acetic acid in lustrous pale yellow scales, insoluble in water, benzene, carbon bisulphide, and chloroform; it is sparingly soluble in alcohol, from which it crystallises in slender yellow needles, melting at 293—295°. Its solutions show a blue fluorescence. By the action of sodium-amalgam or of hydriodic acid and amorphous phosphorus on the acid, hydro-derivatives are obtained. When an alcoholic solution of the acid is warmed with sodium-amalgam, and acetic acid added from time to time to diminish the alkalinity, the solution becomes gradually decolorised. The *dihydro-* and *tetrahydroanthracenecarboxylic acids* obtained are separated by crystallisation from alcohol, the former, $C_{15}H_{12}O_2$, separating first in star-like groups of colourless scales readily soluble in the ordinary solvents; it shows a faint blue fluorescence both in solution and when dry; its alkali salts are readily soluble, those of the alkaline earths and heavy metals sparingly soluble; it melts at 203°. *Tetrahydroanthracenecarboxylic acid*, $C_{15}H_{14}O_2$, is more readily soluble in alcohol than the last-mentioned acid, and crystallises in colourless lustrous rhombic plates melting at 164—165°, and showing no fluorescence. By the action of hydriodic acid (sp. gr. 1·7) and amorphous phosphorus at 220—230°, a mixed product is formed, and on fractionally crystallising it from alcohol, *hexhydroanthracenecarboxylic acid*, $C_{15}H_{16}O_2$, is obtained melting at 232°; it crystallises from benzene, chloroform, and carbon bisulphide in slender colourless needles, and from alcohol in nodules; in solution, it shows a faint blue fluorescence. The more soluble fractions melt between 150° and 200°, and appear to contain the tetrahydro-acid.

A. K. M.

Phellandrium Aquaticum. By L. Pesci (*Gazzetta*, **13**, 496).—This plant yields an essential oil, about 80 per cent. of which consists of a terpene (*Phellanthrene*) boiling at 103—104° under a pressure of 80 mm., and at 171—172° under 766 mm. Sp. gr. 0·8558 at 10°. Refractive index for D = 1·481. Rotatory power $[\alpha]_D = -16·74$. The author has not succeeded in obtaining pure hydrochlorides. Phellanthrene heated at 140—150° in sealed tubes is converted into a transparent neutral solid substance, soluble in ether, insoluble in alcohol, melting at 86°, isomeric with the liquid, but differing from it in having a strong dextrorotatory power. H. W.

Carvol. By A. Beyer (*Arch. Pharm.* [3], **21**, 283—288).—Gladstone has shown that the carvol obtained from dill-oil agrees in its principal physical properties with the carvol from caraway oil. Flückiger found that the carvol obtained from German mint-oil, *Mentha crispa*, differed from the carvol from the other two sources in being strongly lævorotatory. The author has re-examined the carvol obtained from these three oils. To obtain it, the crude oils were distilled, the portion of the caraway oil distilling at 223°, those of the German mint-oil at 215—230°, and 200—215° being employed. The crude dill-oil was used without distillation. The hydrogen sulphide compounds, $(C_{10}H_{14}O)_2,SH_2$, were first obtained in the crystalline state and recrystallised from a mixture of three parts of chloroform and one of alcohol. The yield from caraway oil was 8 per cent., that from dill-oil 40 per cent., whilst the first fraction of the mint-oil yielded 50 per cent., the second fraction 30 per cent. All the hydrogen sulphide compounds melted at 187°. The specific rotatory power $[\alpha]_D$ at 20° of the compound from caraway oil was + 5·53, from dill-oil + 5·44, from mint-oil − 5·55. No crystallographic difference in the compounds could be detected. By the action of hydrogen sulphide on an alcoholic solution, all the three compounds were converted into the amorphous thiocarvol $(C_{10}H_{14}S)_2,SH_2$. The carvol obtained from all the hydrogen sulphide compounds agreed in boiling point and density; and the specific rotatory power of carvol from caraway-oil and dill-oil was nearly the same, being dextrorotatory; the carvol from mint-oil, however, was lævorotatory ($[\alpha]_D = -62·46$ at 2°).

The carvol from mint-oil was distilled from metaphosphoric acid, the resulting *carvacrol* dissolved in potash solution, filtered, decomposed with sulphuric acid, and the carvacrol, $C_{10}H_{14}O$, was dried over calcium chloride. It solidified at − 20° to a crystalline mass. The boiling point was 230—231°; sp. gr. at 4° 0·975, specific rotatory power 0. The crystalline barium salt of carvacrolsulphonic acid was also prepared. It was thus shown that the carvacrol from lævorotatory carvol is identical with the carvacrol from dextrorotatory carvol. A small quantity of a hydrocarbon boiling at 168—171° was obtained from the mint-oil. It was lævorotatory, and appeared to be a terpene. W. R. D.

Cinchocerotin. By A. Helms (*Arch. Pharm.* [3], **21**, 279—283). This substance was exhibited by its producer, Kerner, at the exhibitions at Paris in 1858 and at London in 1862. It had been deposited in copper tubes through which hot alcohol was passed after having exhausted a mixture of calcium hydroxide and South American calisaya bark. The brown mass yielded two different substances when treated with alcohol, the first and larger constituent was a white crystalline body, for which the author proposes to retain the name *cinchocerotin*, the second a light yellow substance of which only a small quantity was obtained. The first constituent is represented by the formula $C_{27}H_{48}O_2$, and melts at 130°. It is dissolved by the ordinary solvents, and when oxidised with chromic mixture, yields butyric and acetic acids, together with an acid which was obtained in crystals melting at 72°. This the author proposes to call *cinchocerotic acid*, $C_{10}H_{22}O_2$. Cinchocerotin is not attacked by alkalis, and is probably allied to betulin and cerin in constitution. The second constituent of the crude mass is decomposed at 230° without melting, and when heated with glacial acetic acid forms a crystalline acid melting at 54°, which is easily soluble in alcohol, ether, and light petroleum. It forms sparingly soluble metallic salts. A further examination of this constituent was not possible owing to the small yield. W. R. D.

Piscidin, the Active Principle of Jamaica Dogwood. By E. HART (*Amer. Chem. J.*, 5, 39—40).—Fluid extract of Jamaica dogwood was mixed with lime, left at rest for half an hour in a warm place, filtered, and water added to the filtrate from which, after 2—3 days, crystals of piscidin separate. After purification, it is obtained in nearly colourless microscopic crystals of the formula $C_{29}H_{24}O_8$, and melting at 192° (uncorr.). It is insoluble in water, slightly soluble in ether or cold alcohol, much more soluble in boiling alcohol, readily in benzene and chloroform. It dissolves in strong hydrochloric acid, and is reprecipitated by water apparently unchanged. It does not seem to be a glucoside, and gives no precipitate with lead acetate. The alcoholic solution is neutral in reaction. A. J. G.

Action of Nitric Acid on Teucrin. By A. OGLIALORO (*Gazzetta*, 13, 498).—In his memoir on *Teucrium fruticans* (Abstr, 1879, 728), the author showed that teucrin, the glucoside of this plant, when treated with dilute nitric acid, is converted into a monobasic acid, $C_8H_8O_3$, melting at 180°. Further experiments on this acid and its derivatives have shown that it is identical with anisic acid.

H. W.

Saponin from "Saponaria officinalis." By C. SCHIAPARELLI (*Gazzetta*, 13, 422—430).—The analyses hitherto made of saponin obtained from different plants are not very concordant, the results varying indeed from 47·52 per cent. C and 7·16 H (Overbeck) to 52·63 C and 7·48 H (Rochleder and Schwarz). Moreover the experiments of the last-named chemist lead to the conclusion that the carbohydrate obtained in the first instance from saponin by decomposition with acids, is not grape-sugar, but a body convertible into that sugar by the further action of acids,—and consequently that saponin is not a glucoside but an amyloïd. To throw further light on this matter, the author has endeavoured to determine whether the products extracted from different plants and included under the name of saponin, are really identical, and in the present paper he describes the results obtained with saponin from *Saponaria officinalis*.

The root of this plant, dried and coarsely pounded, was boiled for three days in a reflux apparatus with alcohol of 90°; after which the boiling alcoholic decoction was separated and left for some days in a cool place, whereupon the sides of the vessel became coated with a copious yellow flocculent deposit which, when freed from colouring matter by treatment with a warm mixture of alcohol and ether, consisted of saponin, still however very impure. Treatment with alcohol and animal charcoal still left it contaminated with about 3 per cent. of mineral matter. It was therefore dissolved in the smallest possible quantity of water; the cold solution was precipitated with saturated baryta-water; the resulting barium saponate, after washing with baryta-water, was suspended in water and decomposed by a current of carbonic anhydride, then heated to the boiling point, and filtered; the filtrate evaporated to a syrup at a gentle heat was precipitated with alcohol; and the still yellowish saponin was further purified with alcohol of 90 per cent. The substance thus obtained still contained barium salts, to remove which it was dissolved in water and treated with dilute sulphuric acid, added drop by drop; and the filtered liquid, after concentration at a gentle heat, was precipitated with alcohol and ether, these operations being repeated a second and a third time, and the product finally purified with boiling alcohol of 90 per cent. in quantity not sufficient to dissolve it completely. The alcoholic solution evaporated in a vacuum left perfectly white flocks of pure saponin, which were washed with ether and dried over sulphuric acid.

Saponin thus prepared gave, as the mean result of five analyses, 52·65 per cent. carbon and 7·36 hydrogen, agreeing nearly with the formula $C_{32}H_{54}O_{18}$, which requires 52·86 C and 7·44 H. Saponin from *Gypsophila* was found by Rochleder to contain 52·65 carbon and 7·34 hydrogen.

Pure saponin is a very white amorphous inodorous powder, which excites sneezing when inhaled by the nostrils; it has a pungent disagreeable taste, and is poisonous; dissolves very freely in water, but is insoluble in ether, benzene, and chloroform, and only slightly soluble in alcohol. Heated on platinum-foil, it decomposes, emitting an odour of burnt sugar, and leaving a porous residue difficult to burn. Saponin is lævogyrate, like most glucosides; specific rotatory power $[\alpha]_D = -7·30$: it is the least optically active of all known glucosides.

Saponin, as already observed, is remarkable for the power of its aqueous solution to dissolve salts which are insoluble in water. When its aqueous solution, mixed with lead acetate, is precipitated by hydrogen sulphide and filtered, the liquid which passes through is black from dissolved lead sulphide, which may be precipitated from it by adding a small quantity of alcohol. A boiling aqueous solution of saponin dissolves barium carbonate (up to 10 per cent.), which may be precipitated by sulphuric acid; nevertheless barium sulphate is slightly soluble in aqueous saponin. This property of dissolving salts throws great difficulty, as already observed, in the way of purifying saponin.

This substance likewise dissolves gases, and incloses them mechanically. A dilute aqueous solution of saponin forms on agitation a very persistent froth.

An aqueous solution of saponin mixed with hydroxide of potassium, barium, or strontium, yields precipitates of the corresponding compounds. The barium compound has the composition—

$$C_{32}H_{53}O_{18}.Ba.C_{32}H_{52}O_{18}.Ba.C_{32}H_{53}O_{18}.$$

Products of Decomposition of Saponin.—An aqueous solution of saponin was heated on a water-bath with dilute sulphuric or hydrochloric acid, the liquid being filtered after two hours, in order to remove the flocculent substance which separated, and thereby prevent its further decomposition by the acid; the filtered solution was then again boiled, the new precipitate separated, and these operations were repeated a third time. The three precipitates thus obtained agreed very closely in composition, giving as the mean result of their analysis. 60·65 per cent. carbon and 8·22 hydrogen, numbers agreeing nearly with the formula $C_{40}H_{66}O_{18}$, which requires 61·06 carbon, 8·38 hydrogen, and 3·56 oxygen. The decomposition of saponin by dilute acids may therefore be represented by the equation—

$$2C_{32}H_{54}O_{18} + 3H_2O = C_{40}H_{66}O_{15} + 4C_6H_{12}O_6.$$

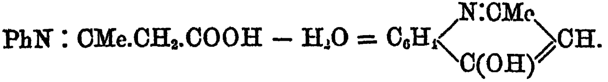
The compound $C_{40}H_{66}O_{15}$ is called by the author saponetin, to distinguish it from the *sapogenin* of Rochleder and others, which was not of constant composition. Saponetin is a whitish microcrystalline substance, insoluble in water, alcohol, and ether.

The glucose formed by the action of dilute acids on saponin is dextrogyrate, its specific rotatory power being $[\alpha]_D = +52·48$. It is fermentable, has a saccharine taste, and has not yet been crystallised, its solution, after concentration to a syrup, having remained for six months without giving any sign of crystallisation. Further experiments are however required to determine whether it is a peculiar sugar distinct from dextrose, or whether the difference between its optical rotatory power and that of the latter is due to some other cause.

H. W.

New Synthesis of Quinoline-derivatives. I. By L. KNORR (*Ber.*, **16**, 2593—2596).—By the action of ethyl acetoacetate on aniline, Oppenheim (*Ber.*, 9, 1098) obtained diphenylcarbamide, alcohol, and acetone. Different results are obtained on modifying the conditions of the experiment. At the ordinary temperature a layer of water separates after some days, whilst a heavy oil is formed which appears to be the condensation-product PhN : CMe.CH$_2$.COOEt. Aniline and ethyl acetoacetate react more readily when the mixture is heated nearly to the boiling point. When the mass becomes dark yellow the reaction should be interrupted; the product is then treated with concentrated sulphuric acid, diluted with water, and alkali added, when *hydroxymethylquinoline*, $C_{10}H_9ON$ (m. p. 222°), is precipitated. The author explains its formation thus:—

$PhNH_2 + COMe.CH_2.COOEt - H_2O = PhN : CMe.CH_2.COOEt;$
$PhN : CMe.CH_2.COOEt + H_2O = PhN : CMe.CH_2.COOH + Et.OH;$



$$PhN : CMe.CH_2.COOH - H_2O = C_6H_4 \left\langle \begin{matrix} N{:}CMe \\ C(OH) \end{matrix} \right\rangle CH.$$

If the reaction be conducted in a sealed tube at 120°, a substance of the formula $C_{10}H_{11}NO_2$ (m. p. 81°) can be isolated, and is probably anilacetoacetic acid, $PhN : CMe.CH_2.COOH$; it yields hydroxymethylquinoline when treated with sulphuric acid. Hydroxymethylquinoline is sparingly soluble in water, more readily in hot alcohol, insoluble in ether; it has both basic and acid properties, but is precipitated by carbonic anhydride from alkaline solutions; it forms a crystalline sodium salt, hydrochloride, sulphate, and platinochloride. When distilled with zinc-dust, it yields α-methylquinoline, and may therefore be designated γ-hydroxy-α-methylquinoline.

A. K. M.

Condensation-products of Methylated Quinolines and Pyridines. By E. JACOBSEN and C. L. REIMER (*Ber.*, **16**, 2602—2608).—It has been shown by the authors (Abstr., 1883, 922) that a yellow dye, $C_{16}H_{11}NO_2$, is formed by the action of phthalic anhydride on quinaldine, or on crude coal-tar quinoline, and that similar dyes are also yielded by the homologues of quinaldine and by pyridine. Further investigation shows that the substance obtained from pyridine is due to the presence of picoline, and that pure pyridine, like pure quinoline, is not acted on by phthalic anhydride. They conclude that Traub's quinophthalone (*Ber.*, **16**, 297) is also most probably derived from a methylquinoline, and that it is either identical or isomeric with quinoline-yellow, $C_{16}H_{11}NO_2$. *Paramethylquinophthalone*, $C_{19}H_{13}NO_2$, is obtained by heating paramethylquinaldine with phthalic anhydride and zinc chloride at 200°, boiling the melt with hydrochloric acid and crystallising from alcohol; it forms long gold-coloured needles melting at 203°, and resembling quinoline-yellow. It is insoluble in water, sparingly soluble in alcohol, readily in glacial acetic and concentrated sulphuric acids; it dyes silk and wool almost exactly like quinoline-yellow. The paramethylquinaldine can be obtained from paratoluidine and aldehyde by Doebner and Miller's method, and purified by fractional distillation and by means of the sparingly soluble chromate $(C_{11}H_{11}N)_2,H_2Cr_2O_7$. It melts at 55° and boils at 259—261°. When coal-tar pyridine is heated with phthalic anhydride and zinc chloride at 200°, and the product treated with hot dilute hydrochloric acid, the greater portion (containing unaltered pyridine) dissolves, whilst the residue, after crystallisation from glacial acetic acid and from alcohol, yields bright yellow silky scales of *pyrophthalone* melting above 260° with partial decomposition. It is almost insoluble in water, sparingly soluble in alcohol, readily in glacial acetic acid. Its formula, $C_{14}H_9NO_2$, indicates its derivation from picoline present in the pyridine, thus: $C_6H_7N + C_8H_4O_3 = C_{14}H_9NO_2 + H_2O$, and experiment proves that it cannot be obtained from perfectly pure pyridine, whilst coal-tar picoline gives an abundant yield. A second substance, apparently of the same composition as pyrophthalone, is also formed; it is, however, more readily soluble in alcohol, and crystallises from glacial acetic acid in slender orange-red needles, melting below 200°; it seems probable therefore that two different picolines exist in coal-tar. Both of these phthalones from picoline dye silk and wool yellow, but much fainter than quinoline-yellow.

The fact that only methylated pyridines and quinolines react with phthalic acid indicates that it is the hydrogen of the methyl-group which becomes substituted, and not that of the pyridine nucleus as was previously assumed. In this case quinoline-yellow will have the formula $C_9H_6N.CH : C_2O_2 : C_6H_4$. This view is supported by the behaviour of the phthalones on oxidation; for if the substitution took place in the pyridine nucleus, pyridinecarboxylic acids (or quinolinecarboxylic acids) would be expected to result from the decomposition of the phthalyl-group. On heating quinoline-yellow with nitric acid (sp. gr. 1·2), phthalic acid is produced, together with resinous substances, and a second acid containing nitrogen; this latter acid is sparingly soluble in water, very readily in mineral acids. A substance of similar properties is obtained when a mixture of chromic and sulphuric acids is employed, the product in this case, however, contains no phthalic acid. On neutralising with barium hydroxide and evaporating the filtrate, a sparingly soluble barium salt is obtained yielding an acid which crystallises in colourless needles melting at 157°. It dissolves very readily in hot, less so in cold water, and very readily in mineral acids; it forms a platinochloride, crystallising in yellowish-red prisms, and when heated with lime emits an odour resembling that of quinoline. It is probably a new quinolinemonocarboxylic acid. Pyrophthalone is also very readily oxidised by nitric acid, yielding phthalic acid and an acid containing nitrogen, which however has not yet been examined.

When quinaldine (1 mol.) is heated with benzaldehyde (1 mol.) and zinc chloride at 160—170°, the product dissolved in hot concentrated hydrochloric acid, and poured into water, the hydrochloride of a solid base (*benzylidenequinaldine*) is precipitated in yellowish needles. The free base, $C_{17}H_{13}N$, is insoluble in water, sparingly soluble in cold, readily in boiling alcohol, from which it crystallises in colourless lustrous needles melting at 99—100°. At a higher temperature, it sublimes without decomposition, its vapour having an odour resembling that of quinoline. Its formation takes place thus:— $C_{10}H_9N + C_7H_6O = C_{17}H_{13}N + H_2O$. Its salts are sparingly soluble in cold water; the acid chromate, $C_{17}H_{13}N,H_2Cr_2O_7 + 2\frac{1}{2}H_2O$, forms slender reddish-yellow needles sparingly soluble even in boiling water. The same base is produced by the action of benzal chloride on quinaldine in the presence of zinc chloride. Benzylidenequinaldine can be readily oxidised, nitric acid (sp. gr. 1·4) yielding a mixture of several acids, from which paranitrobenzoic acid could be isolated. When oxidised with chromic and sulphuric acids, benzoic acid is formed. Picoline also yields a condensation-product with benzaldehyde analogous to that obtained from quinaldine, whilst pure pyridine is not attacked. It is probable therefore that in these reactions the substitution also takes place in the methyl-group, and that benzyildenequinaldine has the constitution $C_9H_6N.CH : CHPh$. Benzylidenequinaldine is identical with the base obtained by Wallach and Wüsten (Abstr., 1883, 1097). A. K. M.

Preparation of Quinaldine on the Large Scale. By G. Schultz (*Ber.*, **16**, 2600—2601).—When aldehyde is added to an aqueous solution of aniline hydrochloride, and the two are allowed to react in the cold, the hydrochloride of a solid base is produced, and on melting this, either alone, or better, with zinc chloride, it is converted into quinaldine. When paraldehyde, acetal, aldol, and similar substances are employed in place of the aldehyde, and other primary aromatic bases in the place of aniline, compounds are obtained which yield bases analogous to quinaldine when melted with zinc chloride. From the product of the action of free aniline on aldehyde a solid base has been isolated, apparently identical with the above. By boiling with hydrochloric acid both are decomposed (although not readily) into aniline and aldehyde, and then converted into quinaldine. The composition of these bases appears to be far from constant, and to vary with the relative proportions of the components. From paraldehyde and aniline hydrochloride, a base was obtained which, after solution in benzene and precipitation with alcohol, had the composition $C_{18}H_{20}N_2$, whilst a base obtained in another way had the formula $C_{11}H_{16}N_2$, agreeing with Schiff's ethylidenediphenamine.

A. K. M.

Sparteine. (Preliminary Notice.) By O. Bernheimer (*Gazzetta*, **13**, 451—454).—This base, $C_{15}H_{26}N_2$, was first obtained from *Spartium scoparium* by Stenhouse in 1881, who determined its composition, and was afterwards examined by Mills, who showed that it is a tertiary diamine. The sparteine examined by the author was prepared from *Spartium scoparium* by a slight modification of Stenhouse's method; it distilled to the last drop at 180—181° under a pressure of 20 mm. Its solution in alcohol at 96° has a specific rotatory power $[\alpha]_D = -14{\cdot}6$ for a concentration of 23·88 at 26°. It bears a heat of 200° without alteration, but becomes partially carbonised at higher temperatures; is not decomposed by heating in sealed tubes with hydrochloric acid. Bromine acts strongly on sparteine at ordinary temperatures, even when it is largely diluted with ether, forming an undefined resinous mass.

On gradually adding 3 parts iodine dissolved in ether to an ethereal solution of 1 part sparteine, the iodine is decolorised, and a black precipitate is formed, which when separated, washed with ether to remove free iodine, and dissolved in boiling alcohol, separates on cooling in beautiful green needles, having the composition $C_{15}H_{26}N_2I_3$. This compound is insoluble in cold water and alcohol, but dissolves readily in those liquids when heated; it is insoluble in ether, permanent in the air, and yields free sparteine when heated with potash.

Sparteine (as sulphate) oxidised with potassium permanganate yields a small quantity of a volatile acid, having the odour of the fatty acids, together with a non-volatile acid having the composition of a *pyridinemonocarboxylic acid*, $C_5H_4N.COOH$; and on distilling a salt of this acid with lime, a volatile base is obtained having all the properties of pyridine. The author intends to continue his experiments as soon as he is in possession of a larger quantity of material.

H. W.

Hydrocyanides of Organic Bases. By A. CLAUS and E. A. MERCK (*Ber.*, **16**, 2737—2748).—Aniline, toluidine, quinine, cinchonidine, and strychnine, dissolve in aqueous hydrocyanic acid. An excess of acid renders the solution very unstable. The salts have not been isolated, as they are decomposed by evaporation in a vacuum. Although the bases are completely withdrawn from these liquids by ether, the solutions are not mere mechanical mixtures, since they yield double cyanides with mercuric cyanide; *e.g.*, when mercuric cyanide is added to a solution of aniline hydrocyanide, white tabular crystals, $NH_2Ph,HCN + Hg(CN)_2$, are deposited, which dissolve in water, alcohol, and ether.

When mercuric cyanide is added to tetramethylammonium iodide, two salts are formed, viz., a white salt of the composition

$$NMe_4I,Hg(CN)_2,$$

freely soluble in water, and a yellow salt, $NMe_4.CN,HgICN$, sparingly soluble in water. The white salt slowly changes into the yellow isomeride at the ordinary temperature, more rapidly at 200°.

Tetramethylammonium cyanide, $NMe_4.CN$, prepared by the action of barium cyanide on tetramethylammonium iodide, has been described by C. Thompson (this vol., p. 286). The clear crystals of the salt become opaque at 150°, decrepitate at 215°, and melt at 295°. The salt can be volatilised at 225—230° without melting. With mercuric cyanide it forms a double salt, $NMe_4.CN,Hg(CN)_2$, crystallising in prisms melting at 275°. The corresponding silver salt,

$$NMe_4.CN,AgCN,$$

has been described by Thompson. Tetramethylammonium cyanide dissolves cobalt cyanide and ferrous cyanide, forming tetramethylammonium cobalticyanide and ferrocyanide respectively. The latter compound has been described by Barth (*Ber.*, 8, 1484). The former crystallises in yellow plates, and resembles the potassium cobalticyanide in its properties.

Cinchonidine ethylcyanide, $C_{19}H_{22}N_2O,EtCN$, prepared by the action of barium cyanide on cinchonidine ethylsulphate, forms white crystalline needles, which are decomposed by carbonic acid, and rapidly absorb moisture from the air. It is soluble in water but insoluble in ether and chloroform. The crystals melt with decomposition at 140°. *Quinine ethylcyanide*, $C_{20}H_{24}N_2O_2,EtCN$, crystallises in needles soluble in alcohol. The crystals melt at 90° and begin to decompose at 95°. *Strychnine ethylcyanide*, $C_{21}H_{22}N_2O_2,EtCN$, is less hygroscopic and more stable than the quinine and cinchonidine compounds. It dissolves freely in water, but is less soluble in alcohol.

W. C. W.

Caffeïne Methhydroxide. By E. SCHMIDT (*Ber.*, **16**, 2587—2588).—In the hopes of obtaining an insight into the constitution of caffeïne, the author submitted caffeïne methhydroxide to the action of hydrochloric acid. He previously showed (Abstr., 1883, 872 and 873) that caffeïne and theobromine yield the same decomposition-products when treated in this way, but the reaction threw no light on the constitution of these substances. Caffeïne methhydroxide,

$$C_8H_{10}N_4O_2,MeOH + H_2O,$$

is readily obtained by the action of moist silver oxide on caffeïne methiodide (*loc. cit.*). When it is dissolved in fuming hydrochloric acid, and left for 14—20 days to evaporate spontaneously, amalic acid separates, with simultaneous formation of methylamine and formic acid, the production of amalic acid being, however, due to a secondary decomposition of the dimethyldialuric acid first formed. A considerable portion of the caffeïne methhydroxide is also converted into caffeïne methylchloride, $C_8H_{10}N_4O_2,MeCl$, whilst a smaller portion gives rise to secondary reactions.

Caffeïne methhydroxide suffers no appreciable change on continued heating above its melting point (137—138°), but is completely decomposed when submitted to dry distillation in a current of hydrogen, caffeïne being produced. Water decomposes it at about 200°, with formation of carbonic anhydride and methylamine. With a solution of bromine in chloroform, it yields a readily decomposible addition-compound which is decomposed by water into hydrobromic acid, methylamine, cholestrophane, and allocaffeïne. This last substance is probably methylapocaffeïne, since it is decomposed into carbonic anhydride and methylcaffuric acid when boiled with water. By the action of hydrochloric acid and potassium chlorate, caffeïne methhydroxide yields dimethylalloxan, allocaffeïne, amalic acid, cholestrophane, and methylamine; with chromic mixture it yields carbonic anhydride, formic acid, cholestrophane, and methylamine. Nitric acid (sp. gr. 1·4) decomposes it at ordinary temperatures, with violent evolution of carbonic anhydride and formation of methylamine and cholestrophane. Baryta-water also decomposes it in the cold. A. K. M.

Quinine Phenolsulphonate. By P. GIURLEO (*Arch. Pharm.* [3], 21, 298).—This salt can be obtained by dissolving quinine in phenolsulphonic acid and by decomposing solutions of lead or barium phenolsulphonates with a solution of quinine sulphate. The salt, which crystallises with difficulty, contains 52 per cent. of quinine, 20 per cent. of phenolsulphonic acid, and 28 per cent. of water.

W. R. D.

Berberine. By E. SCHMIDT (*Ber.*, 16, 2589).—The formula of this body, according to Fleitmann, is $C_{42}H_{36}N_2O_9$, according to Kemp, $C_{42}H_{34}N_2O_7$, according to Stas, $C_{41}H_{38}NO_{10}$, according to Henry, $C_{43}H_{38}N_2O_{10}$, and according to Serrius and Hlasiwetz, $C_{20}H_{17}NO_4,4\frac{1}{2}H_2O$. From numerous analyses of the free base, the hydrochloride, nitrate, and sulphate, the author assigns to it the formula $C_{20}H_{17}NO_4,4H_2O$. Analyses of Hlasiwetz and Gilm's hydroberberine (*Annalen*, Suppl., 2, 191), its hydrochloride and nitrate confirm their formula, $C_{20}H_{21}NO_4$. From its behaviour with ethyl iodide, hydroberberine must be a tertiary base. Berberine is converted into berberine hydriodide by treatment with ethyl iodide. The hydroxide obtained from hydroberberine ethiodide forms colourless needles melting at 165°; it yields crystalline salts with hydrochloric, nitric, and sulphuric acids, and with platinic chloride. On oxidising berberine with alkaline permanganate, a bibasic acid, $C_{10}H_{10}O_6 + 2H_2O$, melting at 165°, is obtained apparently identical with hemipinic acid. A. K. M.

Derivatives of Berberine. By O. BERNHEIMER (*Gazzetta*, 13, 342—347).—When berberine is heated in a retort with five times its weight of potassium hydroxide, it blackens, intumesces, and gives off ammonia, together with a small quantity of an oily liquid which, on examination, was found to be quinoline. From the residue in the retort, two acids were isolated, which were found to have all the properties ascribed to them by Hlasiwetz and Gilm; the author is at present engaged in studying their constitution.

When hydroberberine is heated with methyl iodide at 100° in a closed tube, a yellow crystalline mass is obtained, which may be purified by repeated crystallisation from boiling methyl alcohol. It crystallises in the trimetric system: $a : b : c = 1·10332 : 1 : 1·78880$. Observed forms, 001, 111, 113; combinations, 001, 111, 113; cleavage perfect, 001. The *hydroberberine methiodide*, $C_{20}H_{21}NO_4,MeI$, is sparingly soluble in water or alcohol in the cold, but readily when heated. When the iodide suspended in water is treated with silver oxide, it yields the corresponding hydroxide, which may be obtained in crystalline crusts, $C_{20}H_{21}NO_4,MeHO + H_2O$, on evaporating the solution. It is strongly basic, and liberates ammonia from ammonium chloride. It dissolves in cold alcohol, but is insoluble in ether. On adding hydrochloric acid to its aqueous solution. the chloride is precipitated as a crystalline powder. The platinochloride crystallises in beautiful lustrous plates, soluble in boiling alcohol. When heated in a sealed tube at 150°, the hydroxide is decomposed, with elimination of methyl alcohol. From these results, the author infers that hydroberberine, like berberine itself, is a tertiary base.

When berberine is heated with methyl iodide and methyl alcohol, it yields a methiodide, $C_{20}H_{17}NO_4,MeI$, in stellate groups of slender needles. On treating this with silver oxide, the corresponding hydroxide is obtained, very similar in its properties to the hydroberberine compound. The platinochloride is a yellow powder.

Fleitmann (*Annalen*, 59, 176) in his paper on berberine mentions the formation of the hydrochloride of a base containing sulphur. The author, following Fleitmann's directions, added yellow ammonium sulphide to a solution of berberine hydrochloride, collected the red precipitate, dissolved it in warm water, and added hydrochloric acid; hydrogen sulphide was evolved, and on examining the solution it was found to contain berberine hydrochloride, but no trace of sulphuretted base. The red precipitate mentioned above is probably a persulphide of berberine.

On treating hydroberberine with iodine, both in chloroform solution, a brownish precipitate is obtained consisting of berberine hydriodide, $C_{20}H_{17}NO_4,HI$. It is easily purified by crystallisation from dilute alcohol. C. E. G.

Alkaloïds of Angustura Bark. By KOERNER and C. BÖHRINGER (*Gazzetta*, **13**, 363—367).—In this preliminary notice the authors, after some historical details as to the introduction of the bark, state that it contains aromatic substances and several alkaloïds, the amount of the latter varying in different specimens from 0·8 to 1 per cent. The alkaloïds are mostly in the free state, and may be extracted directly from the bark by means of ether. After the ethereal extract has been washed with dilute potash solution, the addition of oxalic acid or dilute sulphuric acid gives a yellow crystalline precipitate of the corresponding salt of one of the alkaloïds, *cusparine*, whilst other alkaloïdal salts remain in solution.

The precipitated cusparine salt is moderately soluble in boiling alcohol, and, on cooling, crystallises out in slender needles of a magnificent greenish-yellow; this colour is not removed by repeated crystallisation, or by treatment with animal charcoal, and other salts of the alkaloïd, obtained from the yellow precipitate by decomposition, are also intensely yellow. If, however, the free cusparine, $C_{19}H_{17}NO_3$, obtained from these coloured salts, is crystallised several times from light petroleum, and then reconverted into the salt, this is found to be colourless. The author has been unable to ascertain the cause of this yellow coloration. The alkaloïd crystallises from light petroleum in tufts of slender needles melting at 92°; it is moderately soluble in ether, more readily in alcohol. The sulphate, oxalate, and hydrochloride of the base are but sparingly soluble in water; the acetate is much more soluble, but the solution is decomposed if largely diluted; the tartrate dissolves readily. The platinochloride was obtained as an orange-yellow crystalline precipitate.

When treated with potassium hydroxide, cusparine splits up, yielding a new alkaloïd and the potassium salt of an acid which seems to be an aromatic derivative; the acid is sparingly soluble and crystallises readily. The alkaloïd crystallises from alcohol, in which it is very sparingly soluble, in minute, very brilliant, colourless needles; it decomposes at 250° without melting. An attempt to decompose the cusparine in a similar manner by the action of hydrochloric acid failed, as it began to carbonise even at 100°.

In the mother-liquors from which the cusparine was originally precipitated as sulphate or oxalate, another alkaloïd is found, to which the authors have given the name of *galipeïne*, $C_{20}H_{21}NO_3$. The free base crystallises from light petroleum in white needles melting at 115·5°. It may be obtained in well-formed transparent prisms from its solution in ether or alcohol. All the salts of this alkaloïd are more soluble than those of cusparine; several of them are of a magnificent greenish-yellow like uranium salts. The sulphate crystallises in large prisms with 7 mols. H_2O, which it loses in part on exposure to the air; it melts at 15°, and at 100° undergoes decomposition, yielding the sulphate of another alkaloïd and a crystalline nitrogenous substance which melts at 196°. The platinochloride crystallises in prisms with a triangular base.

Besides cusparine and gallipeïne, the authors have found another alkaloïd which melts at 180°, and is very sparingly soluble in ether.

It crystallises from alcohol and furnishes salts, the solutions of which have a blue fluorescence.

The property these alkaloïds have of being transformed into other alkaloïds with simultaneous formation of acids, is interesting, and may throw some light on the constitution of vegetable alkaloïds in general. C. E. G.

Ptomaïnes. By A. Soldaini (*Gazzetta*, 13, 325).—In order to obviate the difficulties usually met with in the extraction and purification of ptomaïnes, the author digests the putrid viscera with alcohol acidified with oxalic acid; the solution is distilled down to remove alcohol, taken up with water, and the acid solution agitated with bisulphide of carbon and with ether. It is then rendered alkaline by lime, and the bases are removed by ether, chloroform, &c. The various extracts are purified by fractional distillation in a current of hydrogen. The author describes the ptomaïnes as colourless liquids, easily alterable in contact with air, and all more or less soluble in water: some are soluble in ether, others in chloroform. They have a pleasant odour, and the higher the boiling point the stronger the basic properties. It is not known as yet whether these compounds are amides, amines, or true alkaloïds. C. E. G.

The so-called Ptomaïnes in Relation to Toxicological Researches. By F. Marino-Zuco (*Gazzetta*, 13, 431—433).—The author's experiments were made on a variety of fresh animal substances, viz., white and yolk of egg, brains, lungs, heart, liver, spleen, and blood, several methods being employed, with strict attention to all the conditions indicated by their respective authors. The result of these experiments was the extraction of a base which exhibited all the usual reactions of the alkaloïds, but had the constitution of an ammonium hydroxide, and in those cases in which an aurochloride could be prepared and analysed, was found to be identical in composition with neurine. In one instance traces were also found of the so-called "animal quinine."

To determine the origin of this neurine, the author applied the methods above mentioned to the lecithins (prepared by Strecker's method from egg-yolk), and found that these substances behave in the same manner as, for example, a mass of brain, egg, lungs, &c. On applying the same method to the albumin remaining after complete extraction of the lecithins, the result was purely negative. Hence it is clear that the so-called ptomaïnes obtained in the extraction of fresh animal substances, originate, not as is generally supposed, from sudden alterations of the proteïds, but from the splitting up of the lecithins under the influence of acids or alkalis.

As neurine hydrochloride is not decomposed by sodium bicarbonate, the author was able to determine the toxicological question in cases of the extraction of alkaloïds from substances in which putrefaction has not yet commenced. The hydrochlorides of the alkaloïd and of the so-called ptomaïnes, simultaneously extracted, are dissolved in water, and the liquid, rendered alkaline with sodium bicarbonate, is agitated with the solvent. The neurine then remains dissolved in the water as hydrochloride, and the alkaloid may then be extracted alone. This has been demonstrated by all the experiments made as above described, and by others on yolk of egg mixed with strychnine.

H. W.

Selmi's Ptomaïnes. By F. Marino-Zuco (*Gazzetta*, **13**, 441—451).—In this paper, the author describes a number of experiments, chemical and physiological, tending to establish the conclusion indicated in the preceding preliminary notice, as to the identity of these bases with neurine. The most characteristic chemical reactions observed in both cases are:

With *Phosphoric acid:* slight brown coloration on heating.
„ *Platinic chloride:* no precipitate, but deposition of yellowish crystals after a short time.
„ *Mercuric chloride:* white precipitate.
„ *Auric chloride:* yellowish precipitate, and after a short time, reduction of metallic gold.
„ *Iodised potassium iodide:* red-brown precipitate, which, however, soon redissolves.

H. W.

Compounds of Silver with Albuminoïds. By O. Loew *Ber.*, **16**, 2707—2709).—On warming silver albuminate with excess of an ammoniacal solution of silver nitrate, a reddish-brown precipitate of variable composition is deposited. It is purified by solution in dilute ammonia and reprecipitation with dilute sulphuric acid. It is insoluble in water and alcohol, but dissolves in alkalis and in dilute sulphuric acid. The ratio of C to N in the compound is the same as it is in peptone. When the compound is digested with baryta-water or hydrochloric acid, metallic silver is deposited, and a substance resembling peptone remains in solution. The silver is not precipitated from an ammoniacal solution of the compound by sulphuretted hydrogen at the ordinary temperature. In many respects this red-brown compound resembles the substance obtained by the action of a dilute ammoniacal solution of silver on the albumin in the living cells of the alga, *Spirogyra*. The latter compound, however, is insoluble in dilute sulphuric acid, and is not even decomposed by sulphuretted hydrogen in warm solutions.

A compound containing as much as 82·4 per cent. of silver was obtained by adding potash to the ammoniacal solution of silver nitrate and albumin. It is a silver-grey powder, insoluble in water and in dilute acids. It dissolves in ammonia, yielding a deep orange-coloured solution.

The author regards these substances as compounds of varying quantities of molecular silver with partially oxidised silver albuminate.

W. C. W.

Permanence of Carbonic Oxide Hæmaglobin. By F. Salfeld (*Arch. Pharm.* [3], **21**, 289).—The absorption-spectrum of this compound was obtained from venous blood 14 days after death, and again after the lapse of one month. The blood was treated with ammonium sulphide, to reduce oxy-hæmaglobin, before examination. After two months, the absorption-spectrum of carbonic oxide hæmaglobin was not observed. W. R. D.

Gelatin Peptone. By P. TATARINOFF (*Compt. rend.*, **97**, 713—714).—Pure gelatin is digested with artificial gastric juice at 40°, and when solution is complete, the liquid is saturated with calcium carbonate, boiled, filtered, concentrated, and precipitated by alcohol. After 24 hours, the precipitate is dissolved in cold water, filtered and dialysed after addition of a few drops of hydrochloric acid. The purified solution thus obtained is concentrated, and the peptone precipitated by alcohol. It has the composition:—

	C.	H.	N.
I.........	50·00	7·26	17·57
II.........	49·53	7·00	17·69

These numbers show that gelatin undergoes no great alteration under the influence of gastric juice, but appears to combine with the elements of water, like the albuminoïds. The same body is obtained by the prolonged digestion of gelatin at a somewhat higher temperature with somewhat stronger hydrochloric acid and without any pepsin. C. H. B.

Physiological Chemistry.

Influence of Air somewhat deficient in Oxygen on Animals. By C. KEMPNER (*Bied. Centr.*, 1883, 565).—The author finds that the amount of oxygen used up by mammals diminishes when breathing such air: in the case of birds, however, there is either no diminution in the amount of oxygen absorbed, or not to the same extent. The latter have the faculty of compensating for the poorer air by increasing the activity of their respiratory organs. J. T.

Nutrition of the Dog. By GUIMARAES (*Compt. rend*, **97**, 645—646).—Dogs fed, under ordinary conditions, on fresh lean beef consumed on an average one-tenth to one-sixteenth of their weight per day; others, to which a strong infusion of coffee was given, consumed from one-ninth to one-eighth their weight; whilst others, which were kept at a temperature of 10—12°, consumed from one-twelfth to one-ninth their weight. Dogs fed on fat pork and tapioca ate only about one-sixtieth of their weight, and rapidly fell off in condition. Others were fed on a mixed diet, consisting of a limited amount of lean beef with a large amount of pork fat. They consumed all the lean beef (180—250 grams per diem) but only a part of the fat, and they gradually fell off in condition, the total daily consumption being from one twenty-fourth to one twenty-second part of their weight, about half of this being carbohydrates. The results were but slightly affected by the size of the animals; the small dogs generally consumed a slightly higher proportion of food than the large dogs. The fæces amounted to 5—6 grams per diem per kilogram of body-weight for dogs under normal conditions, and 6—7 grams per kilogram for dogs to which coffee had been given, or which had been kept at a low temperature. This is less than 8 per cent. of the weight of food consumed. The total of weight of the animals did not sensibly vary from day to day. C. H. B.

Physiological Functions of Maltose. By E. Bourquelot (*Compt. rend.*, **97**, 1000—1003).—A 2 per cent. solution of maltose is not affected, even after 24 hours at 15° or 38°, by saliva or diastase which has been previously filtered through Klebs and Tiegel's apparatus. The same result is obtained in an atmosphere of carbonic anhydride. Maltose is also unaffected by a mixture of saliva or diastase with the invertin of the intestinal juice, and by artificial gastric juice, or natural pancreatic juice. In the latter case, small quantities of glucose are formed after about 10 hours, but this is due to the action of bacteria, which cannot be entirely excluded, since the pancreatic juice cannot be filtered.

Maltose and saccharose, mixed with an unfiltered solution of intestinal juice and kept at 38° for several hours, are partially or completely split up, but if the intestinal juice has been filtered through Kleb's apparatus, no change takes place in either case.

A 1 per cent. solution of maltose is not affected by a 0·2 per cent. solution of hydrochloric acid at 38°, nor by a solution of lactic acid of equivalent strength. A solution of saccharose of the same strength is rapidly inverted by hydrochloric acid, and 33 per cent. is inverted in 36 hours by lactic acid. A similar solution of maltose is not affected by carbonic anhydride at the ordinary pressure and at the temperature of the body, but 3·2 per cent. of the saccharose is inverted in five days under the same conditions.

In all probability, if saccharose is inverted in the small intestine, the active agents are hydrochloric and lactic acids, and if small quantities of saccharose find their way unaltered into the blood, the carbonic anhydride with which the latter is always charged is probably sufficient to cause inversion. Maltose, on the other hand, is not inverted except in the intestine, and the inversion is due either to a zymase, which differs from the invertin of yeast and will not pass through porous earthenware, or to bacteria.

These results do not decide whether maltose is or is not directly assimilated. C. H. B.

Formation of Fat in the Animal Organism. By N. Tschirwinsky (*Landw. Versuchs.-Stat.*, **29**, 317—352).—This investigation was begun when the function of carbohydrates in the system was still an open question, and with the object of determining their influence on the formation of fat in the organism. The experiments were made with two pairs of young pigs, each pair coming from one litter, and carefully selected, after undergoing the same treatment, so as to be as near as possible of the same condition. At the beginning of the series of experiments one of each pair was killed, and the quantity of fat and albumin present determined. Of the remaining two, one was fed with barley alone, and the other with barley and varying proportions of starch and sugar. The greatest care was taken in the daily analyses and weighing of the food, and the troughs were so made and fitted as to prevent waste. Three times during each series of experiments the digestive coefficient was determined. The experiment lasted over 12 days, during the last six of which the excrements were carefully collected and analysed.

The first pair of pigs, Nos. 1 and 2, were fed for some days on barley-meal, and then No. 1 was killed, cut up, and analysed. No. 2 was fed for four months on barleymeal of three sorts, and weighed regularly. Three determinations of the digestive coefficient of the meal were made with the following results:—

Barley.	A.		B.		C.	
	Percentage contained.	Percentage of this digested.	Percentage contained.	Percentage of this digested.	Percentage contained.	Percentage of this digested.
Albumin..	14·44	82·94	11·62	77·94	10·87	75·47
Fat	1·60	61·73	1·21	46·03	1·51	68·49

With the aid of the above figures, the total amounts of albumin and fat digested during the whole time of the experiments were calculated. At the end of four months, the animal was killed, cut up, and after well mixing, samples of the various parts were analysed.

The second pair were treated, at first, as above, then No. 3 was killed, and No. 4 fed for four months; barley alone was given at first, and then a mixture of barley with gradually increasing proportions of starch and sugar, almost equal quantities of the former two being given towards the end. Three experiments were also made to determine the digestive coefficients of the barley, and a considerable depreciation was observed as the quantity of starch increased, the numbers in the last experiment being albumin 55·4 and fat 17·5 per cent., assuming the whole of the starch and sugar to have been digested. At the end of four months No. 4 was killed.

Analyses of the carcases of the four animals gave the following results in grams:—

	No. 1.	No. 2.	No. 3.	No. 4.
Fat........	957	9264	1009	6439
Albumin ..	687	2316	1478	2671

No. 2 had therefore gained during the experiment 8576 grams fat and 1559 albumin, whilst the quantities digested had been only 655 grams fat and 7493 albumin: allowing that the excess of albumin had all been converted into fat, this still leaves a very large quantity of fat gained to be accounted for. In the case of pig No. 4 the same fact was also observed: and even admitting the very improbable contingency that the whole of the albumin given had been digested, there was still a considerable margin left, showing that the fat must have also been derived from other sources. That the carbohydrates therefore participate in the formation of fat in the organism is a necessary inference from the above experiments. J. K. C.

Effect of Exhausted Beetroot Pulp on Cows' Milk. By A. ANDOUARD and V. DÉZAUNAY (*Compt. rend.*, **97**, 809—811).—It is generally believed that beetroot pulp from which the sugar has been extracted by diffusion, constitutes a valuable food for cattle. Experiments made by the authors show that when a cow is fed with pulp which has been kept in silos, the yield of milk increases by nearly 32 per cent. of its original amount; the proportion of casein and inorganic salts is not sensibly affected, but the proportion of fat increases by 12·4 per cent., and that of sugar by 23·64 per cent. of its original amount. The milk, however, has a less agreeable taste, and shows a decided tendency to acid fermentation. Moreover, it was found to be unsuitable for the nourishment of infants.

This alteration in the character of the milk is most probably due to the acids in the exhausted pulp. The pulp used in these experiments contained an amount of organic acid equivalent to 1·08 per cent. of acetic acid, and consequently a cow consuming 50 kilos. of pulp per day (an average quantity) would absorb 540 grams of acetic acid and its homologues. C. H. B.

Partially Oxidised Sulphur in Urine. By R. LÉPINE and G. GUÉRIN (*Compt. rend.*, **97**, 1074—1076).—The incompletely oxidised sulphur in urine cannot all be oxidised by chlorine or bromine; it is completely oxidised only by fusion with potassium nitrate and hydroxide. The unoxidised sulphur may therefore be divided into two portions, *sulphur easily oxidised*, and *sulphur difficult to oxidise*. The sulphur derived from the bile is included in the latter portion, as might have been expected from the known stability of taurine and its derivatives. This conclusion was confirmed by a number of experiments with dogs, in which the amount of bile reabsorbed was increased, the result being that the amount of sulphur difficult to oxidise in the urine was also increased. Some of the sulphur difficult to oxidise is, however, derived from some source other than the bile. A dog with a complete biliary fistula was kept sometimes on soup diet (bread and fat), sometimes on a diet of horseflesh. In the first case, the sulphur oxidised with difficulty was 30 per cent. of the total sulphur; in the second case, it was 23 per cent. If the amount of nitrogen in the urine is taken as 100, then the sulphur oxidised with difficulty was equal to 1·8 in the first case, and 0·8 in the second. Numerous experiments show that the urine contains a large proportion of sulphur difficult to oxidise, in many pathological conditions in which there is no reason to suppose that the amount of bile reabsorbed is in any way increased. C. H. B.

Hydrocyanic Acid from Animals. By M. Weber (*Bied. Centr.*, 1883, 565).—It has been shown chemically by G. Geldensteeden that certain *Fontaria* possess glands capable of secreting free hydrocyanic acid.
J. T.

Stony Concretions in Animals. By F. Schuberg (*Bied. Centr.*, 1883, 565).—The author confirms the view that the introduction of foreign matter induces the formation of intestinal stones. He gives analyses of three stones: (1) given by Abeles, (2) from the *Procesus vermiformis* of a man, and (3) from the *Intestinum rectum* of a boy:—

	(1.)	(2.)	(3.)
Water	22·0	57·3	—
Ammonia-magnesium phosphate	—	24·4	63·9
Calcium phosphate	60·5	6·7	23·8
Magnesium phosphate	4·3	—	—
Calcium carbonate	—	—	4·6
Calcium sulphate	1·1	1·3	0·7
Alcohol-ether extract	0·3	0·8	0·8
Other organic matter	11·3	9·2	6·0

Stones from plant-eating animals often contain calcium carbonate.
J. T.

Connection between Chemical Constitution and Physiological Action. By T. L. Brunton and J. T. Cash (*Proc. Roy. Soc.*, 35, 324—328).—This paper contains a series of investigations on the physiological action of the salts of ammonium, the amines, the alkali metals, and the alkaline earths.

All the ammonium salts affect the spinal cord, motor nerves, and muscles, and tend ultimately to poison these structures, but the course varies with the salt employed. Ammonium bromide, and the sulphate, phosphate, and iodide to a less degree, cause coagulation of the stroma of the red blood-corpuscles. The amines and their salts affect the spinal cord, motor nerves, and muscles, and their action differs most markedly from that of the ammonium salts; the former cause tetanus, the latter motor paralysis. The irritability of the muscle is increased by the hydrochlorides, but their contractile power is less affected by them, more than by the sulphates, and most by the hydriodides. Of the salts of methyl-, ethyl-, and amyl-ammonium, the primary are more active than either the secondary or tertiary, but the tetrasubstituted compounds are the most active.

The chlorides of the alkali-metals differ from ammonia in having very little tendency to stimulate the spinal cord; the chief symptom of poisoning produced by them is increasing torpor. The contractile power of muscles is increased by rubidium, potassium, and cæsium, unaffected by sodium, and invariably diminished by lithium.

The alkaline earths, as regards their action on the nervous system, may be divided into two groups: (*a*), beryllium, calcium, barium and strontium; (*b*), yttrium, didymium, erbium and lanthanum. Group *a* has a tendency to increase reflex action, group *b* to paralyse motor centres. The contractile power of muscles is increased by barium, erbium, and lanthanum, diminished by yttrium and calcium. Contraction is increased by barium, calcium, yttrium, and beryllium; that produced by barium is enormous, resembling the effect of veratria.

The alteration effected on muscle by one substance may be neutralised, but not increased, by another substance having a similar action. Potassium shortens the lengthened curves of barium, calcium, strontium, and lithium; the veratria-like curve of barium is counteracted by almost all the substances, producing a shorter curve than itself.

Some relations are pointed out between the atomic weights of antagonising elements, but the data are too limited to admit of any generalisation.

By alternate application of acids and alkalis, the muscles of a frog describe on a slowly revolving cylinder curves resembling those described by the normal contraction of a muscle on stimulation.

The lethal activity on frogs of the chlorides of the metals of the alkali and alkaline salt-group was also the subject of investigation; potassium chloride is the most, and calcium chloride the least powerful. V. H. V.

Cholera. By R. De Luna (*Compt. rend.*, **97**, 633).—The cause of cholera always exists in the air, and is transmitted by persons and things. It acts exclusively through the organs of respiration, and incubation generally takes place when the individual is in a passive condition, and particularly during sleep. The microbe or ferment acts especially on the blood corpuscles and prevents hematosis, producing a kind of gradual asphyxia. According to the experience of the author and of Spanish physicians, the only means of saving infected patients in the stage of chills is the careful inhalation of oxides of nitrogen mixed with air. The effect is very rapid, two or three inhalations being sufficient to place the patient out of danger in a few hours. As a precaution against the disease, rooms, vessels, &c., should be fumigated with the nitrogen oxides twice a day—on retiring and after rising. C. H. B.

Distribution of Arsenic in a Human Body. By R. H. Chittenden (*Amer. Chem. J.*, **5**, 8—14).—In a case of suspected poisoning by arsenic, the internal organs were removed and analysed soon after death; about six months later the body was exhumed, and about one half of the entire muscle and bony tissue removed for further examination in order to ascertain the distribution and entire amount of arsenic in the body.

Such of the internal organs as had been placed in alcohol were ground to a thick paste with the alcohol in a mortar and weighed portions then taken for analysis. The muscle and bony tissues were dissolved in nitric acid at a gentle heat, and portions of this liquid then used for the determinations.

The arsenic was estimated by the process previously described by the author (Abstr., 1881, 648). The figures given are those calculated on the entire organs, &c., from the (generally duplicate) results so obtained:—

	Grain As_2O_3.
Stomach and œsophagus	0·158
Liver	0·218
Intestines	0·314
Kidneys	0·029
Heart	0·112
Lungs and spleen	0·1719
Brain	0·075
Trachea, larynx, and tongue	0·081
Diaphragm	0·010
Left arm (weight, 43¼ oz.)	0·094
Right leg, except thigh bone (weight, 164 oz.)	0·118
Thigh bone (weight, 7½ oz.)	—
Transverse section of body at pelvis, including pelvic bones (weight, 143½ oz.)	0·186
Muscle from breast (weight, 18¼ oz.)	0·098
Muscle from back (weight, 24 oz.)	0·356

The entire body would therefore contain about 3·1 grains of As_2O_3. In the author's opinion there is a marked difference in the distribution of arsenic in the muscular tissue according to whether the poison has been administered in a single dose, when the distribution is very irregular, or in long-continued small doses, when the regular distribution of the arsenic is very noticeable. A. J. G.

Colorado Beetle. By J. D. Forbes (*Arch. Pharm.* [3], 21, 314).—The author has examined the Colorado beetle, *Doryphora decemlineata*, for a vesicating substance. No distinct evidence of such a constituent could be obtained when the live beetles were crushed in a mortar, extracted with various solvents, and the residues from the latter examined. After killing the beetles with ether, drying, powdering, and exhausting with chloroform, a dark oil was obtained by the chloroform extract which had marked vesicating properties.

W. R. D.

Chemistry of Vegetable Physiology and Agriculture.

Reduction of Nitrates by Ferments. By A. Springer (*Amer. Chem. J.*, 4, 452—453).—According to the author, the roots of plants are covered with small organisms which reduce nitrates, with evolution of nitric oxide. This ferment closely resembles the butyric ferment, and is probably identical with the *Microzyma cretæ* of Bechamp; it is composed of small cylindrical rods rounded at the extremities, generally isolated, but sometimes joined two by two. They move rapidly with a wriggling motion, and often bend their bodies until

they form a perfect circle. Another ferment or modification is somewhat smaller, and spins round its smaller diameter as an axis. Phenol has no appreciable action on the new ferment. Similar results have been obtained since the author first announced his results, by Gayon and Dupetit (Abstr., 1883, 229), and Déhérain and Maquenne (*ibid.*, 230).
A. J. G.

Fermentation of Cane-Sugar in Contact with Arable Soil. By P. P. Déhérain and Maquenne (*Compt. rend.*, **97**, 803—805).—When cane-sugar is mixed with arable soil, chalk, and water, and the mixture kept at 35—40° for a considerable time, the whole of the sugar disappears. The gas which is given off at first is almost pure hydrogen, but as fermentation proceeds the proportion of carbonic anhydride becomes greater and greater. The other products of the fermentation are small quantities of ethyl alcohol, and still smaller quantities of higher alcohols of the same series; acetic and butyric acids, together equal in amount to about half the weight of the sugar, and a smaller quantity of propionic acid, but no acid higher than butyric. These facts show that the ferment existing in arable soil belongs to the class of butyric ferments.
C. H. B.

Comparative Poisonous Action of Metals on Bacteria. By C. Richet (*Compt. rend.*, **97**, 1004—1006).—The liquid employed was a mixture of 900 grams sea-water, 100 grams neutralised urine, and 1 gram commercial peptone, and the particular metal was added in gradually increasing quantity in the form of chloride until no bacteria were developed after 48 hours at 16—20°. In the following table column A gives the minimum quantity of each metal per litre which will prevent the development of bacteria after 48 hours, and column B gives the minimum quantity of each metal per litre which will kill marine fishes in 48 hours.

	A.	B.
Mercury (Hg″) ...	0·0055 gram.	0·00029 gram.
Zinc	0·026 ,,	0·0084 ,,
Cadmium	0·040 ,,	0·017 ,,
Copper (Cu″)	0·062 ,,	0·0033 ,,
Nickel	0·018 ,,	0·125 ,,
Iron (Fe‴)	0·24 ,,	0·014 ,,
Barium	3·35 ,,	0·78 ,,
Lithium	6·9 ,,	0·30 ,,
Magnesium	7·2 ,,	1·50 ,,
Manganese	7·7 ,,	0·30 ,,
Ammonium	18·7 ,,	0·064 ,,
Calcium	30·0 ,,	2·40 ,,
Sodium..........	43·0 ,,	24·00 ,,
Potassium.......	58·0 ,,	0·10 ,,

The amount of each metal which will kill fish is always much less than that required to prevent the development of bacteria. The marked poisonous action of ammonium, lithium, and potassium on fish and all animals is in striking contrast to the slight effect which these metals exert on plants and bacteria. Poisons may be divided into two classes, viz., general poisons, of which mercury is the most perfect, which even in small quantities have a deleterious action on both plants and animals; and special poisons, such as potassium and ammonium salts and the alkaloids, which are injurious only to animals, and exert little or no poisonous action on plants. The difference is probably due to the fact that poisons of the second class act only on nerve cells, whereas those of the first class act on all cells. Possibly the action of ammonium and potassium salts may serve to distinguish between plants and animals in the lower forms of life.

C H. B.

Distribution of Water in Heliotropically inclined Parts of Plants. By A. THADF (*Bied. Centr.*, 1883, 568).—Kraus has found, amongst other results, that in positive heliotropically inclined organs, the shady side contains more water than the light side. The author found from 12 experiments a difference of 0·004 per cent. only. Normal growing plants similarly examined gave a difference of 0·115 per cent. as the average of six experiments. The author shows that different ways of treating the plant give considerable differences in the amount of water found.

J. T.

Plants from Seeds of Various Sizes. By HELLRIEGEL (*Bied. Centr.*, 1883, 530—542).—The magnitude and development of the embryo, and the reserve stock of nutriment in seed, may be assumed to be closely related to the size of the seed in cases where the latter has not a complicated envelope.

Influence of the Absolute Weight of Seeds.—Grains of barley having a sp. gr. between 1·19 and 1·2 were divided into four groups, according to weight, and sown. The development of the heavier seeds proceeded more quickly at first, but in course of time the weight of the plants produced became nearly equal.

Influence of Specific Gravity.—Experiments with barley seeds of varying sp. gr. showed that differences in this respect produced no difference in the plant.

Influence of Relative Ripeness.—Rye seeds reaped at five different stages of growth were used for experiment. I. Cut when grain and straw were still green, the former very small, with clear watery sap. II. Straw still green, grain strongly grown, sap milky. III. Straw becoming yellow, grain full size but still green, and very soft. IV. Straw yellow and tolerably dry, grain hard, no sap (said to be yellow-ripe). V. Straw and grain dry, the latter easily removable (said to be over-ripe or dead-ripe). Each group was divided into four classes:—*a*. The seeds were carefully separated from the plant—after-ripening thus prevented. *b*. The ears were cut off and bundled—restricted after-ripening. *c*. Stalks cut some inches above the ground as in ordinary reaping. *d*. The whole plant was taken up and placed in distilled water, the most favourable condition for after-ripening. The seeds were sown partly in vessels and partly in the open ground. The soil consisted of rich garden mould and poor sandy ground. The following results were obtained:—In poor soil, the unripe seeds were exceedingly backward; part did not germinate, and part remained weakly all through life. In rich soil, however, the backwardness was much less marked, and was mostly shown by the non-germination of some of the seeds; the plants, although weak at first, became completely developed. The after-ripening of the seed, when left for a time in contact with the remaining parts of the plant, has a decidedly favourable influence on the germinating power of the seed, but much less in increasing the producing power of the resulting plant.

Experiments with potatoes showed that large potatoes give the best yield, which is opposed to common practice, where moderate sized ones are chosen. The sp. gr. of the potato appears to have no influence on the yield. J. T.

Mineral Constituents of the Seeds of Forest Trees. By R. HORNBERGER (*Landw. Versuchs.-Stat.*, 29, 281—289).—The author has analysed the ash of seeds of elm, ash, hornbeam, maple, birch, pine, and larch. The seeds were obtained from dealers, having been gathered in the most various localities, and representing therefore an average material. They were incinerated, and the ash constituents determined according to well-known methods. The following results were obtained:—

	Ash per cent	In 100 parts ash								
		K_2O.	Na_2O.	CaO.	MgO	Fe_2O_3.	Mn_3O_4.	P_2O_5.	SO_3.	SiO_2.
Elm......	9·30	32·29	0·62	23·73	6·27	3·24	0·32	11·22	4·86	13·94
Ash......	4·24	44·18	0·85	21·77	6·57	0 89	0 09	15·21	9·06	1·29
Hornbeam	2·4[illegible]	25·15	0·[illegible]2	35·62	7·82	5·69	2·64	14·28	3·93	5·05
Maple....	6·79	37·37	0·84	27·66	5·82	2·94	2·49	14·16	5·27	6·18
Birch	4·20	27·03	1·38	23·77	9·20	8·91	2·73	10·89	4·80	8·94
Pine......	4·28	24·02	0·72	1·63	14·22	2·10	2·05	37·77	4·45	16·00
Larch	2·07	34·68	1·25	2·41	12·81	1·30	1·83	34 15	4 09	5 88

The most striking feature in the above table is the great difference in the lime contained in the seeds of the pine series and in those of the other trees. Whilst the former contain less than 2½ per cent., the latter contain from 20 to 35 per cent. of lime; on the other hand, the pine seeds are very much richer in magnesia and phosphoric acid. The large quantity of silica in the seeds of the pine and elm seems to stand in some connection with the fact noticed by previous observers that the woods of these trees take up large quantities of silica

J. K. C.

Constituents of the Larch Fungus. By E. JAHNS (*Arch. Pharm.* [3], 21, 260—271).—Although the larch agaric (*Polyporus officinalis*) has been investigated by more than one chemist, conflicting statements concerning its constituents still exist. The author, with the view of clearing up the question, has re-investigated this plant. By extraction with hot strong alcohol it yielded about 18 per cent. of a crystalline acid melting at about 139°, and easily soluble in alcohol, glacial acetic acid, and turpentine, less soluble in ether, and nearly insoluble in chloroform, benzene, and cold water. The acid is dibasic, forming normal salts with the alkali metals, which are easily soluble in water, and acid salts which are only slightly soluble: with the majority of the metals, it forms insoluble salts, which are precipitated in the amorphous state from aqueous solutions. Analysis showed that *agaricic acid* was a homologue of malic acid, represented by the formula $C_{16}H_{30}O_5,H_2O$. On oxidation with nitric acid, it is converted into succinic and butyric acids. The principal salts are described in the paper. This acid is identical with the "agaricic acid" of Fleury, the "laricin" of Martius; and the substances named by Schoonbroodt "agaricin" and "pseudo-wax" by Trommsdorff, are probably the same acid in an impure state. The original alcoholic extract of the fungus also yields a substance which crystallises in needles from a solution in absolute alcohol. It is insoluble in water, and nearly so in ether, chloroform, and cold alcohol, but dissolves in potash solution. It melts at about 272°, and sublimes in white needles. This substance, which is probably an alcohol, exists to the extent of about 5 per cent. in the plant. The alcoholic mother-liquors from this substance contain a white amorphous body, which is deposited in a colloidal form from its solution in chloroform. It appears to be an acid, and occurs to the extent of about 4 per cent. in the fungus. Finally a red amorphous resin was obtained from the original alcoholic extract, in which it was very soluble. This is the bitter purgative constituent of the fungus, and is present to the extent of about 30 per cent. W. R. D.

Paraguay Tea. By A. W. SELLIN (*Arch. Pharm.* [3], 21, 292).—This substance, which is also known as *maté*, is yielded by the *Ilex paraguayensis*, which grows in the highlands of Southern Brazil, the Argentine Republic, and Paraguay. The leaves are gathered in the spring, dried at a low temperature, and packed. An infusion of it is drunk by the South Americans in the place of tea. W. R. D.

Glycogen in Plants. By ERRERA (*Biol. Centr.*, 1883, 355).—Glycogen has been detected in *Ascomycetes pilobolus*, &c., and also in plants of a higher order, as *Solanum*, *Linum*, &c. A compound analogous to dextrin is found in *Solanum* and *Agaricus*, but not in *Peziza* or *Lemanea*. Glycogen may as a rule be readily detected in plants by the microchemical method, when it exhibits all the properties possessed by this compound as obtained from the animals. E. W. P.

Minjak-Lagam Balsam. By G. HAUSSNER (*Arch. Pharm.* [3], 21, 241—256).—Minjak-Lagam, a balsam resembling copaiba, but the botanical origin of which is unknown, has been chemically examined by the author. On distillation with water, it yielded one-third of its weight of an essential oil of sp. gr. 0·928 at 15°, and similar to the essential oil yielded by copaiba and gurgun balsams. The analysis and vapour-density determination correspond with the formula

$C_{20}H_{32}$, and it yields a crystalline hydrochloride, $C_{20}H_{32},4HCl$, melting at 114°. The resin remaining in the retort after the distillation of the oil, contained an amorphous acid which formed uncrystallisable salts with many of the metals. The copper salt, on analysis, gave figures pointing to the formula $C_7H_{12}O_3Cu$. The resin when fused with potash, heated with acid and ether in the usual way, and the extract distilled with water, yields butyric acid, whilst a substance remains in the solution which appears to be an acid derived from benzene, as it gives a violet colour with ferric chloride. Minjak-Lagam balsam therefore resembles gurgun balsam in many of its characters, and probably has a similar botanical origin, namely, a species of *Dipterocarpus.* It appears to differ from this balsam in yielding an uncrystallisable resin acid which has a lower molecular weight than the resin acid of gurgun. It is probably further distinguished by the fact that its resin yields an aromatic acid as well as butyric acid when fused with potassium hydroxide. W. R. D.

Phylloxera. By T. TOZZETTI and others (*Bied. Centr.*, 1883, 547—551).—According to Henneguy this pest has considerably increased in the vineyards in the district of Béziers, where carbon bisulphide has not been employed. P. Mouillefert states that potassium thiocarbonate is being applied to the vineyards of Médoc and the south of France. Culeron has applied the same substance for more than five years with good results, and has made many comparative experiments on the subject. He recommends the application to be made from October to April. J. T.

Indian Wheat. By BALLAND (*Compt. rend.*, **97**, 805).—Indian wheat contains a relatively considerable quantity of seeds of *leguminosæ* and some other plants. Wheat shipped at Bombay was found to contain seeds of *Vicia peregrina; Cicer arietinum; C. arietinum*, var. *nigrum; Ervum uniflorum; Cajanus indicus*; *Acacia lubeck; Tamarindus indica; Cassia* (?); *Rhynchosia* (?); *Citrullus vulgaris; Ricinus communis; Liniens usitatissimum.* C. H. B.

Maize as Food for Horses. By GERSSDORFF (*Bied. Centr.*, 1883, 566).—7·5 to 9 kilos. per head per day, mixed with chaff and followed by good hay, kept the animals in as good condition as 10 kilos. oats. J. T.

Fermenting Maize for Milch Cows. (*Bied. Centr.*, 1883, 567.) —The cows were previously fed on mangel-wurzel; gradually this was diminished to one-half, and replaced by maize fermented in pits. The amount of milk and butter obtained remained the same; but the latter was somewhat whiter than before. There was no apparent change in the bulk of the animal. J. T.

Palm-oil Residue as Fodder. By MÄRCKER (*Bied. Centr.*, 1883, 566).—The author gives three analyses of palm-kernel-meal, (1) after being stored three weeks; (2) nine months; and (3) quite fresh:—

	(1.)	(2.)	(3)
Water	9·16	9·75	9·43
Ash	5·68	3·93	3·56
Proteïn	12·31	15·13	15·31
Cellulose	23·27	25·27	21·20
Nitrogenous matter (extractive).	44·91	41·23	43·46
Fat	4·67	4·56	7·04

The author combats the view that this is not a good milk-fodder, and asserts that the most important constituents for milk production are the nitrogenous substances and not the fat. J. T.

Earth-nut Cake. By Holdefleiss (*Bied. Centr.*, 1883, 526—528).—This cattle food having given unsatisfactory results of late, although numerous analyses show 40 to 50 per cent. proteïn, and several per cent. albumin, with other food constituents normal, it was microscopically examined, and in many cases was found to contain quantities of fungus spores. 48 to 60 hours after moistening with very little water. the meal becomes covered with a yellow coating of an *Aspergillus*, similar to *Aspergillus flavus*. This fungus is of special interest, as in Japan it induces the fermentation and formation of sugar in rice. In the presence of more moisture, a black *Aspergillus* appears in colonies, also a thick covering of mucor-like fungi. These fungi cause changes in the meal, primarily a disappearance of albumin. Enormous quantities of bacteria were observed in many samples. J. T.

Composition of Beetroot. By Pagnoul (*Bied. Centr.*, 1883, 570).—The author gives analyses of beetroot—(1) grown in soil excessively manured with stable dung, and (2) grown in soil ordinarily manured with an artificial manure containing Chili nitre:—

	(1.)	(2.)
Weight of the root	820 g.	492 g.
Sugar	13·51 p. c.	4·42 p. c.
Alkalis	0·40 „	1·07 „
Nitrate	0·04 „	0·73 „
Salt, per 100 sugar	2·27 „	24·12 „
Nitrate „	0·31 „	16·47 „

J. T.

Sugar Beet. By G. Marek (*Bied. Centr.*, 1883, 543—547).—The author took varieties richest in sugar to ascertain the connection, if any, between the absolute and sp. gr. of portions, and the yield in sugar. Generally the sp. gr. of the whole root is less than that of parts of the root. Of the parts of the root, the point is the heaviest, next the middle part or body, then a side piece of the body, and lastly the head. The author is of opinion that weighing the whole root gives better results than judging by appearances; and that weighing various portions of the root is advisable in selecting for seeding; for this purpose a portion from the side of middle part is most suitable to weigh, in order to separate light from heavy roots. The sap from the various portions gave over all a higher sp. gr. than the root itself. Sap from the middle portion was the heaviest; then followed the root, and last the top. Sap from a number of roots generally gives higher rotation with a higher sp. gr., but this is not invariable. Of the parts of the same root, sap from the middle part gave the highest rotation, next from the side piece of the middle; then point, and lastly that of the head. Beets with rosette-like arrangement of leaves were found to be richer than those with a more vertical arrangement. The author shows that the so-called "*aufschussrüben*" as compared with normal plants have a lighter sap, less sugar, and lighter root, with a greater weight of leaves and head. When the seed-shoots of such plants are removed beforehand, the roots become still poorer in sugar, and richer in salts and cellulose. The increased amount of cellulose interferes prejudicially with the extraction of the sugar.

J. T.

Soil Temperature in Relation to the Air Temperature. By W. HOSSFELD (*Bied. Centr.*, 1883, 562).—Observations, made daily during the first six months of this year, showed that in a clay soil at Kranichfeld the temperature increased from the surface downwards to a depth of 2 meters until March 12; after this the temperature diminished from the surface downwards. The observations were made at 8 A.M. J. T.

Irrigation as Preventive of Injury from Frost. By T. v. NEERGARD (*Bied. Centr.*, 1883, 561).—The injurious action of night frost on grass, &c., in spring can be prevented by covering the meadows with 4—6 cm. of water; this practice should be continued until the end of May, until the frost has entirely disappeared.

J. T.

Nitric Acid in Soils and Subsoils at Rothamsted. By Sir J. B. LAWES, J. H. GILBERT, and R. WARINGTON (*Jour. Roy. Agri. Soc.*, 1883, 331).—The unmanured and uncropped soils of the three drainages have yielded drainage waters containing on an average of six years 40.2 lbs. of nitric nitrogen per acre. This amount must be below the annual produce of good soil. Nitric acid was determined in many soils: the samples were taken by driving a rectangular iron tube, 6 inches square and 9 inches deep, into the ground, removing the contents as a sample, and again driving the tube down to obtain samples of the succeeding depths: the soils were at once broken up and dried at 55°. The nitric acid was determined by a modification of Schloesing's method (Trans., 1882, 345—351). The immediate drying of the soil is indispensable, otherwise the results are too high.

Fallow Soils.—Three soils in fair condition, cultivated as bare fallow, contained at the end of summer 56·5—59·9 lbs. of nitric nitrogen per acre to a depth of 27 inches. Estimating as far as possible the preceding loss of nitrate by drainage, it would appear that about 80 lbs. of nitric nitrogen per acre were produced during the season (15 months) of fallow. Land in poor condition contained much less nitrate. When the preceding summer had been dry, the nitrate was chiefly near the surface.

Soils growing Cereal Crops.—Where no excess of nitrogenous manure is employed, very small quantities of nitrate are found in the soil during summer, owing to assimilation by the crop. If rain occurs after harvest, and especially if the land is ploughed, considerable formation of nitrate takes place. Nitrate continues to be present through the winter, notwithstanding loss by drainage, slow production being always in progress. In late spring or early summer, the nitrate again disappears if the land is under crop.

Determinations of nitric acid were made in the soils of the experimental wheat field, taken October, 1881. Much rain had fallen since harvest, and the land had been ploughed; conditions were thus favourable to nitrification. Plots permanently unmanured contained 15·0—17·9 lbs. of nitric nitrogen per acre to a depth of 27 inches. Plots receiving ash-constituents alone, 21·2 to 24·3 lbs. Plots receiving ash-constituents, with 400 lbs. of ammonium salts or 550 lbs. nitrate of sodium the preceding spring, contained 24·6—39·8 lbs. Plots with the above-mentioned nitrogenous manure alone, 28·3—54·1 lbs. With 1700 lbs. of rape cake, 34·2 lbs. With 14 tons of farmyard manure, 52·2 lbs. The last two manures were applied the preceding autumn. On plots receiving no nitrogenous manure, or not excessive quantities of ammonia or nitrate, the nitrate found was due to nitrification of crop and weed residues and of the humic matters of the soil; the quantity of nitrate generally bore a distinct relation to the quantity of the preceding crops. Where an excess of nitrate of sodium had been applied, a considerable residue of the manure was found in the subsoil. Where rape cake or farmyard manure was used, the nitrate was partly derived from the nitrification of residues of manure. The nitrogen of permanently unmanured soil nitrifies with more difficulty than the nitrogen of soil which has yielded large crops, or than nitrogenous residues of rape cake or farmyard manure.

The soils of the experimental barley field were sampled in March, 1882, to the depth of 27 inches. The permanently unmanured land contained 15·7 lbs. of nitric nitrogen per acre. That receiving ash-constituents alone, a mean of 20·1 lbs. That receiving 200 lbs. ammonium salts, or 275 lbs. nitrate of sodium, with or without ash-constituents, a mean of 23·3 lbs. Plots receiving 1000 lbs. rape cake, with or without ash-constituents, a mean of 30·1 lbs. The plot receiving 14 tons farmyard manure, 44·1 lbs. The washing of the autumn and winter rains had tended to equalise the amounts of nitrate. The influence of crop residues is not so marked as in the wheat field, barley leaving a smaller residue in the soil than wheat.

Soils growing Leguminous Crops.—The nitrate in soils that have grown beans or clover is much smaller than that found in similar uncropped soils. Although leguminous crops thus assimilate nitric nitrogen, the total quantity of nitrogen found in such crops often greatly exceeds the quantity of nitric nitrogen at present recognised as occurring in soils. We must thus apparently assume for leguminous crops a further source of nitrogen; in the case of cereal crops, the nitric nitrogen of the soil appears to furnish an adequate supply.

Few determinations of nitric nitrogen have yet been made for depths below 27 inches; in most cases only small quantities were found. It is a question whether the nitrates in a clay subsoil are not destroyed by reduction. R. W.

Yield of Crops under Steam Cultivation. By M. MÄRCKER (*Bied. Centr.*, 1883, 508—511).—Experience with Fowler's steam ploughs during the period 1872—80 leads to the following conclusions:—

Against hail, frost, rust, and the depredations of animals, &c., it has no advantage over animal cultivation; but in very wet or very dry seasons it greatly reduces the injurious results of such abnormal weather. In dry weather, the plants can more readily get deeper in search of moisture, whilst in wet seasons the excess water more readily drains away into the subsoil. Another essential advantage is the immediate destruction of weeds. Further, the after cultivation of the crop is facilitated. From figures given the wheat crops averaged 19·4 per cent. better; barley, 32·1 per cent.; oats, 1·2 per cent.; maize, 12·5 per cent., and beet, 26·8 per cent. The wheat crops compared were six years before and six after the introduction of steam cultivation, the other crops were nine years before and nine after. J. T.

Coexistence of Ammonium Carbonate and Potassium Sulphate in Guano. By E. CHEVREUL (*Compt. rend.*, 97, 786—787).—Guano not unfrequently contains compact homogeneous moist snow-white masses consisting of ammonium subcarbonate, associated with potassium sulphate and water. C. H. B.

The Guano of Cape Vert. By A. ANDOUARD (*Compt. rend.*, 97, 858—859).—The guano is mixed with a considerable quantity of stones. When these are removed it has the composition:—

Moisture	15·21
Organic nitrogen	0·28
Nitrogen as ammonia	0·04
Organic matter	10·63
Phosphoric acid	11·37
Lime, magnesia, and ferric oxide	20·49
Salts soluble in water	0·92
Silica and silicates	41·06
	100·00

C. H. B.

Nitrogen in Bone-meal. By WAGNER (*Bied. Centr.*, 1883, 563).—Commercial bone-meal contains 1 to 4 per cent. of nitrogen, on an average 3·2 per cent. This variation in amount depends on the previous treatment to which the bone has been subjected for the extraction of its fat. Hence it is advisable to extract the fat by means of solvents such as petroleum. Bones so treated contained 4½ to 5 per cent. of nitrogen, and consequently have an increased value. J. T.

Weathering of Bone Manure. By J. König (*Bied. Centr.*, 1883, 562).—Steamed bone-meal mixed with stable dung spread on a field in the spring of 1883 had quite disappeared at the present time, whilst in another case raw fragments of bone can be found which was applied along with stable dung from two to four years ago. Such bone fragments washed and analysed gave, after two, three, and four years on the soil respectively—of nitrogen, 1·1, 0·7, and 0·4 per cent. respectively; of phosphoric acid, 10·1, 0·7, and 0·3 per cent. respectively; and of calcium carbonate, 41·2, 49·1, and 42·7 respectively. Hence raw bone takes at least four years to weather completely.

J. T.

Influence of Superphosphates on the Quality of the Yield. By F. Farsky (*Bied. Centr.*, 1883, 511—512).—The author had opportunity during some manure experiments of comparing the effects of Chili nitre and superphosphate on buckwheat. His results show (1) that superphosphate induces early maturity in the plant, and (2) that it also increases the absolute and relative weight of the seeds. Further Chili nitre retards the harvest, and in no instance produces heavier seeds. J. T.

Phosphate from the Rata Island. (*Bied. Centr.*, 1883, 562.)—The material has been repeatedly analysed in England; it contains:—

	Analyst.

Effect of Potassium and Sodium Nitrates on the Growth of Potatoes. By P. P. Déhérain (*Compt. rend.*, **97**, 998—1000).—Two pieces of land were sown with potatoes; one was manured with potassium nitrate, and the other with an equal quantity of sodium nitrate, the quantity applied being equivalent to 400 kilos. per hectare. In both cases the average yield was the same, viz., 805 grams per root, a yield considerably in excess of that obtained under ordinary conditions. The influence of the nitrates is very considerable, but the nature of the base does not seem to affect the results. The potatoes manured with sodium nitrate, or with other salts of sodium, contain only potassium and no sodium. It would appear therefore that the sodium salts applied as manure decompose the potassium compounds in the soil with formation of potassium salts, which are absorbed by the plant.

Haricot beans were watered with solutions of sodium chloride of gradually increasing concentration until the plant died. The ash contained 11·3 per cent. of chlorine, whereas the ash of similar beans grown in the same soil without addition of sodium chloride contained only 0·53—0·49 per cent. of chlorine. Notwithstanding the large excess of chlorine, the ash contained no sodium, from which it appears that the plant was killed by abnormal absorption of potassium chloride.

Since sodium nitrate is cheaper, and contains a higher proportion of nitrogen than the potassium salt, the latter can only be used with advantage in the case of soils which are poor in potassium compounds.

C. H. B.

Manuring Experiments in Posen in 1882. By E. Wildt (*Bied. Centr.*, 1883, 516—520).—Experiments made in 1881 with a liberal application of phosphoric acid and nitrogen gave negative results only, probably owing to a lack of potash in the soil. The present experiments were generally a repetition of the previous ones, with the addition of potash. The experiments were made on five different estates. The nitrogen was added as ammonium sulphate, potash as potassium chloride, the soluble phosphoric acid as Curaçao superphosphate, the phosphoric acid soluble in citric acid as precipitated calcium phosphate, and reverted phosphoric acid as phosphorite superphosphate, half of whose acid was soluble in water, and the other half reverted.

I. Soil, slightly loamy sand 10 inches deep; subsoil lighter, and below siliceous sand. Crop, potatoes; previous crop, rye, with stall manure. Nitrogen was given in every case, along with soluble phosphoric acid alone in one case, with potash alone in the second case, and with potash and the various phosphates in all other cases. In all plots in this group, the yield was considerably increased, but an economical result was obtained only when potash and soluble phosphoric acid were added together; the phosphoric acid must be present in sufficient quantity, or the increased yield will be that solely due to the potash. The amount of starch in the potatoes was considerably reduced by the chlorine in the potassium salt. The phosphoric acid soluble in citric acid gave only a small increase; but it may be expected to influence the following crop, as another experiment shows: thus, parcels manured the previous year were cropped again without manure. Nitrogen alone gave no increase, whilst all the phosphate manures gave increased yields, and those most backward the first year did best in the second year.

II. Soil, sandy loam, 4 inches deep; subsoil, loam; previous crop, wheat, manured with superphosphate; experimental crop, potatoes. The nitrogen added showed no effect on the crop, on the contrary, the phosphoric acid, and still more the potash, afforded good results; but 10 kilos. per morgen of soluble phosphoric acid gave no better result than 5 kilos.; the action of the reverted acid is not perceptible, and the result of the acid soluble in citric acid is said to be inexplicable, because the yield is the same as with soluble acid.

III. Soil, sandy loam, 1 foot deep; subsoil, loamy marl. From 1874 to 1880 lucerne was grown; after that summer wheat without manure. The experimental crop was barley. All the manures gave only a slight increase, and in no case do they appear to be economically useful. No conclusion can be drawn as to the action of the various forms of phosphoric acid, the increased yield is so small.

IV. Sandy soil; subsoil sandy, below clay marl. Barley was sown. The potash gave no results; the phosphoric acid acted slightly, and only the nitrogen produced any marked effect, and this was only economically successful when the increased yield of straw was considered.

V. Soil, clayey sand, 8 inches thick; subsoil mixed with marl. Before the experiment no artificial manure had ever been applied, but only a little stable manure. The previous crop was wheat; the experimental crop was oats. Whilst potash and phosphoric acid did not increase the yield, the action of the nitrogen was somewhat considerable, indeed taking into account the straw, a not inconsiderable profit was obtained. J. T.

Manuring Experiments on Tobacco. By J. NESSLER (*Landw. Versuchs.-Stat.*, **29**, 309—312).—The chief object of this investigation was to study the effect on the combustibility of tobacco produced by various kinds of manure, such as chloride, sulphate and nitrate of potassium, superphosphate, stable dung, &c. To this end the dried leaves were ignited, and the time during which they continued to glow noted down. Potassium nitrate and sulphate were found to increase the burning properties of the tobacco, whilst potassium chloride produced the opposite effect. The experimental results, however, exhibit great inequalities, partly due, no doubt, to the fact that the soils were in various states of cultivation in the previous year. Phosphoric acid, however, seems to be not at all an essential constituent of the manure. It is recommended to grow a crop of swedes or beetroot on the land, using a potash manure, and then to follow with tobacco, when Chili saltpetre might be employed.

J. K. C.

Manuring of Marshy Land. By H. J. CARSTEN (*Biel. Centr.*, 1883, 564).—Limed and unlimed portions, manured with raw Peruvian guano, gave similar yields, showing that lime was practically without effect. Another portion of new land, treated five years successively with guano, and sown with oats, gave a yield increasing from 36 hl per ha in the first year to 55 hl per ha in the fifth year. From this it would appear that such land can be converted into profitable arable land by the addition of artificial manure alone, without stable or town manure. J. T.

Analytical Chemistry.

Use of Ammonium Thiosulphate instead of Sulphuretted Hydrogen in Qualitative Analysis. By A. ORLOWSKI (*Zeits. Anal. Chem.*, 22, 357—366).—Barium, strontium, and lead are precipitated as sulphates by adding ammonium thiosulphate to their neutral or slightly acid solutions. The filtrate is acidulated with hydrochloric acid, heated to boiling, and thiosulphate added until no further precipitation of sulphur takes place. The precipitate may contain the sulphides of arsenic, antimony, tin, platinum, gold, silver, copper, mercury, bismuth, and cadmium. These metals are separated from each other in the ordinary way. To the filtrate ammonium chloride, ammonia, and ammonium sulphide are added, precipitating the metals of Group III, besides the sulphide of cadmium, which may not have been completely separated with the previous group. The cadmium is separated from zinc and manganese by adding sodium thiosulphate in excess to the neutral or feebly acid solution, and then boiling. A yellowish-brown precipitate is formed, to which, when cool, hydrochloric acid is added until the evolution of chlorine ceases. The precipitate now consists of hydrated manganese peroxide only; it is collected, and caustic soda in excess is added to the filtrate, the cadmium is thereby precipitated, whilst the zinc remains in solution.

P. F. F.

An Indicator showing the Neutral Point in Alkalimetry and Acidimetry. By A. GAWALOWSKI (*Zeits. Anal. Chem.*, 22, 397).—By mixing alcoholic solutions of phenolphthaleïn and dimethylaniline-orange (methyl-orange) an indicator is obtained, which turns deep-red in an alkaline and rose-red in an acid solution, whilst in a neutral solution it is pale lemon-yellow. P. F. F.

A new Fractioning Apparatus. By C. Winssinger (*Ber.*, **16**, 2640—2645).—This apparatus, which combines both the cooling and washing methods, yields extremely good results. It cannot be succinctly and clearly described without the diagram.

A. K. M.

A new Form of Hot Filtering Funnel and an Apparatus for Obtaining Sublimates. By R. Richter (*J. pr. Chem.* [2], **28**, 309—310).—By coiling a thin lead tube round an ordinary funnel, and passing steam through it, the filtration of substances, even sparingly soluble in hot alcohol, is readily accomplished. By placing a coil of lead piping, through which cold water is passed, on the upper watch-glass of a pair used for sublimation, the author found it possible to obtain with great ease crystalline needles of substances melting at 26°. A. B.

Determination of the Quantities of Gases Dissolved in Watery Liquids. By A. Longi (*Gazzetta*, **13**, 479—481).—The author makes use of the apparatus described in his paper "On the Estimation of Nitrous and Nitric Acids" (p. 366 of this volume).

H. W.

A new Method of Determining Nitrogen in Organic Substances. By J. Kjeldahl (*Zeits. Anal. Chem.*, **22**, 366—382).—The dried substance is digested in a flask for several hours with a large excess of concentrated sulphuric acid, at a temperature approaching the boiling point of the acid. Some fuming sulphuric acid or a little phosphoric anhydride may, with advantage, be added to combine with any trace of water that may be present. In this manner the greater part of the organic nitrogen is converted into ammonia, and this conversion is completed by oxidation with potassium permanganate, which is added cautiously as a fine powder in very small quantities at a time. The addition of permanganate is continued until the solution becomes green, showing that an excess has been employed. When cold, the liquid is diluted with water, rendered alkaline with a strong solution of caustic soda, and then distilled into a receiver containing a measured quantity of standard acid. The author has obtained satisfactory results with nitrogenous organic substances of the most varied character. P. F. F.

Estimation of Nitrogen in Nitro-, Azo-, and Diazo-compounds. By A. Goldberg (*Ber.*, **16**, 2546—2556).—Several unsuccessful attempts have been made by chemists to estimate the nitrogen in nitrates by Will and Varrentrapp's method, by adding a reducing agent to the soda-lime. In the author's experiments stannous sulphide was employed; a mixture of this with soda-lime yielding hydrogen when heated. The results obtained are too low; the addition of sulphur produces somewhat better results, but even then the percentage of nitrogen is generally 1—1·5 too low. This mixture (100 parts soda-lime, 100 parts stannous sulphide, and 20 parts sulphur) yields however satisfactory results with nitro- and azo-compounds. To charge the tube, a layer (5 cm.) of coarsely-powdered soda-lime is first introduced, then a layer (15—20 cm.) of the mixture through which the substance is distributed in the usual way by means of a wire, then another layer (5—10 cm.) of the mixture alone, and finally coarsely powdered soda-lime. The ammonia is absorbed by means of dilute sulphuric acid, and titrated with baryta-water. In the case of the azo-compounds the method is more troublesome than in that of nitro-compounds, owing to the chemical indifference of the former class of substances and to the readiness with which they sublime; the difficulty is overcome, however, by employing a longer tube. When moderately stable, diazo-compounds, such as diazosalicylic acid and paradiazobenzenesulphonic acid, are treated as above, they yield either no ammonia, or at most a very small percentage.

A. K. M.

Detection of Nitric Acid in presence of other Acids capable of Interfering with its Reactions. By A. LONGI (*Gazzetta*, 13. 468—469).—In testing for nitric acid in solutions containing ammoniacal salts, together with chlorates, bromates, iodates, chromates, and other oxidising salts, an error may arise from the conversion of part of the ammonia into nitric acid by the oxidising action of those salts, whence it may appear that nitric acid was present in a solution which previously contained none. This source of error may, however, be avoided by treating the solution with sulphurous acid before heating it, the bromates, chlorates, &c., being thereby reduced to bromides, chlorides, &c., while the nitric acid remains either as such, or in the form of a sulphuroso-nitric compound in which the nitric acid may be detected by the ordinary tests. Bromine and iodine, if present, may be eliminated by G. Vortmann's method (*Ber.*, 13, 2024). Lead dioxide does not oxidise ammoniacal salts in a solution containing acetic acid.

H. W.

Paratoluidine Sulphate as a Test for Nitric Acid. By A. LONGI (*Gazzetta*, 13, 465—468).—If to a liquid containing nitrates a few drops of *p*-toluidine sulphate be added, and then a quantity of ordinary sulphuric acid equal in volume to the nitrate solution, and in such a manner that the liquids shall form two distinct layers, a deep red coloration will appear at the surface of separation, changing after some time to a dark yellow. In solutions of chlorates, bromates, iodates, chromates, and permanganates, the same reagent produces a blue coloration of such intensity as completely to mask the red colour produced with nitrates, even when the quantity of either of the salts just mentioned is very small in comparison with that of the nitrate. Aniline sulphate does not produce any coloration with nitrates, but a mixture of the sulphates of aniline and *p*-toluidine (crude aniline oil) produces a deeper red colour than the toluidine alone.

This test for nitrates is less delicate than that which is afforded by brucine or by diphenylamine, the former of which produces a red colour in solutions containing only 1 part of nitric acid in 256,000 parts of liquid, the latter a blue colour, sensitive to 1 part in two millions; but the toluidine test has the advantage of not giving the same colour with chlorates, bromates, &c., or with nitrites, with which it develops a yellow coloration gradually passing into red.

H. W.

Volumetric Estimation of Nitric Acid. By A. Longi (*Gazzetta*, 13, 482—485).—The blue colour produced by diphenylamine in a solution of nitric acid is destroyed by stannous salts, and this reaction may be made available for the volumetric estimation of nitric acid. The salt employed is Marignac's stannoso-stannic sulphate, and its reaction with nitric acid may be represented by the equation $4SnSO_4 + 4H_2SO_4 + 2HNO_3 = 4Sn(SO_4)_2 + 5H_2O + N_2O$, showing that 4 mols. of the stannous salt are required for the decomposition of 2 mols. nitric acid, or 2 mols. $SnSO_4$ for 1 mol. HNO_3.[*] The method is especially applicable to the estimation of small quantities of nitric acid. H. W.

Estimation of Nitrous and Nitric Acids, separately or together. By A. Longi (*Gazzetta*, 13, 469—479).—For the estimation of nitrous acid, the author makes use of the well-known reaction with urea and acetic acid. Nitrates are first reduced to nitrites with hydrochloric acid and arsenious acid. The paper contains a description of the apparatus employed, and tables of analytical results. H. W.

Estimation of Iodine in presence of Chlorine and Bromine by means of Ferric Sulphate. By A. Gavazzi (*Gazzetta*, 13, 327; and 454—455).—Duflos' process for determining the amount of iodine in iodides by boiling them with ferric chloride and condensing the vapours in a concentrated solution of potassium iodide is not applicable when bromides are present, as bromine passes over along with the iodine. If, however, ferric sulphate be substituted for the chloride, this difficulty is obviated, the iodine alone being volatilised; but the sulphate should be heated to a little below redness to remove free acid, and it is as well to add a little ferrous sulphate to increase the solubility of the ferric salt. This reaction can be employed in testing commercial potassium iodide for chlorine, as all the chlorine remains in the retort quite free from iodine. The method is also useful for detecting traces of iodine in mixtures containing large quantities of chlorine and bromine; and may be used, moreover, for preparing pure iodine. C. E. G.

Assay of Commercial Potassium Iodide. By W. Lenz (*Zeits. Anal. Chem.*, 22, 391—393).—The author has investigated the method of assaying potassium iodide by means of a standard solution of mercuric chloride. He finds that the results are inaccurate, the end-point of the reaction being greatly influenced by temperature. P. F. F.

A new Microchemical Test for Sodium. By A. Streng (*Jahrb. f. Min.*, 1883, 2, Ref., 365).—The author proposes to employ uranium acetate as a test for sodium; by its action on any sodium solution, crystals of uranium sodium acetate are formed, which are but sparingly soluble in water. They appear in the form of tetrahedra, and these minute yellow crystals cannot be mistaken for the rhombic crystals of uranium acetate, which separate out as the solution dries, on account of their action on polarised light. The reaction is very sharp, as the double salt contains a very low percentage of soda (6·6 per cent.). B. H. B.

---

[*] In the original paper it is said that 4 mols. of the stannous salt are required to decompose 1 mol. nitric acid; but this is clearly inconsistent with the equation above given.

Detection and Estimation of Zinc and Lead in Presence of Iron. By A. Deros (*Compt. rend.*, **97**, 1068—1070).—*Zinc.*—The hydrochloric acid solution of 1 gram of the substance is poured gradually, with agitation, into an excess of ammonia, and when cold the mixture is electrolysed in a platinum capsule which acts as the positive electrode, the negative electrode consisting of a platinum spatula or a coil of platinum wire. The current employed should give 300—400 c.c. of detonating gas per hour. Care must be taken to keep the liquid ammoniacal, and after three or four hours the negative electrode is withdrawn, carefully washed, and then treated with a few drops of dilute sulphuric acid, which dissolves the greyish deposit. The solution is evaporated to dryness in a platinum dish with addition of a few drops of cobalt solution and strongly heated; a green residue shows the presence of zinc.

In order to estimate the zinc, the solution of 1 gram of the substance is treated as just described, the negative electrode consisting of a sheet of platinum 3 cm. broad and 4—5 cm. long. After 12 hours the zinc will be completely precipitated, which can be proved by placing a new electrode in the liquid. The negative electrode is rapidly washed by immersing it in water, care being taken not to detach any of the somewhat loosely adhering deposit, and is then immersed in a solution of potash or soda of 8° or 10° B., which dissolves only the zinc. The alkaline solution is again electrolysed, the zinc being deposited as a firmly adherent crust on a weighed platinum cone. The deposit is washed successively with water, alcohol, and ether, and dried at 90—100°. It is advisable to wash with water before interrupting the current.

Lead.—1 gram of the finely powdered substance is placed in a conical flask with 3 or 4 grams of pure cadmium, and very gently warmed with dilute hydrochloric acid. When the solution is complete, and no bubbles of gas are given off from the cadmium, the lead is completely precipitated. The liquor is carefully decanted off, and the residue washed several times by decantation. 5 or 6 c.c. of nitric acid are then added, and the solution of lead and cadmium is transferred to a crucible which acts as the negative electrode, the positive electrode being a weighed platinum cone. Rather less battery power is required than in the case of zinc, and in four or five hours the lead is completely precipitated on the positive electrode in the form of peroxide, which is washed with water, dried, and weighed. This process will detect 0·0005 gram of lead in 1 gram of substance.

C. H. B.

Volumetric Estimation of Iron by means of Sodium Thiosulphate and Salicylate. By G. Bruel (*Compt. rend.*, **97**, 954—955).—It is well known that when solutions of ferric salts are mixed with sodium salicylate a deep violet colour is produced. If sodium thiosulphate is now added to the slightly acidified solution, the iron is converted into a double ferrous sodium thiosulphate, and the colour is discharged. To estimate iron by means of this reaction, dissolve 1 gram of pure iron in 20 c.c. of hydrochloric acid, with addition of potassium chlorate, boil until all chlorine is expelled, and then dilute to 1 litre. Prepare also a solution of sodium thiosulphate containing 1 gram per litre. Take 10 c.c. of the ferric solution, dilute with four times the volume of water, heat to boiling, and add 0·1 gram of sodium salicylate. Then add the thiosulphate solution drop by drop from a burette, until the liquid has only an almost inappreciable rose tint. Having thus standarised the thiosulphate, the total amount of iron in a salt or mineral, or the relative proportions of ferrous and ferric iron in any substance, may be determined in a similar manner. In the latter case the ferric iron is determined in 1 part of the solution after acidifying with hydrochloric acid, and the total iron is estimated after boiling with potassium chlorate and hydrochloric acid. C. H. B.

Detection of Manganese in Presence of Zinc, and of Bismuth in Presence of Lead, by Electrolysis. By A. GUYARD (*Compt. rend.*, **97**, 673—674).—Calamine, zinc slag, &c., is treated with dilute sulphuric acid, the solution allowed to clarify by standing, and then electrolysed, the negative electrode being of copper or brass, and the positive electrode of platinum. In a short time the liquid round the positive electrode is coloured violet by permanganic acid. In testing metallic zinc, the latter is fused in contact with air, and the scum of oxides which forms is treated as above.

When a concentrated solution of pure zinc sulphate is electrolysed, the negative electrode being platinum, and the positive electrode a sheet of commercial lead, the lead becomes gradually covered with a layer of lead dioxide, and any bismuth or copper present in the lead is deposited with the zinc on the negative electrode. On treating the latter with dilute sulphuric acid, the zinc is dissolved and the copper and bismuth are left undissolved, and may be separated by the usual methods. C. H. B.

Detection of Arsenic. By E. REICHARDT (*Arch. Pharm.* [3], **21**, 271—279).—After noticing the occurrence of arsenic in different pigments, &c., and the legal prohibition of the use of arsenical compounds for colouring papers, foods, &c., the author describes Fleck's modification of Marsh's test, which has been recommended for the detection of small quantities of arsenic. While admitting the improvement in this modification, the author does not recommend Marsh's test for general use, but prefers, as simpler and safer, to pass the arsenic hydride through a solution of silver nitrate, which has been rendered strongly acid with pure nitric acid. In this way the tenth of a milligram of arsenious oxide can be detected. Marsh's test, in which an arsenic mirror is obtained, cannot be quantitatively applied, but this process can be at once qualitatively and quantitatively used. After precipitation has ceased, bromine is added to the silver solution, and the arsenic precipitated as magnesium ammonium arsenate.

For further particulars concerning this method see Abstr., 1881, 195. W. R. D.

Determination of Organic Matter in Water. By A. R. LEEDS (*Phil. Mag.* [5], **169**, 13).—In this paper is described a process for the determination of organic matter in potable water, based upon the readiness with which metallic silver is separated from solutions of its salts by organic matter. The details of the process are as follow:—To 250 c.c. of the water to be examined, 100 c.c. of decinormal silver nitrate solution are added, and the mixture allowed to stand for about two days, when the solution will have become clear, the entire precipitate collecting at the bottom. This precipitate is washed first with ammonia, to get rid of the chloride, and then dissolved in nitric acid, the amount of silver being subsequently determined by Pisani's process. On comparison of this with the permanganate process, it was found that sometimes the former, sometimes the latter, gave the higher result; the general inference was deduced from the results that, whilst a solution of potassium permanganate was reduced to a greater or less extent by most organic substances soluble in water, the silver nitrate is the more readily reduced by easily decomposing organic compounds, akin in their nature to sewage. V. H. V.

Prothistological Examination of Potable Waters. By L. MAGGI (*Gazzetta*, **13**, 323).—Cartes has proposed the use of a solution of osmic acid (1·5 : 100) to detect the presence of so-called microbes in potable waters: 1 part of the solution added to 30 or 40 of water kills the organisms, which then settle to the bottom of the vessel, and can be detected by microscopic examination of the deposit. The author, on the supposition that they were killed and rendered invisible from induration produced by the action of the osmic acid, tried other reagents, and obtained satisfactory results with a solution of palladium chloride (1 : 800), and also with hæmatoxylin, methyl-violet, magenta, and Lyons blue. C. E. G.

Petroleum Testing. By F. BEILSTEIN (*Zeits. Anal. Chem.*, **22**, 309—316).—The author has examined the methods of determining the flashing point devised by Abel, Engler, and others. These methods yield concordant results only when the apparatus used is of precisely the same dimensions. The method least open to this objection is that devised by L. Liebermann (Abstr., 1882, 1326) and developed by Stoddard (Abstr., 1883, 517). The author finds that with Stoddard's apparatus the results are concordant, even when the dimensions are different, provided the length of the tube is five, six, or seven times its breadth. The author, by employing a slightly modified form of Stoddard's apparatus, obtained results agreeing within 0·25°, thus securing greater accuracy than with any previously known method of testing. The author further points out the greater importance of testing petroleum by distillation, which not only determines whether the oil is safe or not, but also shows its fitness or unfitness for lighting purposes. By distillation, petroleum may be broken up into three fractions: light oil, boiling under 150°; burning oil (kerosene), boiling at 150—270°; heavy oil, boiling above 270°. The author considers that good mineral oil for lamps should contain less than 5 per cent. of light, and not more than 15 per cent. of heavy oil. A higher percentage of heavy oil in American is much more objectionable than in Russian petroleum, as in the latter the heavy oil is more readily raised by the wick. Thus, a Russian petroleum, with 20 per cent. of heavy oil, was found to be well adapted for lamps. If lamps were constructed with the summit of the wick nearer the surface of the oil, it would be possible to consume petroleum with considerably higher proportions of heavy oil; the price would thereby be reduced, the safety increased, and as the author asserts, the American oil displaced from the European market by the Russian.

P. F. F.

Action of Iodine Pentabromide on Essential Oils. By M. FORNEY (*Arch. Pharm.* [3], **21**, 311).—The action of iodine pentabromide on the principal essential oils was examined in reference to the colour which is produced with the pure oils alone; also when mixed with 25 per cent. of turpentine oil, and when dissolved in 25 per cent. of alcohol (95 per cent.). The results are recorded in a table.

W. R. D.

Alcohol in the Brain in Cases of Inebriation. By H. F. KUIJPER (*Zeits. Anal. Chem.*, **22**, 347—357).—The author describes the detection of alcohol in the stomach, brain, and liver of two persons supposed to have died in a state of inebriation. P. F. F.

Detection of Bordeaux Red in Wine. By C. THOMAS (*Arch. Pharm.* [3], **21**, 304—305).—The colouring matter is absorbed from the wine by silk, which is washed with cold water, and then heated with boiling water, when the artificial colouring matter is dissolved, but the natural colouring matter remains on the silk. In the red liquid so obtained, sulphuric acid develops a violet colour, and ammonia a chestnut-brown. In the estimation of the potassium sulphate by precipitation as barium sulphate, the Bordeaux red is carried down with the precipitate to which it remains attached. When this precipitate is ignited, an aromatic odour resembling naphthalene and nitrobenzene is noticed. W. R. D.

Estimation of Glucose. By P. LAGRANGE (*Compt. rend.*, **97**, 857—858).—The precipitate formed on adding lead acetate to a solution of sugar, carries down with it a considerable proportion of the glucose. An accurate determination of this substance cannot therefore be made in the filtrate from the lead acetate precipitate, but must be made in the original liquid. C. H. B.

Starch Varieties detected by the Swelling Process. By W. H. SYMONS (*Biel. Centr.*, 1883, 571).—The author proposes to use instead of definite temperatures, alkaline solutions of definite strength. The most suitable are caustic soda solutions of 0·5—1·5 per cent. strength; 1 gram of the starch is repeatedly stirred up with 1 c.c. of the particular soda solution, and after ten minutes examined under the microscope. It is then found that with one solution very few granules are swollen; with a stronger solution, the greater part are swollen; and with a more concentrated still, all are swollen. The following table gives the results for various starches:—

	Order of magnitude of the granules.	Few granules swollen with	Greater number of granules swollen with	All granules swollen with

J. T.

Detection of Hydrocyanic Acid. By C. BRAME (*Arch. Pharm.* [3], 21, 307).—The author has noticed that hydrocyanic acid precipitates albumin from solution, and this occurs when the vapour of hydrocyanic acid is passed into a solution of albumin. For the detection of the acid in toxicology where owing to decomposition it cannot be directly recognised, the author proposes to detect the ammonium formate in the liquid after evaporation over sulphuric acid in a vacuum. W. R. D.

Pyroligneous Acid. By G. VULPIUS (*Arch. Pharm.* [3], 21, 256—260).—The author proposes to test the strength of the rectified pyroligneous acid, which is official in the German Pharmacopœia, not only with regard to the amount of acetic acid which it contains, but also in reference to the empyreumatic bodies present. The first is accomplished in the ordinary way with a standard solution of sodium hydroxide, using phenol-phthaleïn as indicator. The author estimates the empyreumatic constituent with a standard solution of potassium permanganate; 10 grams of the acid are diluted to 400 c.c. with water, acidulated with hydrochloric acid, and titrated until the colour of the potassium permanganate is permanent after one minute. A rectified pyroligneous acid should not contain less than 6 per cent. of acetic acid, and should decolorise at least ten times its volume of the standard solution of potassium permanganate recognised by the German Pharmacopœia. It should also become sensibly darker in colour when exposed to sunlight. W. R. D.

Trustworthiness of Berthelot and Fleurieur's Method for the Estimation of Tartaric Acid. By P. FERRARI (*Landw.*

Versuchs.-Stat., **29**, 353—354).—According to Amthor, this method does not answer for plastered wines, as these contain acid potassium sulphate, which on addition of alcohol and ether, is in part thrown down and then titrated as cream of tartar. The author, however, proceeds to show that this is not the case; when a solution of acid potassium sulphate is treated with a mixture of alcohol and ether, neutral potassium sulphate is thrown down, and sulphuric acid is left in solution, a result which does not vitiate the figures obtained by the above method. J. K. C.

Potassium Tartrate in Plastered Wine and Estimation of Tartaric Acid. By P. Pichard (*Bied. Centr.*, 1883, 559).—The diminution in the amount of potassium tartrate contained in wine which has been treated with gypsum in the cask, is ascribed by the author to the fact that the former salt is not in a position to saturate a solution containing a certain amount of potassium sulphate. The precipitation of potassium bitartrate by potassium sulphate is employed by the author to quickly estimate the former salt in wines. Free tartaric acid hinders the estimation through forming bisulphate with simultaneous separation of bitartrate. The method is also not applicable to plastered wine, which always contains free tartaric acid, but good results are obtained with unplastered common wines, which but rarely contain any free tartaric acid. Malic, benzoic, and other acids usually found in wines do not influence the result. J. T.

Detection of Salicylic Acid in Dietetic Substances. (*Arch. Pharm.* [3], **21**, 296.)—Salicylic acid may be detected in liquids by diluting with water and distilling; the distillate is then tested with ferric chloride. When only a small quantity of salicylic acid is present, the first fraction of the distillate contains no salicylic acid, subsequent fractions easily give the reaction. In this way, 0·005 per cent. of the acid can readily be detected. Salicylic acid does not distil with the water if alcohol or tannic acid is present; in the latter case the liquid should be acidulated with dilute sulphuric acid before distillation. Salicylic acid in butter is detected by distilling with water and testing as above. When the volume of the distillate is large, it is made alkaline with ammonia evaporated to dryness, and the residue tested with ferric chloride. The ferric chloride reaction is not obtained in presence of free acids, alkalis, or large quantities of salts.

W. R. D.

Volumetric Method for the Estimation of Fat in Milk. By L. Liebermann (*Zeits. Anal. Chem.*, **22**, 383—390).—50 c.c. of the milk are placed in a glass cylinder and treated with 5 c.c. of a solution of potassium hydroxide (sp. gr. 1·2); 50 c.c. of washed ether are then added and the contents of the cylinder well shaken for two minutes. The liquid is allowed to separate, and then 20 c.c. of the ethereal layer are taken out with a pipette and placed in a small flask (about 50 c.c.), the capacity of which is accurately known. The ether is evaporated on a water-bath, and the flask is then heated for 15 minutes to 100—105°, care being taken to avoid any bubbles forming in the melted butter. The flask is plunged into water at the atmospheric temperature, causing the butter to solidify on the bottom of the flask, which is now nearly filled with a measured quantity of water from a burette, and then exactly filled by delivering the water from a small graduated pipette. The difference between the volume of water required and the capacity of the flask indicates the volume of butter in 20 c.c of the milk. On multiplying by 5, the percentage of fat by volume is obtained, and by means of a table the corresponding percentage by weight can be ascertained. The results agree very closely with those obtained by the ordinary gravimetric methods. P. F. F.

Separation of Morphine in Toxicology. By E. SCHEIBE (*Arch. Pharm.* [3], 21, 290).—The author recommends the following process for the separation of morphine from organic matter. The solid residue is extracted repeatedly with acidulated water, filtered, evaporated to a syrup at 100°, and then extracted with four or five times its volume of alcohol (90 per cent.), and again filtered. The alcoholic liquid is distilled, the residue in the retort filtered, and the filtrate successively extracted with amyl alcohol until colouring matter ceases to be removed. The acid liquid is warmed to 50° or 60°, mixed with an equal volume of amyl alcohol, rendered alkaline with ammonia, and agitated; the amyl alcohol is separated, and the alkaline liquid again extracted with amyl alcohol. The two quantities of amyl alcohol are mixed, then distilled, and the residue extracted by acidulated water with the aid of a gentle heat. After filtering, the acid filtrate, which should be again extracted with amyl alcohol, is mixed with 10 parts of anhydrous ether and 1 part of alcohol, and made alkaline with ammonia. After agitation, the ether-alcohol is run off, and the liquid several times extracted with more of the mixture. The morphine is obtained free from colouring matter on evaporating the ether-alcohol solution. W. R. D.

Determination of Ammonia in Vegetable Juices and Extracts. By E. BOSSHARD (*Zeits. Anal. Chem.*, **22**, 329—347).—The results obtained, both by Schlösing's method of treatment with limewater in the cold and that of distillation with magnesia, are too high if asparagine or glutamine are present, the latter being by far the more objectionable of the two. Tolerably accurate but somewhat low results may be obtained, however, if these amides are first precipitated with mercuric nitrate, and the filtrate, after removal of the excess of mercury by sulphuretted hydrogen, is distilled with magnesia. Satisfactory results are also obtained by acidulating the vegetable extract with hydrochloric or sulphuric acid, and then precipitating the ammonia with phosphotungstic acid. The precipitate is filtered after two hours, washed with more of the phosphotungstic acid solution, then dissolved in hot water, and distilled with magnesia.

P. F. F.

Detection of Asparagine and Glutamine in Vegetable Juices and Extracts. By E. SCHULZE (*Zeits. Anal. Chem.*, **22**, 325—328).—The author has previously shown that glutamine, an amide of glutamic acid, is present in beetroot juice and in the sprouts of gourds (this Journal, 1877, i, 104, and ii, 324), and also that this glutamine is a homologue of asparagine (Abstr., 1883, 658). It may not unnaturally be inferred, therefore, that glutamine is as widely distributed in the vegetable kingdom as asparagine. The two amides may be detected by precipitation with mercuric nitrate. The juice or extract is precipitated first with basic lead acetate and then with mercuric nitrate. If either of the amides is present, the mercuric precipitate when decomposed with sulphuretted hydrogen yields a solution which evolves ammonia when heated with caustic alkalis, and dissolves cupric hydrate to a deep blue solution. Allantoïn would also be precipitated with mercuric nitrate, but would not give the reaction with cupric hydrate, and it is also easily distinguished by being precipitated with silver nitrate and ammonia. In order to prove the presence of asparagine and glutamine in the solution obtained as above, it is necessary to isolate them or their products of decomposition, aspartic and glutamic acids. By neutralising the solution with ammonia and evaporating to a small bulk, the asparagine is readily obtained in the crystalline form, and afterwards by boiling the solution with hydrochloric acid, the glutamine is converted into glutamic acid, of which the lead salt may be prepared by adding basic lead acetate, filtering, and after concentrating the filtrate, precipitating the lead salt by alcohol. P. F. F.

Analysis of Flour. By BALLAND (*Compt. rend.*, **97**, 496—497).—The quantity of gluten obtained from the same flour varies with the mode of operation, and especially with the degree of hydration of the gluten and the amount of washing. The proportion of water of hydration is higher in gluten from soft wheat than in that from hard wheat, and in gluten from fresh paste than in that from paste which has stood for two hours; it is also higher in gluten from old flour. Sodium chloride, ammonium acetate, potassium carbonate, glycerol, and certain other substances, have the power of dehydrating gluten, which loses weight and becomes hard: in contact with a large quantity of water, however, the gluten reabsorbs water, and regains its original weight and properties. On prolonged washing, gluten loses weight, the loss being greater with gluten from soft wheat than with that from hard wheat, with gluten from paste, which has stood two hours than with that from fresh paste, and with gluten from old flour than with that from new flour. Gluten from new flour, if placed in water for 24 hours and then washed, loses about 10 per cent., whilst gluten from old flour loses more than 20 per cent. under the same conditions.

In order to estimate gluten, 50 grams of flour are made into a paste with 20 to 25 grams of water, and allowed to stand 25 minutes. The paste is then divided into two equal portions, from one of which the gluten is extracted immediately, whilst the other is allowed to stand an hour. As soon as the wash-water is clear, the gluten is tightly squeezed and weighed. It is then washed for five minutes more, and again weighed. Four numbers are thus obtained, and the mean of these is taken as the amount of gluten present. C. H. B.

Chloroform-water and Ether in Dialysis. By H. STRUVE (*Bied. Centr.*, 1883, 569).—The author remarks on the defects of parchment-paper, and recommends bladder. Substances containing animal or vegetable albumin are apt to decompose during the long time usually required for dialysis. To prevent this decomposition, the author proposes chloroform-water for the outer liquid, which, on account of its powerful antiseptic properties, hinders decomposition. In long operations, it is also advisable to place some chloroform-water directly with the substance under treatment. The author also recommends ether as the outer fluid with bladder as diaphragm. Fresh bruised malt so treated gave sugar and diastase. Beer-yeast similarly treated gave a solution with strong inverted rotative power, due to sugar; it contained also leucine, tyrosine, phosphoglyceric acid, albumin, and peptone. The residue within the bladder consisted of a thick pap, containing white round bodies which on analysis proved to be pure tyrosine. The yeast dried at 100° had the following composition:—

Albumin	1·29
Invertin	4·19
Extractive matter	51·12
Yeast residue	42·02
Ether residue	1·38

The ether residue remained as crystalline needles, which were not cholesterin. J. T.

Estimation of Chloroform in the Blood of an Anæsthetised Animal. By GRÉHANT and QUINQUAUD (*Compt. rend.*, **97**, 753—755).—96 c.c. of blood are taken from an artery or vein out of contact with the air, and are distilled in a vacuum. Gases are given off at 45°, and liquid passes over at 63°. Almost all the chloroform is given off with the gases, and is removed from the latter by agitating four or five times with successive quantities of water out of contact with the air. The wash water and the distillate are mixed, and the volume carefully noted; 18·7 c.c. of the mixed liquid is heated in a sealed tube at 100° with 1 c.c. of Barreswil's cupro-potassium solution, the air having been expelled by a current of carbonic anhydride. A similar blank experiment is made with the cupro-potassium solution and distilled water, since the latter sometimes exerts a reducing action. If the 1 c.c. of cupro-potassium solution is not completely reduced, a second experiment is made with 18·7 c.c. of the liquid and less than 1 c.c. of the copper solution, and if necessary the experiment is repeated until the amount of the cupro-potassium solution, which is just reduced by the 18·7 c.c. of the liquid to be examined, is ascertained.

The cupro-potassium solution is standardised by means of a solution of 0·5 c.c. of chloroform in 2800 c.c. of distilled water.

A number of experiments show that the blood of an anæsthetised animal contains 1 gram of chloroform in 1800—2181 c.c. of blood, or about 1 gram of chloroform in 2000 c.c. of blood. Other experiments prove that the amount of chloroform necessary to produce insensibility is only very slightly smaller than that which causes death.

C. H. B.

Detection of Blood Stains on Washed Clothes. By C. Husson (*Compt. rend.*, **97**, 955—956).—When the microscope and spectroscope have failed to detect hæmoglobin or hæmatin, it is not advisable to rely on the detection of fibrin, as this process is liable to many serious errors. It may be useful, however, to ascertain whether special pains have been taken to wash the suspected spots. If this is the case, those parts of the fabric will in all probability retain a small quantity of soap, and the object of the examination is to detect this substance. A small portion of the suspected cloth is heated with water on a watch-glass at 40° for about two hours, care being taken to replace the evaporated water. The cloth is then squeezed, and the liquid evaporated drop by drop on a glass slip, and the residue moistened with a drop of a 1 per cent. solution of potassium iodide or chloride. The same piece of fabric is treated on the watch-glass with a small quantity of acetic acid, and the solution is carefully evaporated on the first residue on the glass slip. A cover-glass is now placed over the residue, and glacial acetic acid is introduced between it and the slip, and then heated to boiling. If hæmatin is present, crystals of the hydrochloride will be seen. If soap is present, yellow oily drops of oleic acid, and characteristic needles of margaric acid will be visible. These needles are frequently more or less contorted, and if the amount of soap is considerable, they aggregate, sometimes forming fibrous bundles, which closely resemble fibrin in appearance. It is mainly for this reason that filaments of fibrin alone, without any hæmatin, cannot be regarded as proof of the presence of blood.

If there is sufficient cloth, another portion is boiled with water, filtered, and the solution evaporated to dryness and ignited in a platinum dish. The residue is moistened with water and tested for alkali with litmus-paper. C. H. B.

Separation of Wheat Meal from Rye Meal. By Kjärske (*Arch. Pharm.* [3], **21**, 292).—The meals are first treated with very dilute potash solution and allowed to stand for 24 hours. The liquid is then decanted, the meals shaken with water and allowed to stand for some time. The largest starch granules are formed at the bottom of the vessel, above them a layer of husks and small starch granules, and above those the smallest starch granules. The starch is removed and the husks are submitted to further examination. W. R. D.

Chemical Properties of the Violet Colouring Matter in Ergot and its Detection in Flour. By R. Palm (*Zeits. Anal. Chem.*, **22**, 319—323).—The assumption that the violet colouring matter in ergot is combined with alkaline earths is erroneous, because both aqueous and alcoholic ammonia completely extract this colouring matter from ergot, and from such ammoniacal solutions, the colouring matter is wholly reprecipitated by solutions of alkaline earths. The colouring matter is insoluble in absolute alcohol and ether, but soluble in water and in spirit of 20—50 per cent. It gives a slate-blue precipitate with lead acetate, which becomes rose-red on adding concentrated sulphuric acid. Small proportions of ergot may be detected in flour in the following manner:—The thoroughly dried flour is digested at 30—40° with 10—15 times its weight of alcohol (35—40 per cent. Tralles.), to which a few drops of ammonia have been added. The filtered extract is then completely precipitated with basic lead acetate, collected, and, after being well pressed, digested at a gentle heat with a cold saturated solution of borax. In the presence of ergot, the borax solution assumes a characteristic violet colour; and on adding concentrated sulphuric acid, the colouring matter is precipitated in violet flocks. In this manner, 0·05 per cent. of ergot can be detected in flour. In order to detect ergot in bread, the latter is dried, pulverised, and gently heated for 5—10 minutes with 10—15 times its weight of alcohol (40 per cent.). The solution after being filtered through charcoal is evaporated nearly to dryness on the water-bath, and the residue again extracted with alcohol (40 per cent.). The extract is again filtered through charcoal and then completely precipitated with normal or basic lead acetate. The quantity of precipitate serves as an indication of the proportion of ergot in the bread. Ordinary ergot yields on an average 8 per cent. of such a precipitate. By this process the author could not detect less than 1 per cent. of ergot with certainty. P. F. F.

Estimation of Copaiba Balsam. By H. HAGER (*Arch. Pharm.* [3], 21, 289).—The Maracaibo balsam, which is official in Germany, should yield a clear solution when mixed with 1½ volumes of alcohol of 90 per cent. Turbidity may indicate the presence of resin oil, colophony, gurgun balsam, or fixed oil. If the solution remains clear, it should be further diluted with about 1 volume of alcohol. This liquid should be very turbid; if it is only slightly so, castor-oil or turpentine-oil is present. Sassafras-oil cannot be detected in this way. W. R. D.

Technical Chemistry.

Gases Occluded by Coke. By F. H. STORER and D. S. LEWIS (*Amer. Chem. J.*, 4, 409—426).—The only satisfactory method of obtaining the gases occluded by porous substances is by heating in the vacuum produced by means of a Sprengel pump. Reichardt's method (*Jahresb.*, 1866, 53) does not yield good results, and in particular appears to extract the occluded nitrogen with much greater readiness than the carbonic anhydride, the figures for the latter always showing an enormous deficiency in comparison with those obtained by means of the Sprengel pump. It was found, in general, to be impossible to get rid of all the entangled air which clung to the coke, either by immersion in water or by subjection to a current of nitrogen. Numerous analyses are given. The figures quoted below give the results of heating at 200° in a vacuum, after previous treatment with a current of pure nitrogen and exhaustion at the ordinary temperature.

A. Air-dried coke from dwelling house. B. Air-dried coke from store house. C. Old coke from a heap that had been exposed to the weather for three years or more.

	A.	B.	C.
Carbonic anhydride	51·46	74·51	60·78

A. J. G.

Glacialin. By Besana (*Arch. Pharm.* [3], **21**, 296).—This substance, which is used as an antiseptic, consists of 18 parts of boric acid, 9 parts of borax, 9 parts of sugar, and 6 parts of glycerol. Another antiseptic called *Glacialin-salt* is entirely boric acid.

W. R. D.

Extraction of Perfumes and Essential Oils. By L. Naudin (*Pharm. Journ.* [3], **14**, 44—48).—This paper contains an account of the various processes which have been proposed for the extraction of perfumes and essential oils from plants, and the disadvantages which accompany their use. The author describes in detail a process which he has successfully applied for the isolation of perfumes in a great state of purity. The plants, &c., are extracted in a vacuum by solvents of very low boiling point, such as butane, pentane, methyl and ethyl chlorides, and light petroleum, without the aid of heat. A diagram of the apparatus employed is given in the paper. The perfumes obtained in this way are not contaminated by any foreign odour, and are not liable to spontaneous alteration, because they are not associated with other constituents of the plants which in decomposing destroy the characteristic odour.

By the use of a mixture of butane and pentane, the author has been able to obtain the distinctive odour from roasted coffee, and also from different kinds of tea, toasted bread, human skin, &c. The time of day at which a flower is collected has an appreciable influence on the perfume which is subsequently obtained: thus, the pink only yields its perfume when collected two or three hours after exposure to sunlight, and false acacia gives a different perfume when gathered in the morning, midday, or evening. The author considers that in many essential oils the hydrocarbon is not the source of the perfume, neither is the fat of many aromatic fatty oils, but that these substances hold in solution a minute quantity of some highly odorous compound which has not yet been isolated.

W. R. D.

Formic Acid in Rum. By E. List (*Arch. Pharm.* [3], **21**, 290).—The author has tested different specimens of rum by neutralising with soda, evaporating to dryness, dissolving the residue in water, and then distilling under diminished pressure, after acidifying with dilute sulphuric acid. The distillate powerfully reduced silver nitrate solution, from which it is inferred that formic acid was present in the rum, having been produced during the fermentation of the cane-sugar molasses.

W. R. D.

Colour Mordants for Wood. (*Dingl. polyt. J.*, **249**, 143.)—Godeffroy criticises the erroneous statements found in books concerning wood mordants, and recommends the following process for obtaining a red colour on wood:—A solution of potassium thiocyanate is prepared and the wood immersed therein, after which it is dried and painted with a solution of a ferric salt. Potassium ferrocyanide and cupric sulphate or uranium acetate give brown tints. D. B.

Novelties in Calico Printing. (*Dingl. polyt. J.*, **249**, 35—37.)—In the *Bulletin de Rouen*, 1882, 577, Blondel discusses the use of bismuth sulphide in calico printing. Naquet's patents for the application of this substance in dyeing hair are published in the *Moniteur Scientifique* (September, 1882). On account of its high price, bismuth is of but little use in dyeing and printing. Naquet's solution is colourless; the bleached cotton steeped therein and subsequently dried at 25° to 30° gradually developes a light chestnut-brown colour, which, when steamed, changes to chocolate brown. By treating the steamed fabric with a weak solution of sodium thiosulphate, a still darker shade is produced. These colours resist extreme soaping. Naquet uses the following mixture:—100 parts bismuth, 280 nitric acid, 75 tartaric acid, 0·06 ammonia, and 75 sodium thiosulphate.

Balanche prepares a manganese brown in the following manner:—He found that by mixing a solution of potassium dichromate with manganous chloride, no precipitate is obtained; whilst by substituting the normal salt for the dichromate a copious precipitate is formed. Based on this reaction, a printing colour was prepared, which consists of a mixture of potassium dichromate, manganous chloride, and sodium acetate. On warming the solution, the sodium acetate suffers decomposition, the dichromate is neutralised, and the above-mentioned precipitate formed on the fibre. The following proportions are used:—180 grams of potassium dichromate, 850 water, 150 wheaten starch, 210 manganous chloride, and 210 sodium acetate solution (16° B). After steaming, a dark-brown colour is obtained, which resists soaps and does not attack the fibre. D. B.

Incombustible Paper and Colours. By G. Meyer (*Chem. News*, **48**, 164).—Samples of the author's incombustible paper, printed with his incombustible colours, were submitted to the heat of a muffle furnace and to an air-gas burner; the colours retained their brilliancy, and the paper its flexibility, suffering but a slight alteration of texture. D. A. L.

Preparation of Waterproof Materials. (*Dingl. polyt. J.*, **249**, 143.)—Hitherto it has been the practice to pass the tissues after treatment with linseed oil or similar oils over press cylinders. York proposes to use scraping knives, the result being the removal of all superfluous oil, without, however, expressing the oil within the pores of the tissues. D. B.

Preparation of Artificial Stone. (*Dingl. polyt. J.*, **249**, 142.)—For rendering stone impervious to water, Michelet and Tescher propose to treat artificially dried or burnt stone, consisting of caustic lime and clay, with tar, asphalte, or similar substances, according to the process described by Berkel for obtaining hard and weatherproof stone.

For the preparation of blocks for artificial stone and stucco, Poestges mixes gypsum with sand and lime slaked with alum water, and moistens the dry powder with glue solution and acetic acid. No sand is used when the blocks are employed for stucco. The latter can be painted with oil colours. When these are not to be used, a coating, obtained by mixing concrete mortar with dilute acetic acid, is laid on. For colouring walls evenly, the paint is made up with dilute acetic acid and sulphuric acid, which causes the colour to penetrate more deeply.

Arnold recommends to prepare bricks filled with coal-ash in the following manner:—The plastic clay is formed into the shape of a box, into the interior of which a measured quantity of ash is introduced, and the whole covered with a layer of clay. A few air-holes are made into the bricks, so that on heating the unburnt parts of the coal-ash burn away.

For the preparation of artificial grindstone, flooring slabs, &c., Simon and Petit fuse together a mixture of asphalt, sulphur, and gumlac, and add a certain amount of mineral powder. The mass is then formed into blocks by subjecting it to hydraulic pressure.

Borchert presses plastic letters and numbers out of tripoli mixed with borax and alum, after which the letters are boiled in linseed varnish and dried.

For the purpose of manufacturing porous grindstones of porcelain, according to Buchholz and Neddermann, cork cuttings are dried thoroughly and ground. They are then soaked in water, which causes them to swell strongly, and mixed with the porcelain clay. As it dries, the cork shrivels up, so that on burning irregularly formed pores are left which impart to the stone a good grinding surface.

D. B.

Refining of Shellac. By E. L. Andés (*Arch. Pharm.* [3], 21, 291).—The crude shellac is refined in the following way:—1½ kilos. of soda are dissolved in 45 litres of water contained in a small boiler or kettle; 5 kilos. of the crude shellac are added in small quantities at a time. This turbid solution has the characteristic odour of shellac and a violet-red colour. The liquid is boiled for a few minutes, and, while hot, a wooden air-tight cover is cemented on the vessel. When the liquid is quite cold, the cover is removed, and the thin cake of fat which is found on the surface is separated. The solution is filtered through linen, the clear filtrate slowly decomposed with dilute sulphuric acid, and the resulting shellac washed with water until no acid reaction remains. The washed resin is now pressed and melted in boiling water, when it can be shaped with the fingers. This shellac is cooled in water containing glycerol, and, when hard, is dried. The refined shellac forms yellowish-white glistening tufts or bars which, when dry, are yellowish-brown; it should entirely dissolve in alcohol.

General and Physical Chemistry.

Absorption Spectrum of Blood in the Violet and Ultra-violet. By J. L. Soret (*Compt. rend.*, **97**, 1269—1270).—With a layer of 10 mm. of a 0·1 per cent. solution of blood, the absorption band in the violet is very distinct, and occupies about half the interval between G and H, its centre being at *h*. The ultra-violet rays are not absorbed. With a 0·166 per cent. solution the band fills the entire space between G and H, and the region beyond H is darkened; and with a 0·25 per cent. solution the band extends beyond both G and H, and there is considerable absorption in the ultra-violet. The band in the violet extends as far as the magnesium line $\lambda = 383$; there is a maximum of transparence at Cd 9, then a band at Cd 12, probably due to hæmaglobin, a maximum of transparence at the magnesium line $\lambda = 309$; then another band, evidently due to serum, at Cd 17, and another maximum of transparence at Cd 18, beyond which the absorption gradually increases to the end of the spectrum. The numerical results, however, vary considerably with different samples of blood.

When blood is treated with carbonic oxide, the band in the violet is slightly displaced towards the more refrangible end, and there is less absorption in the ultra-violet than with a solution of oxygenated blood of the same strength. In the ultra-violet the magnesium line $\lambda =$ 383 undergoes less absorption, and the succeeding band is also slightly displaced towards the more refrangible end. C. H. B.

Crossed Dispersion of several Rhombic Substances. By G. Wyrouboff (*Jahrb. f. Min.*, 1884, 1, Ref., 4—6).—From the optical examination of a large number of rhombic bodies, the author found in $(K,NH_4)C_4O_6 + 4H_2O$ and in the sodium ammonium sulphate and chromate, $(Na,NH_4)SO_4 + 2H_2O$ and $(Na,NH_4)CrO_4 + 2H_2O$, optical anomalies similar to those observed by Des-Cloizeaux and Mallard (*Jahrb. f. Min.*, 1883, 1, 358) in prehnite, which he explains in the same way, although pseudo-symmetrical axes for these salts could not be fully established. B. H. B.

Chemical Action of Light: Decomposition of Oxalic Acid by Ferric Chloride. By G. Lemoine (*Compt. rend.*, **97**, 1208—1212).—Solutions of ferric chloride and oxalic acid containing a gram-molecule of the respective substances per litre were mixed in different proportions and exposed to light under comparable conditions, the carbonic anhydride which was given off being collected over glycerol and measured. Decomposition takes place in accordance with the equation $Fe_2Cl_6 + H_2C_2O_4 = 2FeCl_2 + 2HCl + 2CO_2$ (Marchand; Jodin). The rate at which decomposition takes place depends on the intensity of the light. For a given intensity, it is at first almost uniform, but when about half the total quantity of carbonic anhydride has been given off, the rate of decomposition gradually diminishes. The greater the volume of the liquid, the longer of course is the time before decomposition slackens. When the two solutions are separately exposed to light for several hours and then mixed, decomposition takes place more rapidly than if the solutions had not been previously insolated. Other conditions being equal, dilution with water increases the rate of change, an effect which may be due either to the partial decomposition of the ferric chloride by the water, or to a diminution in the absorptive effect of the ferric chloride due to dilution. When ferric chloride is in excess, less gas is given off than when the two substances are present in equivalent proportions: a similar effect is produced by adding ferrous chloride to the mixed solution. An excess of oxalic acid exerts an effect similar to that produced by dilution.

Water exerts little or no absorptive effect on the waves which bring about the reaction, but a screen of ferric chloride solution almost entirely prevents the decomposition. C. H. B.

Electrochemical Energy of Light. By F. Griveaux (*Compt. rend.*, **97**, 1123—1125).—The author has investigated the effect of variations in the different conditions on the electromotive force developed by the action of light. His results will be published subsequently. C. H. B.

Position of Amalgams of Zinc and Cadmium in Electropotential Series. By W. L. Robb (*Wied. Ann.*, **20**, 798—814).—The researches of Poggendorff have established that the amalgams of zinc, tin, and lead in a sulphuric acid cell are electropositive to the non-amalgamed metal. On the other hand, the amalgams of iron and cadmium under the same conditions are electronegative to the pure metal. Henrici, on further study of this phenomenon, was led to attribute it to some secondary reaction.

This memoir contains a detailed account of some experiments on the electric relation between zinc or cadmium, and their respective amalgams, when introduced into dilute acids or solutions of salts of these metals. The E.M.F. set up was measured by Du Bois-Reymond's modification of Poggendorff's compensation method, a Daniell's cell being used as the constant. Chemically pure zinc was obtained by an electrolytic deposition on a stick of wax, which was subsequently removed. The zinc sulphate into which the plates of pure and amalgamed metal was introduced was kept neutral by the presence of zinc carbonate. The results of the experiments show that amalgamated and pure zinc, in zinc sulphate solution, only give a difference of potential equal to $\frac{1}{1000}$ Daniell, and if the solution be kept perfectly neutral, this difference becomes infinitesimally small. But amalgamated zinc is electropositive to the pure metal when immersed in dilute acids, although this result is principally to be attributed to the formation of the salt of the metal on the surface of the zinc plate.

In the case of cadmium the amalgamated metal is electro-negative to the pure metal in cadmium sulphate solution; the difference of potential, immediately after the amalgamation, is about 0 05 Daniell, but it diminishes with the time of contact, until a certain limit is reached. V. H. V.

Difference of Potential of the Electric Layers of Two Liquids which are in Contact. By E. BICHAT and R. BLONDLOT (*Compt. rend.*, **97**, 1293—1295).—The authors determine the electrical differences between two liquids, by determining the difference between each of them and a standard liquid consisting of a solution of 1 part of sodium sulphate in 24 parts of water. The electrical differences between liquids are much more constant than those between two metals, or between a metal and a liquid. This is probably due to the fact that liquids do not, like solids, retain modifications of structure caused by external forces. It would seem that the differences between two liquids are not affected by variations of temperature much greater than those which take place in an ordinary laboratory. C. H. B.

Electrochemical Researches on Nitrogen. By G. S. JOHNSON (*Chem. News*, **48**, 253—257 and 264—268).—The author confirms the results of Thénard and of Berthelot as to the formation of ammonium nitrite by the action of the silent discharge on nitrogen gas in presence of aqueous vapour. He is of opinion that to render the nitrogen *active*, the gas must be perfectly dry and the electricity of high tension. The author has tried various experiments with nitrogen and hydrogen; with nitrogen, hydrogen, and oxygen; and with hydrogen and air in the Grove's gas battery. The effect of the silent discharge on tubes of nitrogen in the gas battery circuit has also been studied, when the nitrogen is found to combine completely with hydrogen in proportion of 1 vol. to 3 vols. These results and others in which currents were observed between nitrogenised and hydrogenised platinised plates, the nitrogen in the platinised plates existing apparently in an electronegative condition, are brought forward by the author as evidence of the duality of nitrogen. Other conclusions arrived at are that nitrogen and hydrogen can generate currents in Grove's gas battery which are inversely proportional to the internal resistance. The hydrogen always contracts, but if the external resistance is great, and the internal small, the volume of the nitrogen increases, but there is no combination between the nitrogen and hydrogen. When the internal and external resistance is reduced to a minimum, combination takes place, and the hydrogen contracts much more rapidly than the nitrogen expands. Ammonia has been found in the acid over which air and hydrogen, and nitrogen and hydrogen have been observed to contract. D. A. L.

Production of very Low Temperatures. By L. CAILLETET (*Compt. rend.*, **97**, 1115—1117).—The production of low temperatures by allowing a jet of liquid ethylene to play upon the object to be cooled, necessitates the use of large quantities of liquid ethylene, and can only be carried on discontinuously. The author has therefore constructed an apparatus by means of which very low temperatures can be maintained for any length of time, the same ethylene being used over and over again. It consists of a copper tube bent in the form of a helix, and enclosed in a steel cylinder, beyond which the ends of the tube project. Two tubes communicate with the inside of the cylinder and are attached to it by screw-nuts. One of these tubes is connected with the exhaust valve of the author's pump, by means of which an almost perfect vacuum can be obtained; the other is connected with a reservoir containing liquid ethylene condensed by the pump and cooled by means of methyl chloride. The liquid ethylene issues from the second tube through a stopcock of special construction, expands into the vacuum, and is removed through the first tube to the pump, by which it is again condensed and sent back through the apparatus. The substance to be cooled is contained in the copper helix enclosed in the cylinder. By means of this apparatus the author hopes to obtain large quantities of liquid oxygen, and then to use this liquid oxygen for the condensation of hydrogen.

C. H. B.

Heats of Formation of Lead Oxychlorides and Oxybromides. By G. André (*Compt. rend.*, **97**, 1302—1303).—The oxychlorides and oxybromides were obtained by precipitating a solution of the haloïd salt with the requisite amount of potassium hydroxide. The precipitates were completely dried, and then treated in a calorimeter with hydrochloric acid saturated with lead chloride, or hydrobromic acid saturated with lead bromide, as the case might be. The results were as follows:—

PbO	anhydrous	+ $PbCl_2$	anhydrous,	develops	+ 6·52 cal.
2PbO	„	+ $PbCl_2$	„	„	+ 9·24 „
3PbO	„	+ $PbCl_2$	„	„	+ 10·60 „
PbO	„	+ $PbBr_2$	„	„	+ 4·00 „
2PbO	„	+ $PbBr_2$	„	„	+ 6·06 „
3PbO	„	+ $PbBr_2$	„	„	+ 8·40 „

The addition of each equivalent of lead oxide develops approximately 2 cals.

C. H. B.

Melting Points of Nitrates. By E. Maumené (*Compt. rend.*, **97**, 1215—1218. See also this vol., p. 3).—Barium nitrate is decomposed when heated alone, but it can be fused with sodium nitrate without undergoing decomposition. If the two salts are mixed in equivalent proportions, there is no considerable reduction of the melting point, but when they are present in equal proportions the mixture solidifies at 322—288°, whereas the calculated melting point is 374°, that of barium nitrate being assumed to be 450°.

Lead nitrate can also be fused with an equal weight of sodium nitrate without undergoing decomposition, the fused mass forming a very transparent liquid. This mixture solidifies at 282°, the calculated melting point being 374°, that of lead nitrate being taken as 450°. A mixture of equal weights of lead, sodium, and potassium nitrates melts to a liquid which is not so transparent as the mixture of lead and sodium nitrate only. It solidifies at 259°, the calculated melting point being 358°.

Ammonium nitrate when heated alone melts at 153°, and solidifies at 135°; it begins to decompose at 212° under a pressure of 760 mm

If, however, a mixture of sodium and potassium nitrates in equal or equivalent proportions is fused and a quantity of ammonium nitrate equal to that of either of the other nitrates is thrown into it, the ammonium nitrate melts without decomposition, and the mixture forms a limpid, very transparent liquid, which deposits crystals at 144°, but appears to have a definite melting point at 136—137°, the calculated melting point being 259°. Even when the quantity of ammonium nitrate is equal to that of the other two salts together, fusion still takes place readily, and the mixture has a very definite melting point at 122°, the calculated temperature being 233°. If equal weights of sodium and ammonium nitrates are finely powdered and intimately mixed, and thrown in small quantities at a time into a heated crucible, the mixture melts to an almost transparent liquid without any decomposition or evolution of any vapours of the ammonium salt. The liquid deposits crystals at 135°, but appears to have a definite melting point at 114·5°, the calculated temperature being 225·5°. This mixture may be used as a bath for temperatures about 120—125°; vapours of ammonium nitrate are not given off below 200°. A mixture of equal weights of potassium and ammonium nitrates does not melt quite so readily. If the salts are not very finely powdered, there is a loss of 5—10 per cent. of ammonium nitrate. This mixture melts at about 230°, the calculated temperature being 240°.

Manganese nitrate is easily decomposed when heated alone, but can be fused without decomposition in a mixture of sodium and ammonium nitrates. The mixture of the three salts may be heated to 140° without any manganese dioxide being formed. The fused mass cools to 76° without completely solidifying, and if the manganese nitrate is perfectly dry, it remains liquid even at 15°.

Strontium nitrate can in a similar manner be fused with its own weight of a mixture of sodium and potassium nitrates without alteration. The fused mixture solidifies between 295° and 214°. In the process of fusion, a small quantity of oxygen is given off, but no nitrogen oxides are evolved, and the weight of the salts is not diminished.

It is evident that oil-baths can be conveniently replaced by mixtures of alkaline and other nitrates. C. H. B.

Note by Abstractor.—Veley (Trans., 1883, p. 374) gives the melting point of ammonium nitrate as 159°, and the point at which decomposition begins as 186°.—C. H. B.

Pressure of Mercury Vapour at Ordinary Temperatures. By H. McLeod (*Chem. News*, **48**, 251).—The vapour-tension of mercury at 20° C. is given by Hagen (*Ann. Phys. Chem.* [2], **16**, 610) as 0·021 mm., by Hertz (*ibid.*, **17**, 193) as 0·0013, and now by the author as 0·00574 mm. In one of the author's experiments, a glass tube, 14 mm. diameter, filled with freshly distilled mercury, was suspended in a flask, 1·9 litre capacity, which was covered with a greased glass plate, and exposed to the ordinary temperature for nine days. A small quantity of boiling nitric acid was then poured in, which after some time was neutralised with ammonia, acidified with hydrochloric acid, and treated with hydrogen sulphide. The brown coloration thus produced was compared with a standard, from which the mercury vapour present in the flask was assumed to be 0·00009 gram. In another experiment a tube of 24 mm. diameter was employed, and after exposure for a month, the mercury found was 0·00012 gram; which calculated out gives the above tension (0·00574 mm.). D. A. L.

Molecular Volume of Liquid Substances. By R. Schiff (*Annalen*, **220**, 278—334).—In a previous paper (Abstr., 1883, 1044), the author gave the results of the determinations of the molecular volumes of a number of liquids. The present communication is chiefly taken up with the discussion of the conclusions to be drawn from these results.

In the first place, the author calls attention to the considerable differences between his observed numbers and those calculated by Kopp, and points out that these differences are due to the fact that when Kopp published his researches, little was known of the isomerism of chemical bodies and of its influence on their physical properties. Kopp's atomic constants were therefore the *means* of his various experimental numbers, whereas the author now shows that although the atomic volumes of the elements are constant for similarly constituted compounds (*i.e.*, members of a homologous series, &c.), those of multivalent elements vary when the mode of combination differs (*i.e.*, between isomeric compounds, and series, &c.).

In his comparison of results, the author uses the terms normal and secondary, with the usual meaning in the fatty series, but in the aromatic, he calls those bodies normal which contain only *one* side chain, secondary those with *two* side chains, &c. In the fatty series, the normal hydrocarbons—which have a higher boiling point—show a smaller density and higher molecular volume than the corresponding secondary compounds. In the aromatic series, the normal hydrocarbons—with a lower boiling point—show a greater density and smaller molecular volume than the secondary. The author therefore concludes that to get satisfactory results, normal compounds of the fatty series must be compared with secondary aromatic bodies and secondary fatty bodies with normal aromatic. Acting on this plan, the vol. C_2 = vol. H_4 in comparable bodies. As the result of a comparison of alkyl salts of the fatty acids, the author concludes that "The molecular volumes of isomeric and analogously constituted ethers are greater the smaller the number of carbon-atoms in the acid-radical, and the greater that number is in the alcohol-radical." This result combined with Linnemann's similar deduction in regard to boiling points, may be expressed as follows:—"Of isomeric bodies composed of carbon and hydrogen, or of carbon, hydrogen, and oxygen, the one possessing the highest boiling point has also the greatest molecular volume."

On comparing the three compounds—

1. Diisobutyl, C_8H_{18} .... Vol. = 184·5
2. Caprylene, C_8H_{16} .... Vol. = 177·22
3. Ethyl-benzene, C_8H_{10} .... Vol. = 138·95,

we have between 1 and 2 a difference of 2H, between 1 and 3 of 8H. The difference in vol. between 1 and 3 is 45·55 for 8H, and if the difference were regular, the vol. of 2 should be 173·12 or 4·08 less than found. Similarly with the three compounds—

1. Normal hexane, C_6H_{14} .... Vol. = 139·7
2. Diallyl, C_6H_{10}............ Vol. = 125·82
3. Benzene, C_6H_6 .... Vol. = 95·94

the observed vol. of 2 is 8·00 greater than the number as calculated from 1 and 3 should be. But in the first instance (caprylene) we have *one* double-linking, in the second (diallyl) *two*, and in all other similar cases the presence of a double-linking always raises the molecular volume about 4. From these results the author is led to believe that the so-called double-linking in unsaturated and in aromatic compounds cannot be of a similar nature. He is inclined to consider this fact as an argument against Kekulé's formula for benzene, and in favour of the formula .

From the fact that the unsaturated compounds occupy a larger relative molecular volume than the saturated, he contends with Brühl that the linking in the former case is not so much a *double* as a *looser* linking than that in the latter, and that ethylene for instance would be more accurately represented by the formula CH_2——CH_2 than by the formula $CH_2 \vdots CH_2$. The same is the case with oxygen. When oxygen is linked to one atom of carbon only (in aldehydes, &c.), it has a much larger molecular volume than when it is linked to two carbon-atoms or one carbon- and one hydrogen-atom; and he therefore supports the formulæ CH_3—CH——O and  $\overset{\displaystyle CH_3}{\underset{|}{}}\!\!\!\!\!\!\!\! HO{-}C{-\!\!-\!\!-}O$ for acetaldehyde and acetic acid respectively. The actual value of C seems to vary between 8 and 13, of O between 5·6 and 19. Hydrogen has a constant volume 5·6.

In conclusion, the author gives the following as a very brief summary of the most important results of his work :—

1. The specific volumes of carbon and oxygen are variable, their variation depending on that of the linking of the atoms.

2. The presence of a so-called double-linking always increases the molecular volume. This increase is 4 units for each double-linking.

3. The benzene-ring cannot contain any so-called double-linkings.

4. There are no double-linkings. Where they have hitherto been thought to exist, the linking is looser than in other cases; or in other words, a greater space exists between two atoms thus said to be doubly-linked, than in the normal state.

The following additional experimental results have been obtained since the last communication :—

Ether, Et_2O	106·24
Propyl formate, $H.COOPr$	108·73
Isobutyl propionate, $Et.COOBu^\beta$	173·54
Methyl butyrate, $Pr.COOMe$	126·35
Methyl isobutyrate, $Pr^\beta COOMe$	126·43
Propyl butyrate, $PrCOOPr$	173·85
Propyl isobutyrate, $Pr^\beta COOPr$	174·20
Isobutyl butyrate, $PrCOOBu^\beta$	197·66
Isobutyl isobutyrate, $Pr^\beta COOBu^\beta$	198·20
Methyl valerate, $BuCOOMe$	148·32
Ethyl valerate, $BuCOOEt$	172·99
Propyl valerate, $BuCOOPr$	196·82

Dissociation of Ammonium Carbonate in Presence of an Excess of one of its Elements. By ISAMBERT (*Compt. rend.*, **97**, 1212—1215).—The author has determined the tensions of mixtures of ammonium carbamate with varying proportions of carbonic anhydride or ammonia at temperatures ranging between 34° and 52·6°, and finds a close agreement between the observed pressures and those calculated from the known excess of carbonic anhydride or ammonia on the assumption that the ammonium carbonate decomposes at the moment of volatilisation (compare Abstr., 1882, 269). C. H. B.

Inorganic Chemistry.

Specific Gravity of Liquid Oxygen. By S. v. WROBLEWSKI (*Wied. Ann.*, **20**, 860—870).—Dumas, on the occasion of the liquefaction of oxygen by Pictet, recalled his supposition that the sp gr. of liquid oxygen was unity; for on theoretical considerations oxygen and sulphur must possess equal atomic volumes, and therefore their sp. grs. in the liquid state will be in the ratio 1 : 2.

Pictet deduced from his experiments the values ·9883 and ·9787, but Offret subsequently pointed out errors in the calculation which would reduce the value to ·84. However, much confidence cannot be placed in this value, for Pictet had assumed that Gay-Lussac's law held good between the wide limits of temperature + 485 and −130; moreover, it would be difficult, under the conditions of the experiment, precisely to fix the temperature of the liquefying tube, and the exact volume filled by the liquefied gas.

In order to re-determine the value for the sp. gr. of liquid oxygen, the author has made use of his apparatus, which has been described at length in a former memoir. The method is as follows:—The capillary tube of the apparatus is filled up to a certain mark with oxygen, condensed at −130°.

Then the quantity of oxygen taken $Q_1 = v_1 d_1 + q_1$ (1) in which formula v_1 and d_1 are the volume and density of the liquid oxygen, and q the quantity remaining gaseous. If then the tube be filled up to the same mark with carbonic anhydride or nitrous oxide liquefied at 0°, then $Q_2 = v_2d_2 + q_2$ (2).

If equation (1) be divided by (2) and all referred to d_1, then

$$d_1 = d_2\frac{v_2Q_1}{v_1Q_2} + \frac{q_2Q_1 - q_1Q_2}{v_1Q_2};$$

but for practical purposes the latter fraction may be neglected, so that

$$d_1 = d_2\frac{v_2Q_1}{v_1Q_2}.$$

The mean value of twelve concordant experiments was found to be ·899 at a temperature of −130° C (this vol., p. 14), and the pressure of liquefaction. But Dumas in answer has suggested that the liquefied gas has a large coefficient of expansion, and if it were possible to cool the oxygen still further, the value of its sp. gr. would more nearly approximate unity. Further criticisms of Pictet are also met and discussed. V. H. V.

Solidification of Superfused Sulphur. By D. GERNEZ (*Compt. rend.*, 97, 1298—1301; 1366—1369; and 1433—1435).—Octohedral sulphur, crystallised from carbon bisulphide, was dried at 95° for 24 hours, placed in a graduated U-tube not more than 2 mm. in diameter, heated to fusion at a constant temperature T, during a time $\mathfrak{T}$; then immersed in a bath at a temperature t below the melting point of sulphur. It remains in a superfused condition, and after the expiration of a time $\mathfrak{T}'$, a crystal of prismatic or octohedral sulphur, as the case might be, was dropped down the U-tube. As soon as the crystal touches the surface of the liquid, the latter begins to solidify, and the time, S, required for solidification to extend through a constant distance (10 mm.) in the limb of the tube was observed.

For constant values of T, $\mathfrak{T}$, t, and $\mathfrak{T}'$, the time required for solidification is proportional to the distance through which solidification extends, in other words, S is a constant. Other conditions being equal, S depends on t, and is greater the nearer t approaches the melting point of sulphur. The value of S also depends on the values of T, $\mathfrak{T}$, and $\mathfrak{T}'$ respectively. The higher the value of $\mathfrak{T}$, *i.e.*, the longer the time during which the sulphur is kept in a state of fusion at the temperature T, the higher is the value of S. In one experiment S increased 8·5 times when $\mathfrak{T}$ was increased seven times, and in another S increased 11·58 times when $\mathfrak{T}$ was increased twelve times. It follows that S is very nearly proportional to $\mathfrak{T}$. Variations in S caused by variations in $\mathfrak{T}'$, the time during which the sulphur remains superfused, are very small when T is but slightly higher than the melting point of sulphur, but become very considerable when T exceeds 170°. In one series of experiments when T = 219°, $\mathfrak{T}$ = 5 minutes, t = 101°, the following values were obtained:—

$\mathfrak{T}'$	0 hr. 15 mins.	3 hr. 15 mins.	4 hr. 45 mins.
S	23·04 seconds.	9·12 seconds.	7·70 seconds.

beyond which the value of S remained sensibly constant. Other conditions being the same, the time of solidification depends on the initial temperature T. When $\mathfrak{T} = 5$ minutes, $t = 100·3°$, and $\mathfrak{T}' =$ 15 minutes, the values of S for certain values of T are as follows:—

T =	129·5°	139·0°	142·5°	154·5°	160·5°	164·5°	167·5°	173·5°.
S =	0·50″	0·59″	0·70″	1·93″	5·70″	10·61″	18·08″	25·59″

T =	177°	181°	189°	204°	219°	243°	274°	350°	440°.
S =	24·98″	21·65″	21·41″	21·66″	21·43″	19·41″	18·07″	17·0″	16·06″.

There is a sudden alteration in the value of S when T passes from 167·5° to 173·5°.* At this last temperature, S attains a maximum, and beyond this point it very slowly diminishes as T approaches the boiling point of sulphur.

These values all refer to octohedral sulphur which is fused for the first time. If the process of fusion and solidification in prisms is repeated several times, the value of S increases, and after eight successive operations it becomes more than twelve times its original amount. In other words, the superfused liquid yields prisms more slowly when it has been formed by the fusion of prismatic sulphur that when it has been formed by the fusion of octohedral sulphur, and the time of solidification is longer the more frequently the sulphur has been solidified in the prismatic form. If, however, the sulphur is allowed to cool for some time between each successive operation, this effect is much less marked, and if the interval extends to several days, the values of S obtained at each operation are sensibly the same.

All these variations in the time of solidification of the prisms are evidently connected with changes in the specific heat of the liquid sulphur and in the heat of solidification of the prisms. The liquid sulphur at a constant temperature undergoes some modification, which depends on the duration of the action of heat, and it is evident that when the temperature of the sulphur is raised, the sulphur undergoes alterations which require time for their completion, and which do not disappear entirely until some time after the liquid has been brought to its original condition. It would seem as if the liquid in the first phase of the operation absorbed heat, which it only partially gives up in the second phase.

Solidification of Octohedral Sulphur.—The octohedral crystal dropped into the superfused sulphur must be very small, since the cooling effect produced by a large crystal results in the formation of prisms. In every case, the solidification of the sulphur in octohedra is very much slower than its solidification in prisms. The time of solidification (S) varies with T, $\mathfrak{T}$, t, and $\mathfrak{T}'$ as in the case of the formation of prisms. The effect of variations in $\mathfrak{T}'$ is very small, but variations in $\mathfrak{T}$ and T produce a much greater effect than in the first case. The value of S attains its maximum, 274 minutes, when T = 188°, but beyond this point it decreases more rapidly than in the case of the prismatic form.

---

* *Note by Abstractor.*—Between 167·5° and 173·5° the difference is 7·51 seconds for 6°, whereas between 164·5° and 167·5° it is 7·47 seconds for only 3°.—C. H. B.

It is noticeable that in the case of both the octohedral and prismatic varieties, the sulphur, at about 170°, experiences an alteration which persists whilst superfusion continues, but that if the initial temperature is much higher than 170°, although the sulphur has to cool down through this point, it solidifies almost as rapidly as if it had only been heated slightly above the melting point.

When the process of fusion and solidification in octohedra is repeated several times, the value of S increases, and after three successive operations becomes nearly twice its original amount, but beyond this point it remains sensibly constant, whilst in the case of the prismatic form successive fusions continually diminish the tendency to solidify.

Octohedral sulphur is repeatedly fused in a **U**-tube and caused to solidify in octohedra until it attains the condition of equilibrium represented by a constant value of S. It is then brought into a state of superfusion, and the liquid in one limb is caused to solidify in octohedra; that in the other in prisms. The tube is then heated for five minutes at 129·5°, kept in superfusion at 100·5° for eight minutes, and then the sulphur in *both* limbs is caused to solidify in octohedra, and this experiment is repeated three times. In one case, the successive values of S in the limb which had always remained in the octohedral condition were 2 mins. 20 secs., 2 mins. 20 secs., and 2 mins. 13 secs., whilst the corresponding values in the limb which had been once solidified in prisms were 7 mins. 22 secs., 2 mins. 40 secs., and 2 mins. 20 secs. It is evident that sulphur which has once been converted into the prismatic form yields octohedra much less readily than sulphur which has always retained the octohedral form, and it requires several successive fusions and solidifications to bring it into the condition of equilibrium previously mentioned. This effect is still more marked if the sulphur has been solidified in prisms several times. With respect to the octohedra, the prisms play a part opposite to that which the former play with respect to the prisms, since the formation of the prisms is most rapid in the liquid formed by the fusion of octohedra.

The stable condition into which the octohedral variety is brought by successive fusions and solidifications persists for a long time, whilst the prismatic form after similar treatment, gradually returns to its original condition. This is explained by the fact that the prismatic sulphur gradually devitrifies and passes into the octohedral variety.

The phenomena accompanying the solidification of sulphur are much more complicated than in the case of phosphorus, the difference being probably due to the fact that amorphous phosphorus is insoluble in the fused ordinary variety, whereas the different modifications of sulphur remain mixed together in the fused substance. It is important to note that 170°, the temperature which produces the maximum value of S, is the temperature which, according to Berthelot, produces the maximum quantity of sulphur insoluble in carbon bisulphide.

C. H. B.

Red Sulphur of Japan. By E. Divers and T. Shimidzu (*Chem. News*, **48**, 284).—There is an orange-red variety of sulphur found apparently in all the deposits of volcanic sulphur in Japan. It is known in the native vocabulary by a name equivalent to "massive-red-sulphur;" a specimen contained:—

Te.	Se.	As.	Mo.	Earthy matter.	Sulphur (by diff.)	
0·17	0·06	0·01	trace	trace	99·76	= 100·00.

When treated with carbon bisulphide, the arsenic remains behind as sulphide. The yellow sulphur usually associated with the red sometimes contains traces of tellurium and selenium. The two sulphurs are strikingly different in colour. D. A. L.

Lead-chamber Deposit from Japanese Sulphuric Acid. By E. DIVERS and M. SHIMOSÉ (*Chem. News*, **48**, 283).—The interest of the present paper is derived from the fact that volcanic sulphur only is employed in the Japanese works. The deposit examined came from the lead chambers as a mud; it settled down to a yellow supernatant liquid and a grey-red deposit, with many bright-yellow particles; this sediment, on elutriation, sorted itself into lead sulphate at the bottom, particles of ash and particles of sulphur next, and red particles of impure selenium at the top. The liquor was impure H_2SO_4, sp. gr. 1·15, and contained ferric sulphate and 0·37 gram tellurium and 0·15 gram selenium per litre. The sediment drained on a filter and sun-dried contained:—

Se.	Te.	S (free).	As.	Hg (free).	Cu.	Mo.
10·5	1·2	6·5	doubtful	0·016	trace	trace

PbSO$_4$.	Ash.	$H_2O.H_2S$, organic matter, and $Se_2(SO_4)_3$ [very little].	
29·5	24·5	27·8	= 100·016

The proportions of the selenium and tellurium in the acid liquor and sediment are reversed, which is due to the moist finely divided tellurium, particularly in presence of acid, oxidising more rapidly than selenium. The mercury could be extracted with nitric acid, but not with potassium cyanide solution; it was therefore considered to be uncombined. Many samples of sulphur have been examined for mercury, but this metal has never been detected. This is probably the first time molybdenum has been found in a lead-chamber deposit; it was also detected in the burner-ash. On distilling the sediment, water, sulphurous anhydride, impure sulphur, selenium, tellurium, and selenious oxide passed over, whilst crystalline galena was found among the other fixed matters in the retort. The authors have many gallons of the mud; it is therefore an average and not a special sample. D. A. L.

Preparation of Oxychloride of Phosphorus from Phosphates. By A. OGLIALORO (*Gazzetta*, **13**, 323).—The author points out that Riban's method of preparing phosphorus oxychloride by passing chlorine and carbonic oxide over heated tricalcium phosphate (Abstr., 1883, 287) was described five years ago by Paternò (*Gazzetta*, 8, 233). C. E. G.

Reduction of Metallic Solutions by means of Gases, &c. By G. Gore (*Chem. News*, 48, 295).—A mixture of carbonic oxide and carbonic anhydride gases, passed slowly through various liquids, had the following effects. Palladium dichloride is rapidly decolorised, and all the metal is precipitated as a black powder. Platinum tetrachloride is slowly decomposed, and yields a small amount of a yellow precipitate in two or three days. In potassium iridium chloride the iridium is precipitated after some time. Lime-water contained in a leaden vessel becomes coated with a film of red oxide of lead. Silver nitrate, mercuric chloride, lead nitrate, ferric chloride, manganous chloride, potassium permanganate, chromic acid, and vanadic compounds showed no signs of reduction. A mixture of hydrogen and carbonic anhydride, also pure hydrogen, reduced a dilute solution of palladium dichloride when exposed to it, the palladium being precipitated in 24 hours. The following solutions were kept in contact with coal-gas: they each had a platinum wire immersed in them, and were in a dark place. In palladic chloride, the metal is speedily reduced, and the liquid becomes colourless in a few days. Gold chloride is also reduced, and in the course of a few days bright films of the metal float on the surface and then sink; the liquid is not wholly decomposed in three weeks. Solid gold chloride is also gradually reduced to metal. Platinic chloride only slightly decomposes in ten weeks. With silver nitrate, the decomposition starts in a few hours, but is not complete in seven weeks. Copper sulphate and ferric sulphate are not reduced. A gaseous mixture containing acetylene rapidly decomposed palladic chloride; gold chloride less quickly; platinic chloride but slightly, and potassium iridium chloride not at all. Palladic chloride, gold chloride, and platinic chloride are reduced, more or less rapidly, by amylene, petroleum, benzene, naphtha, light petroleum, mesitylene, and other similar liquids. Bright metallic films are formed between the liquids by light petroleum with palladic chloride, and by amylene with gold chloride. Paraffin and naphthalene reduce gold chloride, but not palladic chloride, whilst ozokerite acts on neither. Gold chloride is also reduced by the chlorides C_2Cl_2, C_2Cl_4, C_2Cl_6, and CCl_4. Benzene decolorises a solution of potassium iridium chloride in two days, whilst amylene produces no visible effect in that time. Amylene slowly precipitates mercuric chloride solution, acts rapidly on permanganate, but does not alter cupric chloride, ferric chloride, chromic acid, or its potassium salt. Benzene reduces permanganate, but not ferric chloride. Naphtha, &c., produces only a slight change in solutions of telluric, antimonious, or bismuth chloride. It is suggested that metals, found in the earth as such, may owe their origin to contact with hydrocarbons derived from organic mineral substances.

Behaviour of Silver Chloride, Bromide, and Iodide with Bromine and Iodine. By P. Julius (*Chem. News*, 48, 284).—By passing dry air saturated with bromine over silver iodide kept in a state of fusion, the iodide is easily and completely converted into bromide after 10 minutes. In the same manner silver chloride can be converted into bromide in 1 or 2 hours. Further experiments prove that both chlorine and bromine may be expelled from their silver compounds by means of iodine vapour, although 6 to 10 hours are required to effect this change with the chloride. Hence any halogen, if supplied in excess, can expel any other halogen from its combination with silver; at least as far as chlorine, bromine, and iodine are concerned.

D. A. L.

Recovery of Barium and Strontium Compounds. By F. MUCK (*Dingl. polyt. J*, **250**, 91).—For the separation of barium and strontium from mixtures of their chlorides and the chlorides of sodium, calcium, magnesium, &c., the concentrated liquor is treated with a hot saturated solution of salt. Thus all the chlorides, with the exception of the sodium chloride contained in the mother-liquor, are dissolved. The salt solution is used over and over again until it is sufficiently saturated, when on cooling a mixture of barium and strontium chlorides crystallises out. By treating a cold saturated solution of these chlorides with twice the volume of hydrochloric acid, barium chloride is precipitated.

D. B.

Cadmium Iodide. By F. W. CLARKE and E. A. KEBLER (*Chem. News*, **48**, 297—298).—The suggestion that the series of elements are developed progressively like series of compounds, such as hydrocarbons, is as yet supported only by the periodic law. Another support is now put forward under the form of isomerism, for the higher we go in a series of hydrocarbons the more frequent are the cases of isomerism; and so it is shown, that the chlorides and bromides are less prone to form isomerides than the iodides. The authors now bring forward a new example of allotropy of iodides in the form of cadmium iodide. By heating together equivalent quantities of cadmium and iodine in a sealed tube exhausted of air, or by digesting these elements under water, or by treating cadmium carbonate with hydriodic acid, or by dissolving together equivalent quantities of cadmium sulphate and potassium iodide, evaporating to dryness, extracting with alcohol and crystallising, a cadmium iodide, CdI_2, is obtained, which is white, and undergoes no change at any temperature below 250°, and has a sp. gr. 5·644. By dissolving cadmium carbonate in hydriodic acid and decolorising by cadmium clippings, or by dissolving cadmium in hydriodic acid, a brownish CdI_2, sp. gr. 4·626, is obtained, which, when heated at 50°, loses weight, and is gradually transformed into the other variety.

Unsuccessful attempts were made to prepare cadmium-lead, and cadmium-thallium iodides. Mercuric iodide dissolves freely in hot solutions of cadmium iodide, and the mother-liquor from the first crop of crystals (mercuric iodide), on standing, deposits golden laminæ, which can be recrystallised from alcohol. They are anhydrous, and a partial analysis points to the formula $CdI_2,3HgI_2$. There was not sufficient substance for further investigation. The authors have prepared zinc iodide from its elements, and found sp. gr. 4·666 (Bödeker found 4·696). They are now working on stannic iodide, and have found two modifications, one darker and less soluble in benzene than the other. D. A. L.

Atomic Weight of Aluminium. By H. BAUBIGNY (*Compt. rend.*, **97**, 1369—1371).—The sulphates of the sesquioxides are perfectly stable at 440°, and some of them, aluminium and chromium sulphates, for example, obstinately retain traces of free sulphuric acid even at this temperature.

Ammonia-alum was repeatedly crystallised, calcined until completely decomposed, the residue washed with water to remove traces of alkalis, calcined to remove organic matter, and dissolved in dilute sulphuric acid. The aluminium sulphate was twice crystallised, and then dried at 440° for a long time. Even when repeatedly powdered and heated at this temperature in a vacuum in presence of fused potash, the last traces of free acid are not expelled. If, however, the dried salt is dissolved in water and precipitated by alcohol and then carefully dried, it is obtained free from any excess of acid. The sulphate is then carefully converted into oxide by ignition. The mean result was Al = 27·016 if S = 32, and Al = 27·064 if S = 32 074. Mallet found Al = 27·02. C. H. B.

Atomic Weight of Titanium. By T. E. THORPE (*Chem. News*, **48**, 251).—After some remarks on the slight experimental basis on which the greater proportion of the accepted values of the atomic weights depend, the author draws attention to the element in question. Its atomic weight was found by Rose to be 48·13 and 49 58, by Pierre 50·25; whilst Mendelejeff has adopted 48. In the present paper the author reports the results of his deduction of the atomic weight of titanium from analyses of the tetrachloride. Three independent values have been obtained based on the ratios:—(1.) $TiCl_4 : 4Ag$. (2.) $TiCl_4 : 4AgCl$. (3.) $TiCl_4 : TiO_2$. Value (1) was obtained by decomposing weighed quantities of the tetrachloride with water, and precipitating the chlorine with silver by Stas's modification of Gay-Lussac's method, the mean of 8 experiments giving Ti (H = 1) = 48·021. Value (2) by treating weighed quantities of the tetrachloride, decomposed with water, with excess of silver nitrate, &c., the mean of 5 experiments giving Ti (H = 1) = 48·018. Value (3) by decomposing the tetrachloride with water, evaporating the solution to dryness and strongly heating the resulting oxide, &c., gave Ti (H = 1) = 47·970. The mean of these three values is 48·003. But if the value of Ti is calculated more accurately from the aggregate weights of the tetrachloride, silver, silver chloride, and titanium oxide respectively, 48·014 is obtained for value (1), 48·016 for (2), and 47·969 for (3), and the mean is 48·000. From these observations, it would appear that the atomic weight of titanium is a simple multiple of that of hydrogen. The author is making similar observations with the tetrabromide and dioxide. D. A. L.

Vanadates and Phosphates of the Alkali-metals. By C. RAMMELSBERG (*Wied. Ann.*, **20**, 928—948).—This paper contains an account of the methods of preparation of the various vanadates of the alkali-metals. The results obtained are compared with those of Norblad, whose original memoir was published in Upsala, and thus has not been widely disseminated.

With the alkali-metals, vanadic acid forms a series of salts represented by the following formulæ, in which M is a monatomic metal:—

Basic vanadates........	$M'_4V_2O_9$.	
	M_3VO_4,	Orthovanadate.
	$M_4V_2O_7$,	Pyrovanadate.
Neutral	$M'VO_3$,	Metavanadate.
Acid..................,	$M_2V_4O_{11}$,	Tetravanadate.
	MV_3O_8	Hexvandate.

Others of intermediate composition have also been isolated, such as some of the ammonium compounds described at length in this memoir. $(NH_4)_4V_{10}O_{27}10 + H_2O$, obtained by adding acetic acid to an aqueous solution of the neutral salts until a permanent red coloration is produced, forms red crystals belonging to the quadratic system, and consisting of two prisms with a regular octohedron. $(NH_4)_3V_7O_{19} + 2H_2O$, obtained from the above acetic acid solution, is a sparingly soluble golden amorphous salt.

Potassium pyrovanadate, $K_4V_2O_7$, crystallises out when an alkaline solution of the orthovanadate is concentrated to a small bulk. On adding acetic acid to the mother-liquor from this salt, and evaporating the solution, delicate crystals of a salt of the composition $K_{10}V_8O_{25} + 7H_2O$ separate out. Similarly on the addition of acetic acid to a solution of the metavanadate, a brownish-red crystalline precipitate, $K_4V_6O_{17} + 2H_2O$, is produced; but in the case of the ortho-salt, there is formed a red compound of composition $K_2V_4O_{11}$, crystallising in rhombic prisms.

Sodium pyrovanadate, $Na_4V_2O_7$, described also by Roscoe and Norblad, crystallises in tablets belonging to the hexagonal system, optically uniaxial, and giving well-defined interference bands. On the addition of acetic acid to a solution of this salt, a deep red coloration is produced, and on evaporation large red dodecahedral crystals of the composition $Na_4V_6O_{17} + 16H_2O$ separate out. These quickly effloresce in the air, to form a brighter coloured powder.

Lithium orthovanadate, Li_3VO_4, obtained by heating 3 mols. of lithium carbonate and 1 mol. vanadic acid, is a golden powder, insoluble in water; if lithium nitrate is substituted, there is produced lithium pyrovanadate, $Li_4V_2O_7 + 7H_2O$, which forms white ill-defined crystals. On the addition of a trace of nitric acid to the orthovanadate, white crystals are produced of a salt, $Li_6V_4O_{13} + 15H_2O$, sparingly soluble in water. If 1 mol. lithium carbonate and 1 mol. vanadic acid are melted together and the fusion dissolved in water, there separates from the solution the golden crystalline metavanadate, $LiVO_3 + 2H_2O$, moderately soluble in water. If acetic acid be added to a solution of this salt, a red coloration is produced from the formation of a compound $Li_{10}V_{12}O_{35} + 30H_2O$. From the orthovanadate, on acidification, a salt, $Li_6V_8O_{23} + 12H_2O$, is produced, crystallising in red dodecahedra.

A brief description of other salts, $Li_4V_6O_{17} + 15H_2O$, $Li_6V_8O_{23} + 12H_2O$, $Li_3V_5O_{14} + 12H_2O$, is also given.

In the course of the preparation of the lithium salts from the carbonate and vanadic acid, the formation of a black insoluble residue was observed. This dissolves in dilute acids, and is reprecipitated by ammonia; it consists of an oxide, V_4O_9, briefly described by Berzelius, but not further investigated.

If a solution of sodium pyrophosphate be acidified with acetic acid and then evaporated, large transparent crystals of sodium dihydrogen pyrophosphate separate out.

On prolonged heating of thallium dihydrogen orthophosphate, thallium dihydrogen pyrophosphate, $H_2Tl_2P_2O_7$, is produced, which forms a readily soluble crystalline mass; its solution gives a white precipitate with silver nitrate. V. H. V.

Chromic Hydrogen Selenite. By C. TAQUET (*Compt. rend*, **97**, 1435). — Chromic hydrogen selenite is obtained by the regulated action of nitric acid on the normal selenite. It forms irregular plates, smaller and of a deeper green colour than those of the corresponding iron compound. It is almost insoluble in water, but is soluble in acids. When heated it decomposes, at first into normal selenite and selenious acid, and finally into chromium sesquioxide and selenious acid. C. H. B.

Uranium Nitrate or Acetate from Residues. By J. T. SAVORY (*Chem. News*, **48**, 251).—The washed uranium or uranium ammonium phosphate is dried, powdered, and ignited. The resulting phosphate is boiled with pure strong nitric acid, and, while on the water-bath, the solution is treated with coarsely granulated tin, in quantities equal to half the weight of the phosphate. When the action ceases, the mass is evaporated to dryness, gently heated on a sand-bath, and then broken up and boiled out with successive portions of dilute nitric acid (1 to 4), leaving to settle, and filtering after each treatment. The solution of uranium nitrate is concentrated and crystallised. Uranium acetate is prepared by gently igniting the nitrate and dissolving the oxide produced in warm acetic acid, filtering and crystallising. D. A. L.

Oxides of Manganese. By O. T. CHRISTENSEN (*J. pr. Chem.* [2], **28**, 1—37).—The examination is one concerning the two oxides Mn_2O_3 and Mn_3O_4. It is well known that braunite, Mn_2O_3, differs in crystalline form from the other oxides R_2O_3, as also does hausmannite, Mn_3O_4, from the oxides R_3O_4, and on account of this difference these two oxides of manganese have been expressed by other formulæ, viz., MnO,MnO_2 and $2MnO,MnO_2$, which are capable of explaining certain anomalies, and receive strong confirmation from the observations of Forchhammer, Berthier, and Turner, that when treated with dilute hydrochloric or sulphuric acids, or with nitric acid, they are decomposed into their constituents of which the manganous oxide goes into solution, while the manganese dioxide remains undissolved. Manganic oxide was prepared from the dioxide by ignition in a current of oxygen, the dioxide being prepared from manganous nitrate. The pure manganic oxide, treated with boiling dilute nitric acid (17 per cent.), or boiling dilute sulphuric acid (1 vol. H_2SO_4 to 9 vols. H_2O), is decomposed in such a way that exactly one half of the manganese goes into solution, the other half remaining as the dioxide. From 100 parts of the manganic oxide containing 69·35 parts of manganese were obtained residues containing respectively 34·63, 34·58, and 34·62 of manganese. But there are reasons why these oxides should be expressed as Mn_2O_3 and Mn_3O_4, and not as MnO,MnO_2 and $2MnO,Mn_2O_3$. A similar behaviour is shown by cuprous oxide, which, by the action of hydrochloric acid, yields cupric chloride and metallic copper. With oxygen and chlorine, iron has no tendency to form such compounds as FeO_2 and $FeCl_4$. But in combination with sulphur it is otherwise; here FeS_2 corresponds to MnO_2, and the sulphide Fe_2S_3 is decomposed by acids, giving rise to the production of a ferrous salt and FeS_2. Again, the hydrate, $Mn_2O_3.H_2O$, may be compared both in constitution and behaviour with acids to oxalic acid, the first yielding the monoxide and dioxide of manganese and water when treated with HNO_3 of 30—40 per cent., the latter monoxide and dioxide of carbon and water on treatment with strong sulphuric acid. Thus it is evident that the behaviour of manganic oxide with acids is not a proof of the correctness of the formula MnO,MnO_2.

Manganic oxide treated with acetic acid of from 15 to 65 per cent. was scarcely acted on, only 1—1·3 per cent. being dissolved. Manganoso-manganic oxide is acted on by dilute acetic acid of 30 per cent. as though it were $2MnO,MnO_2$, approximately one-third remaining undissolved; but with stronger acid less, and with glacial acetic acid only 1·6 per cent. of manganese goes into solution. The acid solutions in the last case were of a brown colour, the insoluble residue was found to be pure Mn_3O_4, and hence the dissolved portion contained manganese and oxygen in the ratio 3 : 4. The above manganoso-manganic oxide had been ignited; a sample of the hydrated oxide prepared by Moissan's method was more readily acted on, and gave a brown solution which, on standing, deposited a crystalline deposit; this was found to have the composition $Mn_3O_6\overline{Ac}_6 + 4H_2O$, and is therefore the normal manganic acetate. Thus, by treatment with acetic acid, manganoso-manganic oxide (hydrated) yields manganic acetate which crystallises out, and manganous acetate which remains in solution. Strong sulphuric acid acts in a similar manner, manganous and manganic sulphates being formed *without* evolution of oxygen. Thus whilst with dilute acids Mn_3O_4 behaves as $2MnO,MnO_2$, with strong acids it behaves as MnO,Mn_2O_3.

The author then proceeds to show that manganic oxide really belongs to the group of sesquioxides, and that it forms salts resembling the ferric salts.

II. *Manganic acetate* is obtained by the action at the ordinary temperatures of 200 c.c. glacial acetic acid on 5 grams of the air-dried oxide. After about eight days, the whole is heated and filtered; on adding 2 c.c. of water to the filtrate and allowing it to remain for some time, it deposits the salt in brown crystals. The crystals are soluble in hot glacial acetic acid; the solution, and also the dry salt, are decomposed by excess of water, and they afford a number of characteristic reactions. When it is mixed with strong sulphuric acid, and water is added gradually, a deep red solution is obtained, which deposits Fremy's salt, $MnO,MnO_2.4SO_3 + 9H_2O$. Heated to a red heat, it leaves manganic oxide. The analytical numbers agree with the formula $Mn_2O_6\overline{Ac}_6 + 4H_2O$.

Manganic phosphate is formed by decomposing the acetate with phosphoric acid, but more conveniently by adding a concentrated solution of manganous oxide in nitric acid to a hot aqueous solution of phosphoric acid. The salt soon begins to form, with evolution of nitrous fumes; it is washed with water and dried at 100°. It is a greenish-grey powder. It is scarcely acted on by dilute acids; strong sulphuric acid converts it into the sulphate. Analyses show it to be $Mn_2O_6(PO)_2 + 2H_2O$.

Manganic arsenate is prepared similarly to the phosphate. It is a rather dark grey powder. Analyses show it to be $Mn_2O_6(AsO)_2 + 2H_2O$.

Manganic sodium pyrophosphate.—By mixing a solution of the acetate in glacial acetic acid, with sodium pyrophosphate solution, the salt is deposited as a red crystalline precipitate. It is also prepared by treating manganic oxide with concentrated hydrochloric acid, and filtering this solution into a solution of sodium pyrophosphate in large excess. The salt is dried at the ordinary temperature. It easily loses its water of crystallisation. Manganese dioxide may also be used for this preparation, and this supports the statement (Pickering) that when treated with hydrochloric acid the dioxide does not yield the tetra- but the sesqui-chloride. From analyses the formula $Mn_2Na_2(P_2O_7)_2 + 10H_2O$ is deduced; it therefore resembles the corresponding iron salt, and belongs to the series of salts examined by Jörgensen and Wallroth. From these experiments, it is evident that the salts described are in reality manganic salts and analogous to the ferric salts, that is, they contain the hexavalent double atom Mn_2; the author would regard Fremy's sulphate as an acid salt, viz., $Mn_2H_2(SO_4)_4 + 8H_2O$.

III. Manganese dioxide is slowly converted into the sesquioxide when heated, then into manganoso-manganic oxide, and finally into manganous oxide. That the formation of this last oxide is not due to the action of reducing gases is shown by the same results being obtained when the crucible lid, provided with an outlet tube, is cemented on. At high temperatures therefore the monoxide is the most stable of the manganese oxides; but nevertheless under other conditions there is a great tendency for manganese to behave, not as a dyad but as a tetrad element when combined with oxygen. Thus when manganoso-manganic oxide, prepared by gently heating the dioxide in hydrogen, is heated in the air it absorbs oxygen, and when boiled with an ammonium chloride solution a small quantity of manganous chloride is formed.

The manganoso-manganic oxide prepared by Otto's method also absorbs oxygen; even below 100° and at 300° it is oxidised further than to the sesquioxide. Otto states that the oxide is not decomposed by boiling with ammonium chloride solution, but from the author's experiments it is seen that this preparation always contains more oxygen than it should do; if, however, the boiling with ammonium chloride solution be not repeated, but performed only once, then the excess of oxygen contained is very small. This pure preparation is acted on by ammonium chloride solution. H. B.

Phosphides of Iridium and Platinum. By F. W. CLARKE and O. T. JOSLIN (*Chem. News*, **48**, 285).—Iridium for pen-points is prepared from iridosmin, by heating the ore to whiteness and throwing phosphorus upon it; fusion takes place at once, and the excess of phosphorus is removed by subsequent treatment with lime. Iridosmin was found to contain 15·38 per cent. osmium. The "fused iridium" gave on analysis: Ir, 80·82; Os, 6·95; P, 7 09; Ru and Rh, 7·20 per cent.; three other determinations of phosphorus yield an average of 7·61 per cent. The fused iridium appears to be a phosphide of the formula Ir_2P, which would require 7·43 per cent. of phosphorus. The sample analysed is impure, owing to the impurities in the iridosmin. When 15·42 grams platinum were heated to whiteness, and 20 grams ordinary phosphorus thrown upon it, fusion at once took place, and when the excess of phosphorus was burnt off a bright silver-white button was obtained, weighing 19 4663 grams. From this synthesis the numbers following are obtained:—Pt 79·21 and P 20·79 per cent.

A portion of this phosphide—about 71·21 per cent.—is soluble in aqua regia, the insoluble portion can be dissolved by fusion with sodium nitrate and caustic soda, and subsequently boiling with aqua regia; on analysis it proved to be a definite phosphide of the formula PtP, whilst the soluble portion agreed approximately with the formula PtP_2. By re-calculating the analysis of the two separate portions, so as to express the composition of the original phosphide, the following results are obtained:—

	Found analysis.	Found synthesis.	Calculated for Pt_3P_5
Pt	79·39	79·21	79·05
P	20·87	20·79	20·95
	100·26	100·00	100·00

The ratio between the soluble and insoluble phosphides agrees well with the equation $Pt_3P_5 = PtP + 2PtP_2$, especially if some allowance is made, as the boiling with aqua regia was rather prolonged, and therefore some of the PtP was most likely dissolved as well as the PtP_2.

When the Pt_3P_5 is heated in a muffle until the weight is constant, the product is malleable, and readily soluble in aqua regia. It contains 7·36 per cent. of phosphorus, the exact amount required by Pt_2P, this then is the fourth platinum phosphide, and is analogous in composition to the "fused iridium." Some platinum phosphides have been prepared before, but have never been regularly analysed. D. A. L.

A Compound of Rhodium. By H. DEBRAY (*Compt. rend.*, **97**, 1333—1335).—When finely divided rhodium is fused with 20 or 30 times its weight of iron pyrites, a regulus is obtained, which on treatment with hydrochloric acid, leaves a residue of blackish scales with a semi-metallic appearance. This substance whilst moist dissolves completely in dilute nitric acid, forming a highly coloured solution; but if dried it undergoes some alteration and becomes insoluble in dilute nitric acid, but is soluble in strong nitric acid if the drying has not been effected at too high a temperature. When dried at 100° in air or in a vacuum, it contains 9·6 per cent. of water and 8·6 per cent. of oxygen, which form an essential part of its constitution. Water and sulphurous anhydride are given off on heating, and a residue is left which consists of rhodium sulphide containing a trace of iron, and is insoluble in aqua regia. The composition of the black substance may be represented by the empirical formula

$$(RhS)_2,SO_2,H_2O.$$

It is evident that the action of iron pyrites on rhodium at a high temperature can give rise only to the formation of rhodium sulphide, and it follows that the new compound is formed when the regulus is treated with hydrochloric acid. It would seem as if rhodium sesquisulphide was oxidised and hydrated, thus: $Rh_2S_3 + O_2 + H_2O = (RhS)_2.SO_2.H_2O$. A similar reaction takes place when dilute nitric acid acts on lead holding a small quantity of rhodium in solution. A finely divided black residue is obtained, which contains rhodium, lead, and about 15 per cent. of nitrous compounds. This substance decomposes with explosion when heated, giving off nitrogen oxides, and it is readily soluble in warm concentrated sulphuric acid, which does not attack rhodium.

The nitric acid solution of the new compound does not contain rhodium sulphate alone. Part of the sulphur is not precipitated by a barium salt, and only a portion of the rhodium is reduced by formic acid.

It seems probable that the amorphous substances previously obtained in a similar manner from other platinum metals have a similar composition.

Mineralogical Chemistry.

Iron containing Nickel from Sanarka, in the Ural Mountains. By C. Grewingk (*Jahrb. f. Min.*, 1884, 1, Ref., 29—30).—In the gold stream-work near Troizk, a piece of iron weighing 3·5 grams has been found. It is possibly of meteoric origin. It is of a steel-grey colour. H. = 4—5; sp. gr, 7·83. It is entirely soluble in hydrochloric acid, and contains about 2 per cent. of nickel.
B. H. B.

Action of Fused Magmas on Various Minerals. By C. Doelter and E. Hussak (*Jahrb. f. Min.*, 1884, 1, Mem., 18—44).—These researches were undertaken to imitate and, if possible, to throw some light on the various contact phenomena brought about by the action of magmas in a state of igneous fusion. The minerals which were subjected to the action of a fused magma were :—olivine, pyroxene, hornblende, biotite, felspar, quartz, garnet, dichroite and zircon. Finely powdered basalt, andesite, or phonolite, was fused in a porcelain crucible, and the above-mentioned minerals were dipped into the molten mass, and subjected for some time to its action. In several cases the minerals were placed in the powdered rock and fused. No alteration of the porcelain crucible took place.

Pyroxene, when subjected to the action of a fused magma, dissolves at the edges, or is converted into a fibrous or granular aggregate. The conversion into augite crystals, which is observed when bronzite is subjected to the action of fused phonolite, seems to be due not to the heat alone, but also to chemical action. Fused monoclinic augite separates out from the magma in the same state as before, whilst rhombic augite often separates out as monoclinic augite.

Hornblende.—Where the magma has acted on the hornblende, solution of the edges occurs. This so-called opacite edge may be observed in many younger eruptive rocks. If the action be greater, a more or less perfect change of the hornblende into augite takes place. It is remarkable that where the fusion with the magma is imperfect, the form of the hornblende remains unchanged, but on examination under the microscope, it is found to consist of an aggregate of small augite columns and magnetite. Similar "pseudo-crystals" of augite and magnetite after hornblende frequently occur in basaltic rocks, but up to the present time have never been regarded as being caused by contact action.

Olivine.—The author's experiments confirm the view of Roth and Rosenbusch that olivine was the first mineral that separated out of the basaltic magma.

Garnet is altered by fusion in basaltic magmas; these alterations are of two kinds. In one case a new formation of minerals was not observed : the alteration being confined to a peculiar cloudiness, suggestive of Schrauf's kelyphite, granulation and slight formation of opacite. In other cases chemical changes undoubtedly take place; spinel crystals and green augite occurring as products of the alteration.

B. H. B.

Mineralogical Notes. By A. Brun (*Jahrb. f. Min.*, 1884, **1**, Ref., 23—24).—1. *Perowskite* from Rympfischwäng near Zermatt :

TiO_2.	FeO.	CaO.	Total.	Sp. gr.
59·39	0·91	39·80	100·10	3·974

2. *Desmine* from the Viesch Glacier :

SiO_2.	Al_2O_3.	CaO.	H_2O.	Total.
57·44	15·43	8·71	18·03	99·61

3. *Albite* from the moraine of the "Glacier de Trelatete" (Mt. Blanc) :

SiO_2.	Al_2O_3.	Na_2O.	Total.
68·57	19·67	11·90	100·14

4. *Orthoclase* from the protogine-gneiss of Mt. Blanc:

SiO_2.	Al_2O_3.	CaO.	K_2O.	Na_2O.	FeO.	Total.
66·02	19·48	0·88	7·84	5·60	trace	99·82

5. *Ripidolite* from Mt. Blanc:

SiO_2.	Al_2O_3.	FeO.	MgO.	H_2O.	Total.
26·60	18·02	29·67	15·85	9·98	100·12

6. *Pinite* from Auvergne. A number of water determinations were made (1·99; 2·46; 2·75; 3·48 per cent. H_2O) showing that the percentage of this constituent increases with the decomposition of the dichroite and its decrease in hardness.

7. *Borocalcite* from Chile. After the removal of Na_2SO_4 and NaCl by washing with water, the residue gave:—

CaO.	Na_2O.	H_2O.	B_2O_3.	Total.
14·69	1·87	34·95	(48·49)	100·00

from which the formula, $3Na_2B_4O_7 + 9Ca_3B_{14}O_{23} + 19H_2O$, is deduced. B. H. B.

Corrosion Faces of Fluorspar. By F. J. P. v. Calker (*Jahrb. f. Min.*, 1884, 1, Ref., 7—8).—The specimens examined came from Brienz (Switzerland). They were aggregates of sea-green crystals of the combination $\infty O\infty . \infty On$; the faces, however, were all greatly corroded. The corroded planes formed small four-sided depressions with their lateral edges parallel with the combination edges of $\infty O\infty$, O. The corrosion plane was determined to be $\frac{7}{2}O\frac{7}{2}$. Larger depressions also occur which exhibit the form $\infty O\frac{7}{2}$. B. H. B.

A Peculiar Kernel Structure in Fluorspar. By F. J. P. v. Calker (*Jahrb. f. Min.*, 1884, 1, Ref., 7).—On the cubical faces of small violet crystals of fluorspar ($\infty O\infty . \frac{11}{3}O\frac{11}{5} . O$) which filled drusy cavities in zinnwaldite, a finely defined square was always observed. The sides of the square were parallel to the combination edges, $\infty O\infty : O$, and, when examined under the microscope, proved to consist of irregular violet patches, whilst the interior and exterior of the square proved to be colourless. This appearance is explained as being due to kernel structure. A colourless crystal, $\infty O\infty : O$, or, $\infty O\infty : mOm$, must have first been formed, then the violet pigment and on this the planes $\frac{11}{3}O\frac{11}{5}$ and O. B. H. B.

Pyrostilpnite from St. Andreasberg. By O. Luedecke (*Jahrb. f. Min.*, 1884, 1, Ref., 11—12).—The pyrostilpnite or fire-blende from St. Andreasberg gave the following results on analysis:—

Ag.	Sb.	S.	Total.
59·435	22·302	18·113	99·850

The formula is Ag_3SbS_3, which is also the formula of pyrargyrite, so that the compound is dimorphous. The crystallographical examination shows that the mineral is monoclinic, $a : b : c = 0·3547 : 1 : 0·1782$; $\beta = 90° 0'$. The following forms were observed: $-4\breve{P}4$, $4\breve{P}4$, ∞P, $\infty\breve{P}2$, $\bar{P}\infty$, $-\bar{P}\infty$, $-2\bar{P}2$, $\infty\bar{P}4$, $0P$, $\infty\bar{P}\infty$. B. H. B.

Relations between the Crystalline Form and Chemical Composition of Arsenical Iron Pyrites. By ARZRUNI and BAERWALD (*Jahrb. f. Min.*, 1884, **1**, Ref., 10—11).—The authors have examined a number of specimens of crystallised arsenical pyrites to determine whether the angle of the prism, or, what amounts to the same thing, the ratio of the axes *a* and *b*, bears a fixed relation to the percentage of sulphur.

If the results be arranged in a series according to the value of the axis *a*, and if the lengths of this axis and the sulphur-percentage of the two end members be compared, it will be seen that a difference of 0·01872 in the axis *a* corresponds to a difference of 4·42 per cent. of sulphur, or, in other words, an increase of 0·00001 in the axis *a* represents an increase of 0·00236 in the percentage of sulphur. Hence, if the axis *a* be given, the percentage of sulphur may easily be calculated, and *vice versâ*, always supposing that the difference in the length of the axis *a* stands in direct proportion to the percentage of sulphur.

In the following table the sulphur percentage has been thus calculated, and compared with the value actually obtained on analysis:—

Locality.	Axis *a*.	Sulphur found.	Sulphur calculated.
Reichenstein	0·67092	18·051	—
Sangerberg	0·67052 (?)	18·290	17·957 (?)
Hohenstein	0·67725	19·585	19·547
Ehrenfriedersdorf	0·67811	19·761	19·748
"Plinian"	0·67960	20·080	20·099
Sala	0·68066	20·410	20·350
Joachimsthal	0·68215	20·520	20·701
Freiberg	0·68279	20·831	20·852
Binnenthal	0·68964	22·472	—

From the above results it is evident that the crystal form is dependent on the chemical composition. The crystals from Sangerberg do not follow the law; the measurements of the angles being inexact. If the sulphur in these analyses be regarded as being in the form of FeS_2, the remainder of the iron must then bear a varying ratio to the arsenic, viz., 1 : 1·669 to 1 : 2·088. If, however, the ratio be taken as 1 : 2, then 0·7743 to 1·1956 $FeAs_2$ would be required for one molecule of FeS_2 in the various analyses. No explanation can be given of the variable percentage of sulphur in arsenical pyrites; it is, however, clear that the theory that the arsenical pyrites are isomorphous mixtures of FeS_2 and $FeAs_2$, is not allowable. B. H. B.

Identity of Spathiopyrite and Safflorite. By F. SANDBERGER (*Jahrb. f. Min.*, 1884, 1, Mem., 69—70).—L. McCay points out the identity of the *safflorite* of Breithaupt, with the *spathiopyrite* described by the author in 1868. The author now finds that the sp. gr. of the mineral is 7·1 and not 6·7 as originally stated; there can be no doubt, therefore, that the two minerals are identical. B. H. B.

Hæmatite from the Hargita-Gebirge. By A. SCHMIDT (*Jahrb. f. Min.*, 1884, 1, Ref., 12—13).—The crystals occur in fissures of an amphibole andesite. The chemical analysis gave:—

Fe.	O.	Total.
70·27	29·43	99·70

On the tabular crystals the following forms were observed: 0R, $\infty P2$, $\frac{4}{3}P2$, R, $-2R$, $-\frac{1}{2}R$, $-\frac{1}{2}R3$. The nearest analogue to the Hargita crystals are those of Biancavilla (Abstr., 1881, 237).

B. H. B.

Crystal of Stephanite from Wheal Newton. By W. J. LEWIS (*Jahrb. f. Min.*, 1884, 1, Ref., 7).—A crystal of stephanite has been found, for the first time in England, at Wheal Newton, in Cornwall. It was associated with chalybite and quartz. The observed planes were: $\infty P\breve{\infty}$, $\infty P\bar{\infty}$, 0P, ∞P, $\infty P\breve{3}$, P, $\frac{1}{2}P$, $\frac{1}{3}P$, $\frac{2}{3}P\breve{\infty}$, $P\breve{\infty}$, $2P\breve{\infty}$, $2\breve{P}4$, $\frac{3}{4}P\breve{3}$, $\bar{P}\infty$, $\frac{8}{5}P\frac{16}{3}$. B. H. B.

Production of Zeolites in the Cold. By F. GONNARD (*Jahrb. f. Min.*, 1884, I, Ref., 28).—Fournet in his "Géologie Lyonnaise" (p. 658) describes the occurrence of zeolites in cavities of a lava from the volcano of Louchadière. These zeolites are found only in cavities below the usual river-level, and as they are partially filled with water, Fournet inferred that the zeolites were here formed in the cold under the influence of river water. From a closer examination of these "zeolites," the author found that they consisted solely of aragonite. B. H. B.

Vaugnerite at Irigny (Rhone). By F. GONNARD (*Compt. rend.*, **97**, 1155—1157).—The granite in a large quarry below Irigny is traversed by an almost vertical dyke about 10 meters in thickness. The material of which the dyke is composed is highly micaceous, and has undergone considerable disintegration; it very closely resembles the *vaugnerite* which Fournet found near Vaugneray (Rhone), and which Deluse regards as a micaceous diorite. The altered rock contains three principal constituents; mica, in blackish elongated plates; felspar more or less kaolinised, and forming small white masses which surround an unaltered pinkish nucleus; and numerous flattened citron-yellow hexagonal prisms, with an earthy fracture, in all probability produced by the alteration of hornblende. The less decomposed portions of the vaugnerite contain brown crystals of sphene of the Arendal type, and the rock also contains prismatic needles of apatite, which are especially abundant, disseminated in the altered crystals of hornblende. The proportion of apatite, however, is not sufficient to give the rock any industrial value. C. H. B

Formation of Bauxite and Gypsum. By S. MEUNIER (*Compt. rend.*, 97, 1444—1446).—When white marble is left in contact with a solution of aluminium sulphate for a long time, carbonic anhydride is very slowly given off, and the marble becomes covered with a white mamillary crust, which contains aluminium, calcium, sulphuric acid, and water. This crust is a mixture of several substances, viz.:—(1.) An amorphous substance soluble in cold dilute potash. It probably contains aluminium hydroxide, but its solution contains sulphuric acid, and it may therefore be a basic sulphate. (2.) Small acicular crystals of gypsum. (3.) Transparent, brilliant, relatively bulky spheres and ellipsoids, sometimes 0 1 mm. in diameter. They are frequently connected together, and enclose crystals of gypsum. Mixed with these bodies are numerous crystals derived from the regular octohedron, a combination of octohedron and cube being one of the most frequent forms. These crystals occur only in small quantity. They contain sulphuric acid, calcium, and aluminium, and may perhaps be regarded as a kind of alum; they dissolve slowly in cold water and immediately in boiling water, but are insoluble in alcohol.

This experiment throws little light on the formation of bauxite, but it affords a clue to a probable mode of formation of gypsum, especially when it is remembered that the latter is sometimes found associated with websterite (aluminium sulphate). C. H. B.

New Selenium Minerals from Cacheuta. By E. BERTRAND (*Jahrb. f. Min.*, 1884, 1, Ref., 9—10).—Molybdomenite (selenite of lead), cobaltomenite (selenite of cobalt), and selenic acid, are found at Cacheuta, La Plata, associated with chalcomenite ($SeCuO_3,2H_2O$) recently described by Des-Cloizeaux (Abstr., 1883, 31). Molybdomenite forms rhombic lamellæ with pearly lustre. The crystals of cobaltomenite are monoclinic. They are extremely small, and have the colour of erythrine. Selenic acid occurs as very fine white needles, and is due to the decomposition of the molybdomenite.

B. H. B.

Thorite of Arendal. By L. F. NILSON (*Jahrb. f. Min.*, 1884, 1, Ref., 8).—In 1876 Nordenskiold discovered, at Arendal, a crystallised silicate containing 50 per cent. Th and 10 per cent. UO_3. The author is of opinion that this mineral contains uranium in the form of UO_2, corresponding to the ThO_2, and supposes that these two oxides replace each other in thorite in variable proportions. The mineral is thus only a variety of thorite rich in uranium, and not a distinct mineral.

B. H. B.

Hübnerite from the Pyrenees. By E. BERTRAND (*Jahrb. f. Min.*, 1884, 1, Ref., 14).—The author found the pure manganese wolframiate, hitherto only known in Nevada, in the dialogite of Adervielle, Hautes Pyrénées, together with friedelite and manganeseblende. The forms, ∞P, $\infty P\breve{\infty}$, $\infty P\bar{\infty}$, were observed. The crystals were transparent and of a rutile-red colour. B. H. B.

Note on the Optical Properties of Nevada Hübnerite. By A. DES-CLOIZEAUX (*Jahrb. f. Min.*, 1884, 1, Ref., 14—15).—Contrary to the author's theory, according to which the optical axes of the natural hubnerite lie in $\infty P\breve{\infty}$, Groth and Arzruni (*Pogg. Ann.*, 1873, 235) found in artificial crystals the axial plane perpendicular to $\infty P\breve{\infty}$. On a further examination of the natural crystals, the author found that the theory of Groth and Arzruni is correct.

B. H. B.

Jadeite from Thibet. By E. COHEN (*Jahrb. f. Min.*, 1884, 1, Mem., 71—73).—Microscopic examination of a fragment of jadeite presented to the author by Damour proved it to be a member of the pyroxene-group. The analysis gave the following results:—

SiO_2.	Al_2O_3.	FeO.	CaO.	MgO.	Na_2O.	Total.
59·17	22·58	1·56	2·68	1·15	12·93	100·07

The close resemblance of this mineral to the augite from a South African eclogite (*Jahrb. f. Min.*, 1879, 864) induced the author to suppose that the silicate, $Na_2O,Al_2O_3,4SiO_2$, was present, and with this hypothesis to calculate the analysis of the jadeite, as well as several of Damour's older analyses. He, however, invariably obtained a considerable excess of SiO_2, when the remaining constituents were regarded as MgO,Al_2O_3,SiO_2 and RO,SiO_2, as in the African pyroxene.

B. H. B.

Dichroite from Asama-Yama. By E. HUSSAK (*Jahrb. f. Min.*, 1884, 1, Ref., 76—77).—Among the fragments ejected from the Japanese volcano, Asama-Yama, the author found normal andesite lapilli, andesite lapilli with enclosures of a white, finely granular rock containing dichroite, and the latter rock also occurring independently among the ejected fragments. Ejected matter containing dichroite, and almost entirely free from augite and magnetite, gave on analysis the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	CaO.
74·65	15·32	2·34	0·26	1·96

MgO.	K_2O.	Na_2O.	Ignition.	Total.
0·79	1·42	4·11	0·45	101·30

The dichroite forms columnar crystals of the combination ∞P, $\infty P\breve{\infty}$, $0P$, and, strange to say, is always developed as twin crystals along ∞P, in the way frequently met with in the rhombic carbonates of the aragonite series. B. H. B.

Twin Crystals of Dichroite from the Laacher See. By A. v. LASSAULX (*Jahrb. f. Min.*, 1884, 1, Ref., 77—79).—The author describes ejected matter from the Laacher See very rich in dichroite. It is a microscopic mixture of glassy felspar, dark violet dichroite in large badly-developed six-sided columns ($\infty P \,.\, \infty P\breve{\infty} \,.\, 0P$), corundum, biotite, and pleonast. As in the case of the dichroite from the Japanese volcano, Asama-Yama, the dichroite, in which the plane of the optical axes is parallel to ∞P$\breve{\infty}$, is developed as twin crystals along ∞P.

B. H. B.

Culm Conglomerate, containing Variolite, at Hausdorf, in Silesia. By E. DATHE (*Jahrb. f. Min.*, 1884, 1, Ref., 73—74).—Of all the specimens of variolite examined, only one, which unfortunately was not analysed, proved to be a true variolite, that is, an endomorph contact-product of diabase. All the others resemble the true variolites in external appearance only. They consist principally of albite, quartz, muscovite, and iron pyrites. The ground-mass is a mixture of quartz and albite with finely-disseminated chlorite. Analyses of two specimens are given:—

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	Na_2O.
I ..	72·23	0·20	13·90	1·86	0·57	0·23	0·88	2·71
II ..	75·22	—	14·32	1 86	0·57	0·13	0·53	3 62

	K_2O.	P_2O_5.	CO_2.	SO_3.	H_2O.	Organic matter.	Total.	Sp. gr.
I ..	3·57	0·17	0 04	0·17	1 97	0·04	99·54	2·691
II ..	3·91	—	—	—	1·29	—	100·11	2·682

B. H. B.

Green Mica in the Quartzites of Ouro Preto (Brazil). By H. GORCEIX (*Jahrb. f. Min.*, 1884, 1, Ref., 20).—Micas with a small percentage of chromium are widely distributed in the quartz mica schists, containing quartzites and topaz, of the province of Minas Geraës. The author has found a mica rich in chromium in a quartzite belonging to the same horizon at Ouro Preto. This bright green translucent mica (sp. gr. 2·78) has the following composition:—

SiO_2.	Al_2O_3 + Fe_2O_3.	Cr_2O_3.	MgO.	K_2O.	Na_2O.	Ignition.	Total.
46·5	37·2	0·9	0·8	7·9	1·3	4·7	99·3

Unlike the green mica from the Ural Mountains (Abstr., 1883, 1066) here only a small portion of the alumina appears to be replaced by chromium, and magnesia is present to a very small extent.

B. H. B.

New Mineral from Barbin near Nantes. By A. DES-CLOIZEAUX (*Jahrb. f. Min.*, 1884, 1, Ref., 8—9).—A new silicate of aluminium, iron, and calcium occurs, together with quartz and apatite, in cavities in a pegmatite rock at Barbin, near Nantes. The crystals are rhombic and occur in the form of colourless rectangular plates 0·75 mm. long and 0·5 mm. broad. The mineral is probably identical with that from Petit-Port described by Bertrand (*Jahrb. f. Min.*, 1881, 1, 362).

B. H. B.

Analyses of Idocrase from Ala and Monzoni. By E. LUDWIG and A. RENARD (*Jahrb. f. Min.*, 1884, 1, Ref., 24—25).—The results of the analyses are:—

	SiO_2.	TiO_2.	Fe_2O_3.	FeO.	Al_2O_3.	CaO.	MgO.	H_2O.	Total.
I ..	37·36	0·18	4·02	0·39	16 30	36·65	3·02	2·89	100·81
II ..	37·50	0·28	3·76	0·33	16·22	36·31	3·13	2·14	99·68

I. Grass-green idocrase (vesuvian) from Ala; sp. gr. 3·427.
II. Yellowish-brown idocrase from Monzoni; sp. gr. 3·413.

These analyses differ from previous analyses in giving no appreciable quantities of alkalis, and a very low percentage of FeO.

B. H. B.

The Kersantite Vein of the Upper Harz. By A. v. GRODDECK (*Jahrb. f. Min.*, 1884, 1, Ref., 68—70).—The author has discovered a vein of kersantite, 1 m. wide and 8 m. broad, traversing the Upper Devonian and Culm beds near Lauthenthal. He distinguishes three varieties of the rock: 1. Normal kersantite of a bluish-black colour, closely resembling that from Laveline in the Vosges. 2. A variety resembling quartz porphyry; and 3. A violet or reddish variety. Analyses of these three varieties are given (I, II, and III), as well as an analysis of kersantite from Laveline, (IV) made for the sake of comparison.

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	Cr_2O_3.	FeO.	MnO.	CaO.	MgO.
I ...	54·80	0·30	11·20	3·42	0·05	4·80	0·40	8·32	6·00

B. H. B.

Manganese Minerals from Vester-Silfberg in Dalarne. By M. WEIBULL (*Jahrb. f. Min.*, 1884, 1, Ref., 20—22).—1. *Ingelströmite.*—This mineral, described by Ingelström as knebelite, forms part of the gangue of the iron-manganese ores. It forms greyish-white crystalline masses with glassy lustre, splintery fracture and sp. gr. 4·17. The analysis gave:—

SiO_2.	FeO.	MnO.	MgO.	$CaCO_3$.	Total.
29·94	46·88	18·83	3·01	1·14	99·80

It is a member of the olivine-group with the composition,

$$2[2FeO,SiO_2] + 2MnO,SiO_2.$$

2. *Alumina garnet containing manganese* occurs in grains. The analysis gave the following results:—

SiO_2.	Al_2O_3.	FeO.	MnO.	CaO.	Total.
36·03	20·91	21·26	17·79	4·43	100·42

3. *Silfbergite* occurs in translucent, honey-yellow columns with a glassy lustre and white streak. H. 5·5; sp. gr. 3·446. The mean of three analyses gave:—

SiO_2.	FeO.	MnO.	MgO.	CaO.	Ignition.	Total.
48·63	30·49	8·34	8·39	1·74	0·44	98·23

From the analysis the formula $4FeO,SiO_2 + 2Mg(Ca)O,SiO_2 + MnO,SiO_2$ is deduced.

4. *Manganese-hedenbergite* has a greyish-green colour. H. 5; sp. gr. 3·55. The analysis gave:—

SiO_2.	FeO.	MnO.	CaO.	MgO.	Alkalis.	Total.
48·29	24·01	6·47	17·69	2·83	0·22	99·51

which corresponds with the formula $2(FeO,SiO_2 + CaO,SiO_2) + (MnMg)O.SiO_2$.

5. *Lime-dialogite.*—The mean of two analyses gave:—

CO_2.	MnO.	FeO.	CaO.	Insol. residue.	Total.
40·58	24·60	6·95	26·71	1·15	99·99

By the action of the atmosphere this mineral is decomposed into *wad* with the following composition:—

CaO.	MnO.	FeO.	H_2O.	Insol. residue.	Total.
4·38	61·56	20·51	8·43	3·23	98·11

B. H. B.

Artificial Crystals of Manganese-iron-olivine. By H. LASPEYRES (*Jahrb. f. Min.*, 1884, **1**, Ref., 27—28).—At the steel works near Schwelm, crystals of manganese-iron-olivine were found on the sandstone bottom of a forge-hearth. The mean of two analyses gave the following results:—

Metallic Fe.	Sand.	Fe_2O_3.	FeO.	MnO.	SiO_2.	Total.
0·67	16·02	0·77	44·00	13·83	25·21	100·50

After the removal of the metallic iron, the mechanically-mixed quartz sand and the Fe_2O_3, the analysis of the pure slag gave:—

Si_2O_2.	FeO.	MnO.	Total.
30·36	52·98	16·66	10·00

representing the formula $MnFe_3Si_2O_8$.

The crystals have the well-known olivine form $\infty P\breve{\infty}$, ∞P, $2P\breve{\infty}$.

B. H. B.

Artificial Production of Spessartite or Manganese-garnet. By A. GORGEU (*Compt. rend.*, **97**, 1303—1305).—When 1 part of finely powdered pipe-clay and about 15 parts of nearly pure and dry manganous chloride are fused at a cherry-red heat in a current of hydrogen saturated with aqueous vapour by passing through a warm solution of potassium permanganate, a regulus is obtained which, when treated successively with water and dilute hydrochloric acid, yields a residue of yellowish crystals identical in composition, crystalline form (icositetrahedrons), and other properties, with spessartite, but slightly softer than the natural mineral (H. = 6—7; spessartite above 7). By substituting calcium chloride for manganous chloride, the corresponding calcium compound is obtained. Melanite is the only variety of garnet which has hitherto been prepared artificially.

C. H. B.

The Supposed Pre-Cambrian Rocks of St. David's. By A. GEIKIE (*Journ. Geol. Soc.*, 1883, 261—325; *Jahrb. f. Min.*, 1884, 1, Ref., 88—91).—This paper was written to refute the views advanced by Dr. Hicks that there are, at St. David's, three distinct Pre-Cambrian formations: the "Dimetian," the "Arvonian," and the "Pebidian."

The Lower Cambrian beds at St. David's have been folded into an isoclinal curve, and the following rock groups may be recognised:—1. Volcanic group. 2. Quartz conglomerate. 3. Green and red shales and sandstones. 4. Purple and greenish grits, sandstones and shales.

The volcanic group consists mainly of tuffs with occasional breccias and bands of olivine-diabase. Analyses of the olivine-diabase from Rhosson (I), and from Clegyr Foig (II), are given—

	SiO$_3$.	Al$_2$O$_3$.	Fe$_2$O$_3$.	FeO.	MnO.	CaO.	MgO.
I	45·92	18 16	1·18	9·27	0·19	7·19	10·07
II	45·38	16·62	4·06	8·63	0·14	8·19	9·41

	K$_2$O.	Na$_2$O.	Ignition.	Insoluble residue.	Total.	Sp gr.
I	1·78	2·12	4·22	0·04	100·14	2·96
II	0·71	2·20	4·34	0·08	99·76	2·99

The tuffs are partly basic, derived from the disruption of diabase lavas, and partly acid from the destruction of fine felsites. A mass of granite has risen through the eastern limb of the isocline, and this granite is the "Dimetian" formation of Hicks. The metamorphism associated with the granite consists in the hardening of certain bands of rock which have been converted into flinty aggregates. These contact-products represent the "Arvonian" formation of Hicks.

B. H. B.

Anorthitic Rock at Saint Clement, Puy de Dôme. By F. GONNARD (*Compt. rend.*, **97**, 1447—1449).—This rock consists essentially of anorthite and green pyroxene, and therefore belongs to the eukrite-group, but it is also characterised by containing, in unusual abundance, long silky fibres of wollastonite, sometimes almost colourless, but generally white, enclosing green grains of pyroxene, some rare crystals of reddish-brown sphene, and small, very brilliant, transparent or translucent crystals of brown vesuvianite. The wollastonite also forms small veins 2—3 mm. in thickness. The rock also contains quartz, though not in large quantity, and hornblende in deep green fibrous masses, black crystalline bundles, and short crystals. At the outcrop, the rock has weathered, and the constituent minerals have undergone considerable oxidation. C. H. B.

Presence of Phosphorus in Minette. (*Dingl. polyt. J.*, **250**, 330.)—Specimens of this rock from Höhl, in Luxembourg, gave by analysis—

Fe_2O_3.	P_2O_5.	Al_2O_3.	CaO.	Mn_3O_4.	SiO_2.
75·67	3·68	3·10	5·01	0·72	8·70

The phosphorus is in combination with the iron and not with the calcium. D. B.

Glaucophane Schists of the Island of Groix. By BARROIS (*Compt. rend.*, **97**, 1446—1447).—The island of Groix is formed mainly of alternating beds of mica schist and chloritic schists, but in some parts of the island there are found interstratified with these, beds which are characterised by the large number of minerals which they contain. The principal minerals are two varieties of amphibole distinct from hornblende, together with epidote, rutile, garnets, sphene, magnetite, chlorite and calcite in greater or less quantity. The predominant variety of amphibole is glaucophane in bluish polychroic crystals elongated along the faces *h'g'*. The prismatic faces are the dominant faces, and the crystals enclose rutile. The other variety is green amphibole, which is also highly polychroic, but in other directions. Epidote is very abundant in its usual forms, but does not show the common fan-like structure. The garnets are much cracked, as if they have been subjected to powerful mechanical action. The following is the probable order of consolidation: (1) rutile, sphene, magnetite, garnet; (2) glaucophane, epidote, white mica, quartz; (3) chlorite, green amphibole. C. H. B.

The Crystalline Schists of Kaisersberg in Styria. By H. v. FOULLON (*Jahrb. f. Min.*, 1884, **1**, Ref., 85—88).—This paper gives a petrographical description of the rocks of the Wurm Alp, near Kaisersberg, and of the Ennsthal and Paltenthal, all of which belong to the lower carboniferous period. Both in the older crystalline rocks, containing felspar, and in those of the carboniferous formation, the felspars are characterised by a remarkable richness in enclosures. In the rocks of the older crystalline formation, the felspar is mostly albite, but in the phyllite gneiss of the carboniferous formation mostly orthoclase, but partly microcline. Most of the crystalline rocks of the Paltenthal and Ennsthal are characterised by their great richness in titanium, which occurs sometimes as titaniferous iron, sometimes as rutile, or titanite. A number of rocks are remarkable for containing chloritoid, a mineral which up to the present time has not been frequently met with. It is here widely distributed, although the amount present in the rocks is often very small. Analysis of the chloritoid schist from the Wurm Alp gave the following results:—

SiO_2.	Al_2O_3.	FeO.	MnO.	MgO.	CaO.	S.	H_2O.	Organic matter.	Total.
78·84	8·26	6·48	trace	2·69	0·29	0·39	2·88	0·22	100·05

Those rocks of the Paltenthal and Ennsthal, which contain no chloritoid, show a remarkable analogy to the rocks of the Wechsel mountains, recently described by A. Böhm. B. H. B.

Elaeolite Syenite from Jivaara. By F. J. Wiik (*Jahrb. f. Min.*, 1884, 1, Ref., 75).—The Jivaara mountain is composed of elaeolite syenite. Near the summit a coarsely granular vein rock occurs, which is traversed by narrow veins of a finely granular variety. The coarsely granular vein rock is essentially a mixture of elaeolite and jivaarite (titaniferous lime-iron garnet), with subordinate pyroxene, almost entirely converted into amphibole. In contact with the altered pyroxene, cancrinite (sp. gr. 2·45) occurs, which encloses minute columns of pyroxene and amphibole, rich in soda. Felspar does not occur in this rock. In the finely granular variety, unaltered pyroxene occurs; jivaarite also occurs, but cancrinite has not been observed. In addition to these minerals, the rock contains yellow grains of apatite and brown crystals of titanite. B. H. B.

The Cheviot Andesites. By J. J. H. Teall (*Jahrb. f. Min.*, 1884, 1, Ref., 71—73).—The Cheviot district is largely composed of porphyrites, and, in addition to these, masses of volcanic ash and breccia occur, together with a remarkable rock, to which the name *pitchstone-porphyrite* has been given. The most important result of the author's examination is that this pitchstone-porphyrite is exactly similar to many of the augite-andesites of Hungary, Transylvania, Servia, Santorin, and America. An analysis of a specimen of the Cheviot rock (sp. gr. 2·54) gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	Na_2O.	K_2O.	Loss.	Total.
63·0	14·9	4·7	4·8	2·8	4·0	1·9	4·0	100·1

The Cheviot porphyrites are, for the most part, only altered andesites. An analysis of a dark purple porphyrite (sp. gr. 2·56) from Shillmoor Farm gave:—

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	Na_2O.	K_2O.	Loss.	Total.
64·2	16·0	4·3	1·7	2·5	2·9	5·9	3·3	100·8

In conclusion, a specimen of Tuedian "porphyrite" from Stichill is described. The chemical analysis of the rock (sp. gr. 2·95) gave:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	MgO.	Na_2O.	K_2O.	P_2O_5.	Loss.	Total.
47·53	14·95	6·73	8·04	0·73	8·50	7·41	2·98	1·12	trace	1·95	99·94

It appears from microscopic and chemical examination that the rock is not a porphyrite, but a member of the basaltic family.
B. H. B.

The Biotite-holding Amphibole-granite from Syene. By A. Stelzner (*Jahrb. f. Min.*, 1884, 1, Ref., 67—68).—This paper gives the results of the microscopic examination of sections of the rock of the obelisk lately transported to New York from Alexandria. The rock was found to consist of microcline, oligoclase, quartz, hornblende, biotite, titanite, apatite, magnetite, and zircon. Viridite and pistazite are exceedingly rare. B. H. B.

The Trachyte Region of the Rhodope. By A. Pelz and E. Hussak (*Jahrb. f. Min.*, 1884, 1, Ref., 75).—An important microscopic examination of a number of younger eruptive rocks from the Rhodope showed a remarkable analogy to the rocks of the Transylvanian eruptive district. The specimens examined belong partly to the liparites and partly to the andesites. Among the latter, biotite-andesite, containing augite, predominates. Amphibole and augite andesites are of rarer occurrence. B. H. B.

Analysis of the Rocky Portion of the Syssiderite of Atacama. By S. Meunier (*Jahrb. f. Min.*, 1884, 1, Ref., 32).—The proportions in which the different minerals are present in the rocky portion of the syssiderite of Atacama may be thus expressed:—Magnesian pyroxene, 9·0 per cent.; schreibersite, 4·0 per cent.; chromite, 1·2 per cent.; anorthite, 0·1 per cent.; pyrrhotine, 0·5 per cent.; and olivine, 85·2 per cent. B. H. B.

Basic Eruptive Rocks of Mâconnais and Beaujolais. By A. Michel-Levy (*Jahrb. f. Min.*, 1844, 1, Ref., 64—67).—The majority of the pre-granitic basic eruptive masses, which burst through the Cambrian slates and quartzites of Mâconnais and Beaujolais, are granular mixtures of titanite, magnetite, titaniferous iron, pyroxene, and labradorite, and should, according to the author, be classed as diabases. Of these, the author distinguishes two classes: granitoid diabases and ophitic diabases. The felspar of these rocks varies from oligoclase to anorthite: the pyroxene is very frequently converted into amphibole, and when the alteration is complete, rocks are formed, which the author calls diorites. In the series there are a certain number of rocks with a porphyritic structure and holo-crystalline microlithic ground-mass, or in other words, the rocks are developed as amphibolic porphyrites. The disseminated felspar is labradorite, and the microliths of the ground-mass consist of oligoclase. Varieties are exceptionally met with, in which the basicity is exaggerated and the felspar disappears, but olivine never occurs. B. H. B.

Basalt from Naurod, near Wiesbaden. By F. Sandberger (*Jahrb. f. Min.*, 1884, 1, Ref., 79—80).—The rock is, in general, a limburgite containing plagioclase and nepheline. The following are analyses:—I. Of the portion of the rock soluble in hydrochloric acid. II. Of the insoluble portion. III. Complete analysis of the rock:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.
I ..	18·67	11·89	2·33	5·61	0·08	2·65
II ..	26·57	7·33	2·88	—	—	6·53
III ..	45·24	19·22	5·21	5·61	0·08	9·18

	MgO.	K_2O.	Na_2O.	Li_2O.	H_2O.	Total.
I ..	3·18	0·65	1·89	trace	—	46·95
II ..	3·53	0·66	1·48	—	—	48·98
III ..	6·71	1·31	3·37	trace	3·78	99·71

The rock must be regarded as a glassy nepheline-basanite.

B. H. B.

Basaltic Rocks from the Faroe Islands. By A. OSANN (*Jahrb. f. Min.*, 1, 1884, Mem., 45—49).—This paper gives the results of an examination of the series of rocks from the Faroe Islands in the collection of the University of Heidelberg. The rocks may be grouped into two divisions—porphyritic and non-porphyritic. The representatives of the first class are compact, have a dark colour, and contain plagioclase. The rocks of the latter class are coarsely granular; they have a brown colour and an earthy appearance. The rocks of both classes are rich in amygdoidal cavities, filled with zeolites, chalcedony, opal, or delessite. When examined microscopically, it was found that only the porphyritic rocks contain a little olivine, whilst it is entirely absent in the others. This absence of olivine seems to be characteristic of northern basalts. The rock from Kolter may be described as a diallage-andesite, a tertiary equivalent of the gabbros. An analysis of this rock gave the following results:—

SiO_2.	Al_2O_3.	FeO.	CaO.	MgO.	Alkalis.	Total.
52·30	18·22	11·50	10·24	7·23	2·65	102·14

B. H. B.

Volcanic Ashes from the last Eruption of Krakatoa. By H. H. REUSCH (*Jahrb. f. Min.*, 1884, 1, Mem., 78).—The principal mass of the ashes consists of a glass crowded with minute cavities. The larger pieces readily float on water. The glass is generally colourless, but sometimes more or less brown. Microliths were occasionally met with. The cavities in the glass are sometimes round, and sometimes drawn out in a longitudinal direction. In addition to the glass, many more or less perfect fragments of crystals were observed, consisting principally of plagioclase and bronzite, together with small and rather narrow prisms of a greenish mineral, probably augite, and apatite. From the above description, it may be seen that this youngest eruption-product from the Straits of Sunda bears the andesite character so general in the district, and is of special interest on account of the presence of rhombic pyroxene. B. H. B.

The Alfianello Meteorite. By P. MASSEN (*Gazzetta*, 13, 369—374).—The author has examined some fragments of this meteorite; they were in the form of greyish-white laminæ, very fragile, and easily pulverised, except the metallic particles. Qualitative analysis showed that it contained iron, nickel, cobalt, calcium, magnesium, aluminium, chromium, manganese, potassium, sodium, silicon, sulphur, and phosphorus. The following is the average percentage composition of the fragments examined:—

Fe.	Ni.	Co.	FeO.	Al_2O_3.	Cr_2O_3.	CrO_3.	MnO.
5·7608	1·1375	0·0817	24·4184	1·7823	0·1021	0·6175	0·1297

MgO.	CaO.	Na_2O.	K_2O.	SiO_2.	S.	P.	Total.
23·4261	0·8945	1·0884	0·2387	37·6257	2·5432	0·1532	99·9698

The author believes the metallic portion of the meteorite to have the composition of octibehite or teanite, whilst the non-metallic portion appears to consist of olivine and bronzite, both with excess of iron, and troilite. C. E. G.

Contribution to the Geological History of the Pallas Meteoric Iron. By S. Meunier (*Jahrb. f. Min.*, 1884, 1, Ref., 31—32).—According to the author, the iron sulphide in many meteorites has originated from the action of sulphuretted hydrogen on grains of nickel iron, as may be clearly seen in the chrondite of Knyahinya, where the grains consist half of nickel iron and half of iron sulphide. In the meteorite of Krasnojarsk (Pallas iron), this is not the case; here the iron sulphide was formed first, and the nickel iron therefore could not have originated at a very high temperature The author supposes that fissures with fragments of olivine crystals originally existed; then iron sulphide was probably formed by the action of sulphuretted hydrogen on iron and nickel chlorides, and lastly the various compounds of nickel and iron were concentrically deposited. The Pallas iron is an example of vein formation, analogous to the oldest terrestrial metalliferous deposits, and the mode of formation especially resembles that of tin ore veins. The Pallas iron, therefore, should not be classed with the other pallasites of G. Rose.

B. H. B.

The Cranbourne Meteorite. By W. Flight (*Jahrb. f. Min.*, 1884. 1, Ref., 33—35).—Two masses of meteoric iron were discovered at Cranbourne, near Melbourne, in 1854. The Bruce meteorite, the larger mass, is now in the British Museum. The meteorite consists entirely of metallic minerals, and contains no rocky matter whatever. The absence of combined carbon was established by decomposing the iron in a solution of sodium chloride by a galvanic current. The iron thus dissolved was found to have the composition given under I, while the analyses II—VI give the constituents, other than iron, in some of the largest nickel-iron crystals and cleavage plates of various thicknesses:—

	I.	II.	III.		IV.		V.	VI.
Residue	0·93	1·40	0·07		0·10	0·11	—	—
Ni	7·65	8·06	7·71	7·53	9·76	6·48	9·80	9·05
Co	0·50		0·60		0·76		—	—
Cu	0·02	—	—		—		—	—
Si	0·17	—	—		—		0·06	—
P	—	—	0·19		0·02		—	—

In addition to nickel-iron a number of other constituents have been identified and analysed, for example, the thin paper-like plates which lie between the large plates of the nickel iron crystals. They contain 70·14 per cent. Fe and 29·74 per cent. Ni. This is evidently an alloy of well-defined composition, and is the constituent of nickel iron which forms the fine lines constituting the Wiedmannstädtian figures. It is probably identical with the tänite of G. Rose or the meteorine of Zimmermann. The author proposes to call it *Edmondsonite*. The insoluble residue mentioned above, which forms nearly 1 per cent. of the mass, consists of strongly magnetic prisms apparently identical with the *Rhabdite* of Rose. The mean of three analyses gave—

Fe.	Ni.	P.	Total.
49·33	38·24	12·95	100·52

which corresponds with the formula $(Fe_4Ni_3)P$.

The coarse insoluble powder is very brittle and magnetic, and dissolves easily in nitric acid.

The mean of two analyses gave:—

Fe.	Ni.	P.	Total.
56·12	29·18	13·50	98·80

This is doubtless the mineral schreibersite $(Fe_2Ni)_7P$. A large brass-coloured crystal of this substance gave on analysis:—

Fe.	Ni.	P.	Total.
69·55	(14·41)	16·04	100·00

A curious crystal was met with on one or two occasions. It consisted of a square prism with bright and metallic sides, and a square centre of a dull black colour. The analysis corresponded with the formula $(Fe_7Ni_2)_8P$. Graphite occurs in sheet-like masses or nodules, sometimes enclosing troilite. The troilite is not magnetic, and is sometimes accompanied by daubreelite. When digested with carbon bisulphide 0·0207 per cent. sulphur was dissolved. The nickel-iron was further examined for occluded gases, and was found to contain 3·59 times its volume of gas having the following composition:—

CO_2.	CO.	H.	CH_4.	N.	Total.
0·12	31·88	45·79	4·55	17·66	100·00

B. H. B.

Geological History of the Syssiderite of Lodran. By S. MEUNIER (*Jahrb. f. Min.*, 1884, 1, Ref., 32).—The author regards the meteorite of Lodran as a sandstone with metallic cementing material, analogous to the ores of Commern, in Rhine Prussia, and of Coro-Coro, in Bolivia. The meteoric sand may be imagined to have been produced by volcanic action, and the metallic cement by the reduction of chlorides by means of hydrogen. B. H. B.

The Meteorite of Sewrjukowo. By A. EBERHARD (*Jahrb. f. Min.*, 1884, 1, Ref., 30—31).—This meteorite fell on May 12th, 1874, at Sewrjukowo. Its weight was 98 kilos. The following constituents were discovered: nickel-iron phosphide; olivine; bronzite; enstatite; and troilite. Analysis I gave the composition of the silicates soluble in aqua regia; II that of the insoluble residue; III and IV gave the composition of the chromite and nickel-iron phosphide:—

	SiO_2.	Al_2O_3.	FeO.	CaO.	MgO.
I ..	43·60	1·10	14·90	1·20	36·70

The author calculates that the meteorite is composed of 0·94 per cent. troilite; 4·13 per cent. magnetic pyrites; 15·94 per cent. nickel-iron phosphide; 47·74 per cent. silicates decomposed by acids, probably olivine mixed with some other silicate; and 31·25 per cent. silicates not decomposed by acids. B. H. B.

Organic Chemistry.

Action of Sodium Ethoxide on Bromethylidene Bromide. By A. MICHAEL (*Amer. Chem. J.*, **5**, 192—197).—Tawildarow has stated (this Journal, 1874, 348) that two dibromethylenes are formed by the action of sodium ethoxide on bromethylidene bromide; one boiling at 91°, the other at 157°. A third dibromethylene boiling at 109° has been obtained by Sabanejeff by the reduction of acetylene tetrabromide, or by the direct addition of bromine to acetylene. As the existence of three dibromethylenes would necessitate the assumption of the presence of a dyad carbon-atom in one of the isomerides, the author has repeated Tawildarow's experiments, but fails to obtain the dibromethylene boiling at 157°, the products of the reaction being bromacetylene and α-dibromethylene (boiling at 86—88°). The remainder of the paper is occupied with a discussion of the proofs advanced by Demole (Abstr., 1881, 142) of the correctness of the formula assigned by him to α-dibromethylene. A. J. G.

Formation of Acetylene from Iodoform. By P. CAZENEUVE (*Compt. rend.*, **97**, 1371—1373).—Iodoform in contact with finely-divided silver is rapidly converted into acetylene even in the cold, $2CHI_3 + 3Ag_2 = 6AgI + C_2H_2$. The silver is more active if mixed with finely-divided copper. Many other metals, such as mercury, zinc, and iron, also decompose iodoform in presence of water, forming a metallic iodide and liberating acetylene.

When iodoform is mixed with equal weights of powdered zinc and water, gas is given off spontaneously; or if gently heated a liquid heavier than water is also formed having an agreeable ethereal odour, and a sweet taste; it is in all probability an iodo-derivative. The gas which is evolved is a mixture of acetylene and an iodo-derivative which burns with a pale blue flame with purplish edges, forming hydriodic acid and depositing free iodine.

If a saturated solution of copper sulphate is used instead of water, the évolution of gas is still more rapid, for the zinc-copper couple which is produced not only decomposes the iodoform more rapidly, but also partially decomposes the iodo-derivatives. (*Comp.* Gladstone and Tribe, this Journal, 1875, 512.) The action of a moist zinc-copper couple on iodoform may be shown as a lecture experiment.

This reaction confirms the accepted constitution of acetylene, and is analogous to the action of zinc on methyl iodide. Probably the action of zinc on di-iodo-methane would give rise to ethylene.

Acetylene is also formed when iodoform is decomposed by heat.

C. H. B.

Experiments on Mercury Fulminate. By A. Ehrenberg (*J. pr. Chem.* [2], **28**, 56—57).—Aqueous thiocyanic acid does not act on mercury fulminate in the same manner as hydrochloric acid, which forms hydroxylamine hydrochloride, but according to the equation—

$$CHgNO_2NC + 4HCNS + 2H_2O = Hg(CNS)_2 + 2CO_2 + 2NH_4CNS.$$

Ammonium and potassium thiocyanates decompose the fulminate in a manner similar to the alkaline chlorides.

Mercury fulminate heated with ethyl sulphide or with carbon bisulphide in presence of alcohol and water, yields mercury sulphide and fulminurates: if water is excluded from the reaction, other products are formed, and the ammonium fulminurate is therefore merely a secondary product. Further experiments are being made.

H. B.

Action of Carbon Oxychloride on Ethylene Glycol. By J. Nemirowsky (*J. pr. Chem.* [2], **28**, 439—440).—By the action of 1 mol. pure glycol on 1 mol. carbon oxychloride in a closed tube at the ordinary temperature, the author has obtained glycol-carbonate, $CO(OCH_2)_2$, with evolution of hydrochloric acid. This substance is stable, soluble in water, alcohol, and in warm ether, from which on cooling it crystallises in colourless needles. The author continues his investigation.

A. B.

Action of Carbonic Anhydride on Calcareous Solutions of Sugar. By D. Loiseau (*Compt. rend.*, **97**, 1139—1141).—A 10 per cent. solution of sugar is saturated with calcium hydroxide at 20—25°, filtered, and treated with a current of carbonic anhydride. A relatively considerable quantity of the gas is absorbed, and if the liquid is agitated continually, it does not change in appearance; but if the liquid is allowed to remain at rest so that an excess of the gas acts on the same liquid surfaces, a gelatinous white precipitate is produced, which at first redissolves easily in the sugar solution. If portions of the liquid are removed from time to time, it is found that as the passage of the gas is continued up to a certain point, the solution loses its power of yielding a precipitate of tribasic calcium sucrate when heated, or of bibasic calcium sucrate when cooled. It would appear that the presence of the calcium carbonate prevents the precipitation of the sucrates, whilst the presence of the latter prevents the precipitation of the carbonate. If the passage of the carbonic anhydride is continued still further, the solution still fails to yield a precipitate of bibasic calcium sucrate when cooled to 0°, but acquires the property of yielding a precipitate when heated. This contains calcium carbonate, calcium hydroxide, and sugar, and redissolves in the mother-liquor on cooling, like the tribasic sucrate.

If the passage of the gas is continued until the liquid becomes slightly turbid and is then stopped, an abundant gelatinous precipitate separates; this contains sugar, calcium hydroxide, and calcium carbonate, and when it is mixed with about an equal volume of the calcareous sugar solution which has not been treated with carbonic anhydride, the precipitate dissolves as a whole. C. H. B.

Action of Acetic Anhydride and Acetic Chloride on Maize and Potato-starch. By A. MICHAEL (*Amer. Chem. J.*, 5, 359—360).—The acetyl derivatives obtained by heating these starches with acetic anhydride are not coloured by iodine; the granules under the microscope could not be distinguished from those of the parent starches. 2 grams of maize starch was heated with 5 grams of acetic chloride for 15 hours at 55—58°; the product was extracted with chloroform, the solution evaporated to dryness, and the residue dissolved in hot alcohol and treated with bone-black. On cooling, a greyish-white substance separated, from which, by again dissolving in hot alcohol and cooling, a white amorphous substance was obtained. This softened at 148°, and melted constantly at 151—152°. On adding water to the first alcoholic filtrate, it gave a substance melting at 128—129°. Very similar results were obtained with potato-starch.

A. J. G.

Hydration of Crotonaldehyde. By A. WURTZ (*Compt. rend.*, 97, 1169—1172).—Carefully purified crotonaldehyde is mixed at 0° with twice its weight of water and the same amount of hydrochloric acid, and the mixture is left at rest exposed to light for several hours. After some time, it becomes brown and the odour of crotonaldehyde almost disappears. The liquid is neutralised with sodium carbonate in order to precipitate resins, and the filtrate is agitated with ether. On evaporating the ether and fractionating the residue, aldol, paraldol, and other condensation products, and dialdane are obtained, but the yield of the first substance is only small. Possibly the crotonaldehyde at first combines with hydrochloric acid, and the compound thus formed reacts with the water, thus: $CHMeCl.CH_2CHO + H_2O = CHMe(OH).CH_2.CHO + HCl$. Crotonaldol could not be isolated.

C. H. B.

Formation of Crotonaldehyde and β-Hydroxybutyraldehydes from Acetaldehyde. By A. MICHAEL and A. KOPP (*Amer. Chem. J.*, 5, 182—191).—The authors' experiments show conclusively that β-hydroxybutyric aldehyde (aldol) is the primary product of the action of zinc chloride on acetaldehyde, the formation of crotonaldehyde being due to the decomposition by heat of the aldol first formed. Potassium and sodium salts of neutral reaction are without action on acetaldehyde. Saturated solutions of potassium salts of alkaline reaction and dilute solutions of sodium and potassium hydroxides behave like zinc chloride, whilst sodium salts of alkaline reaction give crotonaldehyde, oily substances, and probably aldol in small quantity. Dry potassium carbonate converts acetaldehyde into aldol, whilst dry sodium carbonate has no action on it. Aldol, when heated with moderately concentrated solutions of alkaline salts or of zinc chloride, is converted partly into crotonaldehyde, partly into liquids of higher boiling point, which yield crotonaldehyde on distillation.

A. J. G.

Convenient Method for Preparing Bromacetic Acid. By A. MICHAEL (*Amer. Chem. J.*, 5, 202—203).—This method is based on the formation and decomposition at 100° of the compound $(C_2H_4O_2,Br_2)_4HBr$. A mixture of glacial acetic acid and bromine (the latter slightly in excess of the theoretical quantity) with a small quantity of carbon bisulphide, is heated at 100° in a flask provided with a reflux condenser until hydrobromic acid ceases to be evolved; the product is then submitted to fractional distillation. The yield is about 90 per cent. of the theoretical quantity. A. J. G.

Monochlorethyl Monochloracetate. By L. HENRY (*Compt. rend.*, 97, 1308—1311).—Monochlorethyl monochloracetate is easily obtained by the action of monochloracetic chloride on ethylene monochlorhydrin,

$$CH_2Cl.CH_2.OH + CH_2Cl.COCl = CH_2Cl.CH_2.O.CO.CH_2Cl + HCl.$$

This reaction illustrates the difference between the action of the primary alcoholic chain $CH_2.OH$ on the two chains CH_2Cl and $COCl$. Monochlorethyl monochloracetate is a colourless limpid liquid, with a slightly pungent odour and a burning taste, insoluble in water, and not affected by the action of light. It boils at 197—198° (uncorr.); sp. gr. at 10·6° = 1·3217.

When monochlorethyl monochloracetate is gently heated with an alcoholic solution of sodium iodide, sodium chloride is precipitated, and monochlorethyl moniodo-acetate, $CH_2Cl.CH_2.O.CO.CH_2I$, is formed. It is a colourless oily liquid, insoluble in water; sp. gr. at 18° = 1·9540. It becomes brown when exposed to light, and cannot be distilled without decomposition. Its vapours are very irritating to the eyes. When heated with water for some time, the monochlorethyl moniodo-acetate is completely decomposed, but the liberated iodoacetic acid is very unstable, and splits up immediately.

Monochlorethyl monobromacetate is obtained by treating the preceding compound with bromine and removing the excess of the latter by means of hydrogen potassium sulphite. It is a colourless somewhat viscous liquid, insoluble in water, with a burning taste, and a faint odour exciting tears. It boils at 213—215° (uncorr.) with slight decomposition; sp. gr. at 11·4° = 1·6499. When heated for some time with several times its own volume of water, monochlorethyl monobromacetate is completely decomposed, and yields glycol monochlorhydrin and monobromacetic acid.

It is evident that in presence of monochlorethyl monochloracetate, sodium iodide exhibits an exclusive preference for the chain CH_2Cl united with the group CO in the acetic part of the molecule. This reaction affords further evidence of the influence exerted by oxygen on chlorine united with a carbon-atom which is directly connected with the carbon-atom to which the oxygen is attached.

C. H. B.

Action of Fatty Aldehydes on Malonic Acid and its Ethyl Salt. By T. Kommenos (*Annalen*, **218**, 145—169).—From the general nature of the reaction obtaining between benzaldehyde and ethyl malonate, it would *à priori* be expected that fatty aldehydes would form the ethyl salt of a dicarboxylic acid of general formula, $CHR.C(COOH)_2$, readily decomposing into carbonic anhydride and an aldehyde-substituted acetic acid, $CHR : CH.COOH$.

Former researches of Crismer have established that aldehyde forms two condensation-products with ethyl malonate, one

$$CHMe : C(COOEt)_2,$$

and the other, $(COOEt)_2CH.CHMe.CH(COOEt)_2$. In the present research, it is shown that aldehyde and malonic acid yield, besides crotonic acid, ethylidene-diacetic acid, $CHMe(CH_2.COOH)_2$. In the course of the study of the reaction between aldehyde or paraldehyde and malonic acid when heated with acetic acid or its anhydride, there was noticed the formation of a small quantity of an oil boiling between 282—284°, which solidified on cooling in the form of prismatic crystals of composition $C_6H_2O_3$, although the principal product of the reaction was crotonic acid. The former compound is soluble in alcohol and ether. It dissolves in hot water as an anhydride of an acid to form a dibasic acid, $C_6H_{10}O_4$, or *ethylidene-diacetic acid*, $CHMe(CH_2.COOH)_2$, which crystallises in small prisms or thick tables, melting at 85°, soluble in water, alcohol, and ether, sparingly soluble in benzene and chloroform. By distillation it is readily decomposed into water and the anhydride. Its lead and calcium salts are crystalline substances.

By the action of aldehyde on ethyl malonate there is formed, besides ethyl ethylidene-malonate, $CHMe : C(COOEt)_2$, the *ethyl salt* of *ethylidenedimalonic acid*, $CHMe[CH(COOEt)_2]_2$ (*vide supra*); but the yield of the latter compound is always small. It is a golden coloured liquid, boiling at 209° under a pressure of 20 mm. As it may also be obtained by heating ethylidene malonate with ethyl malonate, it would appear probable that its formation from ethyl malonate and aldehyde is due to the combination of unaltered ethyl malonate with ethyl ethylidene-malonate, thus:

$$CHMe : C(COOEt)_2 + CH_2(COOEt)_2 = (COOEt)_2CH.CHMe.CH(COOEt)_2.$$

When the ethyl salts of ethylidene malonate and ethylidene dimalonate are saponified with alcoholic potash, they yield ethylenediacetic acid.

Propylidene-acetic acid, CHEt : CH.COOH, and *propylidene-diacetic acid*, $CHEt(CH_2.COOH)_2$, are obtained simultaneously by the action of propaldehyde on malonic acid in the presence of acetic acid. The former is a colourless liquid, resembling crotonic acid in its smell; it boils between 194° and 198°; sp. gr. = 0·9922. Its silver salt is a white, voluminous, sparingly soluble precipitate. The latter, or β-ethylglutamic acid, crystallises in white prisms which melt at 66°, easily soluble in water and alcohol.

Chloral and ethyl malonate react in like manner to form a condensation-product, *ethyl trichlorethylidene-malonate*,

$$CCl_3.CH : C(COOEt)_2,$$

a colourless viscid liquid boiling at 160—164° under a reduced pressure of 23 mm. V. H. V.

Isopropylsuccinic or Pimelic Acid. By W. Roser (*Annalen*, **220**, 271—278).—By acting on sodium malonic ether with ethyl α-bromoisovalerate, the author obtained the ether

$$CHMe_2.CH(COOEt).CH(COOEt)_2,$$

a clear liquid which distils at 276—278°, and has an unpleasant and bitter taste. The free acid obtained by the saponification of the ether with potash, is easily soluble in alcohol, ether, and water, and yields monoclinic needles. It melts at 160°, evolving carbonic anhydride at the same time. The *barium*, *silver*, *lead*, and *iron salts* are very sparingly soluble in water. When heated above its melting point, this acid gives off carbonic anhydride, and yields *isopropylsuccinic acid*. The latter acid is easily soluble in alcohol, ether, and water. It melts at 114°, and gives up water at a higher temperature, yielding its anhydride, which boils at 245—250°. Its *calcium*, *silver*, *lead*, *copper*, and *iron salts* are sparingly soluble in water. These properties agree with those of pimelic acid obtained by Hlasiwetz and Grabowsky from camphoric acid. The identity of the two acids is further proved by the equal solubility of their calcium salts. Ammonium isopropylsuccinate, heated in a stream of ammonia, yields *isopropylsuccinimide*, $C_7H_{11}NO_2$. This imide is easily soluble in alcohol, ether, and light petroleum, more sparingly in water, and crystallises in small needles or tables. It melts at 60°, and distils undecomposed. L. T. T.

Gluconic Acids from different Sources. By A. Herzfeld (*Annalen*, **220**, 335—365).—The author has repeated the researches of Barth and Hlasiwetz, Habermann, Fudakowsky, Hönig, Kiliani, and Grieshammer on the acids obtained by the oxidation of the various carbohydrates. He finds that all the different *gluconic* and *dextronic acids* obtained by these investigators are in reality identical, the varying properties observed being due to the presence of saccharic acid as an impurity. The result is the same, whether the primary action on the carbohydrate be carried out with chlorine or bromine, and whether the halogen compound be decomposed by silver oxide or the oxide of any other metal (lead, &c.), or by carbonates (basic zinc carbonate, &c.). When bromine is used, saccharic acid always accompanies the gluconic acid formed, the quantity being largest when zinc carbonate is used to decompose the halogen compound.

Gluconic acid forms a syrup, is monobasic, and does not reduce Fehling's solution. Its rotatory power for polarised light is $[\alpha]_D = 4\cdot8°$.

Calcium gluconate, $(C_6H_{11}O_7)_2Ca + H_2O$, crystallises in microscopic needles. *Barium gluconate*, $(C_6H_{11}O_7)_2Ba + 3H_2O$, crystallises in rhombohedric scales which are double refracting, and appear to belong to the triclinic system. On long standing over calcium chloride these crystals lose 2 mols. H_2O. A concentrated solution of the barium salt treated with a large excess of barium hydroxide gave a flocculent precipitate having the constitution $C_6H_{12}O_8Ba$.

Contrary to the statements of Wachtel, the author was unable to obtain mannitol by the reduction of gluconic acid. Attempts to prove the number of hydroxyl-groups in the acid by converting it into the acetyl compound were equally unsuccessful. The author believes the formula to be most probably $OH.CH_2(CH.OH)_4COOH$.

L. T. T.

Antimony Derivatives of Mucic and Saccharic Acids. By D. KLEIN (*Compt. rend.*, **97**, 1437—1439).—Antimonious oxide dissolves in a boiling solution of sodium hydrogen mucate, and on evaporation the clear liquid deposits a slightly gelatinous amorphous salt, which is very slightly soluble in cold, but is soluble in hot water. It is purified by solution in hot water, from which it separates on cooling. When dried at 100°, it forms a white porous mass of sodium muco-antimonite, $C_4H_4(OH)_3(SbO)(COONa).COOH$, analogous to ordinary tartar emetic. At 145° it loses H_2O, and at 185° it loses an additional $\frac{1}{2}H_2O$. The residue dissolves in warm water, reproducing the original salt. Above 185° it turns brown and decomposes. The potassium salt is precisely similar in appearance and composition, and can be obtained in the same way.

Ammonium hydrogen mucate solution dissolves antimonic anhydride, and if the solution is gently heated at about 50° it deposits a pulverulent salt on cooling; but if it is boiled, the resulting solution filters slowly, and has all the properties of colloïds, and when concentrated and cooled, it gelatinises. Solutions of sodium hydrogen mucate and potassium hydrogen mucate yield similar products when boiled with antimonic anhydride. These antimony derivatives have no appreciable rotatory power. When a solution of ferric chloride is added in excess to a solution of normal ammonium mucate, a precipitate is produced; this dissolves in ammonia, forming a highly coloured solution which gelatinises after some days.

Mucic acid is much more soluble in a boiling solution of boric acid than in water, but no compound could be obtained similar to that formed by tartaric acid, and the solution has no rotatory power.

The acid saccharates also dissolve antimonious and antimonic anhydrides. Potassium saccharate appears to form non-crystallisable derivatives with both these oxides.

C. H. B.

Action of Methyl Iodide on Leucine and Analogous Compounds. By G. KOERNER and A. MENOZZI (*Gazzetta*, 13, 351—358).—The authors find that the first product of the action of methyl iodide on amidated acids dissolved in potash is generally "the iodide of a trimethylated acid which is at the same time a potassium salt;" in some cases this splits up in the course of the reaction, giving trimethylamine and the potassium salt of a new acid. The results obtained with leucine are described in this paper, but the authors also state that glycocine gives the potassium salt of iodide of trimethylglycocine, and that α-alanine behaves in a similar manner. With β-alanine on the contrary the iodide splits up during the reaction, yielding trimethylamine (which forms trimethylammonium iodide with the excess of methyl iodide) and the potassium salt of a non-azotised acid, behaving in this respect like asparagine and aspartic acid.

When natural leucine obtained from caseïn is treated with methyl iodide and potassium hydroxide, the mixture becomes warm, and a slightly coloured neutral liquid is ultimately obtained. This is evaporated to dryness and extracted with absolute alcohol, which dissolves the potassium salt along with a small quantity of potassium iodide. After two or three crystallisations from alcohol, the salt $C_5H_{10}(NMe_3I)$ COOK is obtained in very slender needles which are hygroscopic and very soluble in water. When the aqueous solution of this salt is treated with a solution of iodine in hydriodic acid, a heavy oil is precipitated which after a time solidifies to a mass of metallic green crystals of periodide of trimethyl-leucine. The *iodide of valero-betaïne*, $C_9H_{20}NO_2I$, may be obtained from this by suspending it in water, passing hydrogen sulphide in excess, filtering from sulphur, evaporating, and crystallising the residue from alcohol. The betaïne forms stellate groups of prisms, very soluble in water, but only sparingly in cold alcohol. It melts at 191° with decomposition, evolving trimethylamine. The iodide can be converted into the *chloride* by treatment with silver chloride. The *aurochloride*,

$$C_6H_{11}O_2.NMe_3Cl,AuCl_3,$$

is deep yellow, and very sparingly soluble in water. It melts at 163°. The *platinochloride*, $(C_6H_{11}O_2.NMe_3Cl)_2,PtCl_4$, is orange-yellow and sparingly soluble.

If the potassium salt of the iodide of trimethyl-leucine is treated with silver hydroxide in slight excess, silver iodide is precipitated, and a strongly alkaline solution is obtained which has a feeble odour of trimethylamine. On distilling it, and heating the residue at 120—130°, large quantities of trimethylamine are given off, and a residue is left; when this is acidulated with sulphuric acid and distilled in a current of steam, oily drops pass over, having a strongly acid reaction. This acid has the formula $C_6H_{10}O_2$, and decomposes carbonates readily. It resembles hydrosorbic acid in many points, but does not seem to be identical with it. It boils at 124—127° under a pressure of 26 mm. The barium, calcium, zinc, and silver salts were prepared; the most characteristic salt is that of cadmium, which crystallises in long prisms united in stellate groups. The acid unites with hydrobromic acid, but the author has not yet examined the product. Trimethylamine, and the acid just described, are not, however, the only products of this reaction, as the liquid left in the retort, after the steam distillation, yields a small quantity of a non-volatile acid when treated with ether; on examination this was found to be leucic acid.

When synthetical leucine obtained from isovaleraldehyde is treated with methyl iodide and potassium hydroxide in the manner above described, it yields the potassium salt of the corresponding iodide, from which the betaïne and its salts may be prepared. When the base from synthetical leucine is decomposed by heat, it yields trimethylamine and two acids, one volatile, $C_6H_{10}O_2$, and the other a non-volatile hydroxy-acid, $C_6H_{12}O_3$. It is interesting to note that the volatile acid, which must have the constitution $CHMe_2.CH:CH.COOH$, is not pyroterebic acid, which confirms the opinion recently expressed by Fittig. The author will shortly describe these products more fully, and also those obtained from the leucine from normal valeraldehyde.

C. E. G.

New Synthesis of Allantoïn. By A. MICHAEL (*Amer. Chem. J.*, **5**, 198—202).—Allantoïn is obtained by heating equal weights of mesoxalic acid and carbamide at 110°. The remainder of the paper consists of speculations on the constitution of uric acid.

A. J. G.

Fluobenzene and Fluotoluene. By E. PATERNÒ and V. OLIVERI (*Gazzetta*, **13**, 533—535).—Fluobenzene, C_6H_5F, is prepared by heating in sealed tubes with strong hydrochloric acid the potassium salt of fluobenzenesulphonic acid, which is formed from sulphanilic acid through the medium of the diazo-compound (Lenz, *Ber.*, **10**, 1135, and **12**, 580). Fluobenzene is a limpid liquid, smelling like benzene, boiling at 85—86°, and not solidifying at $-20°$. Vapour-density, exp. 3·13; calc. 3·36 [H. = 1].[*]

Fluotoluene, C_7H_7F, is obtained in like manner by converting *p*-amidotoluenesulphonic acid into the diazo-compound and decomposing this with hydrofluoric acid. It is a liquid having a very decided odour of bitter almonds, and boiling at 114°. H. W.

Cymene from Homocumic Acid. By E. PATERNÒ (*Gazzetta*, **13**, 535—537).—Cumic compounds contain isopropyl, and cymene contains normal propyl; nevertheless, in the transformations of these bodies, the cumic compounds invariably yield cymene, and cymene on the other hand is converted into cumic compounds. The experiments of Nencki and Ziegler, and those of Jacobsen, have shown that cymene, by oxidation in the animal organism, is converted into cumic acid, and from the recent investigations of Errera (*Gazzetta*, **13**, 421, and p. 300 of this volume), it appears that the action of chlorine on boiling cymene gives rise to cumyl chloride, $C_{10}H_{13}Cl$, identical with that which is obtained from cumyl alcohol, $C_{10}H_{14}O$. On the other hand, Kraut (*Annalen*, **192**, 224), by heating cumyl alcohol with zinc-dust, obtained cymene identical with that from camphor, and with that which Paternò and Spica prepared by reducing cumyl chloride with nascent hydrogen. Granting therefore that cymene contains normal propyl, and that the cumic compounds contain isopropyl, it follows that in the reactions just cited, Pr^{α} is converted with the greatest facility into Pr^{β}. To throw further light upon this question, the author endeavoured to prepare isocymene or isopropylmethylbenzene, $C_6H_4MePr^{\beta}$ = Me $CHMe_2$, by the distillation of homocumic acid, $C_6H_4Me(C_3H_6).COOH$. With this view, the calcium salt of homocumic acid was distilled with lime, whereby a hydrocarbon boiling at 173—175° was obtained, convertible into a sulphonic acid the barium salt of which dried at 100° had the composition $(C_{10}H_{13}SO_3)_2Ba,3H_2O$. This shows that the cymene obtained from homocumic acid is not *p*-methylisopropylbenzene, but ordinary cymene, *i.e.*, *p*-methylpropylbenzene: for it is known that isocymene yields a sulphonic acid the barium salt of which crystallises, according to Jacobsen, with only 1 mol. H_2O.

---

[*] The supposed fluobenzene which Schmidt and Gehren obtained (*J. pr. Chem.* [2], 1, 400), by distilling calcium fluobenzoate with lime was nothing but phenol, agreeing with that compound in composition, boiling point, and vapour-density; no attempt was made by Schmidt and Gehren to determine the fluorine supposed to be present. Paternò and Oliveri, in repeating the experiment, obtained a considerable quantity of pure phenol; and after treating the product with potash, they obtained a liquid boiling above 240°, and probably consisting for the most part of diphenyl oxide.

This constancy of the transformation of cumic compounds into ordinary cymene, and the reverse, seems to indicate the identity of the radicle C_3H_7 contained in the two classes of compounds; but the synthesis of propyl- and isopropyl-benzene, and the isomerism of cumic and normal propylbenzoic acids, are facts too well established to render such a view admissible. H. W.

Metabenzyl-toluene, Metatolyl Phenyl Ketone, Metabenzoyl-benzoic Acid, and their Reduction Products. By P. SENFF (*Annalen*, **220**, 225—253).—Metabenzyltoluene was obtained by the action of aluminium chloride on a mixture of xylyl chloride and benzene. The best yield is obtained when xylyl chloride is mixed with about 6—8 times its weight of benzene, about 1—2 per cent. of aluminium chloride added, and the whole gently heated on the water-bath. Before distillation the resulting liquid must be washed with water to free it from intermediate aluminium compounds. The fraction passing over between 260—280° was digested for five hours with sodium to free it from traces of an oxygenated compound from which it could not be separated by fractionating. *Metabenzyltoluene* is a colourless liquid, of slightly aromatic odour, and becomes viscid at low temperatures. It boils at 275° (col. in vapour) at 747 mm. pressure, and has sp. gr. 0·997 at 17·5°. It is easily soluble in alcohol, ether, benzene, chloroform, and glacial acetic acid. From the high-boiling bye-products the author isolated *dixylylbenzene*, a yellowish oil boiling at 392—396°, and soluble in alcohol, ether, and glacial acetic acid; and also a body boiling between 210—220°, which he believes to be *dimethylanthracene*, but has not obtained it quite pure. *Dinitrometabenzyltoluene* was prepared by the action of a large excess of nitric acid (sp. gr. 1·4) at 90°. It melts at 141°, is soluble in boiling alcohol, benzene, and glacial acetic acid, and crystallises in long needles. *Dinitrometatolyl phenyl ketone* was prepared by the oxidation of the dinitro-body in acetic solution by means of chromic acid. It melts at 145°, and is easily soluble in benzene, chloroform, boiling acetic acid, and alcohol, and crystallises in needles or short prisms.

Metabenzoylbenzoic acid, $C_6H_4\overline{Bz}.COOH$, was obtained by the oxidation of the hydrocarbon by means of chromic acid. The results when nitric acid was used were not satisfactory. In both cases the acid obtained gave no constant melting point (the latter generally varying between 140 and 144°), and consisted of a mixture of meta- and para-acid. Metatolyl phenyl ketone was also produced in each case. A partial separation was effected by means of the different solubility of the calcium salts in alcohol, but it was very imperfect. A good result was obtained by converting the mixed acids into benzhydrilbenzoic acid by reduction with sodium amalgam and water. The sodium salt of the meta-acid crystallised out, leaving that of the para-acid in solution. The metabenzhydrilybenzoic acid is easily reoxidised with chromic acid. *Metabenzoylbenzoic acid* is sparingly soluble in cold water, more easily in hot. Alcohol and ether dissolve it readily. It crystallises from acetic acid or water in needles, from dilute alcohol in scales. It dissolves in concentrated sulphuric acid without discoloration. It melts at 161°, and sublimes at a higher temperature. The *barium salt* is pretty freely soluble in water, sparingly so in absolute alcohol, and crystallises under varying circumstances with 2, 3, and 4 mols. H_2O. The *calcium salt* is soluble in water and alcohol; the *silver salt* forms a white amorphous powder almost insoluble in water. The *methyl ether*, prepared from the silver salt, crystallises in prisms soluble in alcohol and ether, and melting at 62°. A much better yield of benzoylbenzoic acid is obtained by oxidising the monobromine-derivative (prepared by passing the vapour of bromine into benzyltoluene heated to 120—130°) in place of the hydrocarbon.

Metabenzhydrilbenzoic acid, $CHPh(OH).C_6H_4.COOH$, obtained, as already mentioned, by the reduction of benzoylbenzoic acid, crystallises in small silky needles melting at 121°, and decomposing at a slightly higher temperature. This acid is easily soluble in alcohol, ether, and benzene, and dissolves in sulphuric acid to an orange solution. The *sodium salt*, $C_{14}H_{11}O_3Na + 4H_2O$, crystallises in fine white needles, melting at 90° in their water of crystallisation, which they lose at 160—180°. It is more easily soluble in alcohol than in water. The *calcium salt* forms a crystalline powder containing 5 mols. H_2O. It is easily soluble in alcohol and ether. The *silver salt*, $C_{14}H_{11}O_3Ag + H_2O$, is precipitated as a white powder, which is slightly soluble in boiling water and crystallises from this solution in small needles.

Metabenzylbenzoic acid, $CH_2Ph.C_6H_4.COOH$, was obtained by the reduction of metabenzhydrilbenzoic acid. The reduction may be effected by the continued action of sodium amalgam on an alcoholic solution of the latter acid, but the reaction is *very* slow. The best method is to heat benzhydrilbenzoic acid with an excess of hydriodic acid (b. p. 127°) in sealed tubes at 170° for three hours; the yield is very nearly equal to theory. Metabenzylbenzoic acid is easily soluble in alcohol, ether, and chloroform, sparingly in cold, more easily in hot water, and crystallises from the latter in minute needles. From dilute alcohol, it crystallises in scales. It melts at 107—108°, and sublimes at a higher temperature. It dissolves in concentrated sulphuric acid without discoloration, and is oxidised by chromic acid to metabenzoylbenzoic acid. The *calcium salt* forms a crystalline powder containing 1 mol. H_2O, and is easily soluble in alcohol and water. The *barium salt* crystallises with $4H_2O$, and is soluble in water and alcohol. The *silver salt* forms a light white powder slightly soluble in boiling water and alcohol, and crystallising from these solutions in small needles.

The author also prepared metabenzylbeuzoic acid by the action of aluminium chloride on $CH_2Br.C_6H_4.COOH$ dissolved in benzene. Toluic acid was obtained by oxidising xylyl chloride prepared from ordinary xylene with nitric acid (1 vol. acid to 3 vols. water). This acid was then brominated at 160—170°, so as to insure the bromine entering the Me-group, and the crude benzylbenzoic acid was purified by conversion into the barium salt. The yield never exceeded 50 per cent. of theory, so that the reduction of the easily obtainable benzhydrilbenzoic acid is by far the better method for the preparation of this acid.

By the oxidation of Zinke's benzyltoluene (from benzyl chloride, toluene, and zinc-dust), and of the products of the action of water on benzyl chloride, small quantities of ortho- and para-benzoylbenzoic acid were obtained; in the latter case a trace of the meta-acid was also detected. Zinc chloride acting on a mixture of benzoic chloride and ethyl benzoate yielded a little ethyl metabenzoylbenzoate, but no ortho- or para-ether. When benzyl chloride was substituted for benzoic chloride in the last reaction, only condensation-products from the chloride were obtained.

Metaphenyl tolyl ketone is, as already mentioned, always amongst the products of oxidation of benzyl toluene. It is a colourless, slightly aromatic oil, boiling at 314—316° (col. in vapour and bar. 745 mm.). Its density at 17·5° is 1·088. It is miscible with alcohol, ether, benzene, chloroform, and acetic acid in all proportions.

L. T. T.

Quinone. By B. Scheid (*Annalen*, 218, 195—231).—In order to throw some light on the constitution of the quinones, the author has studied the action of phosphorus pentachloride and oxychloride, acetic chloride, and other substances on it.

With quinone phosphorus pentachloride forms monochloroquinol, together with smaller quantities of dichloroquinol, the former of which is readily converted into monochlorquinhydrone. Phosphorus oxychloride gives monochloroquinol only. By the action of phosphorus pentachloride on quinol, a product intermediate between

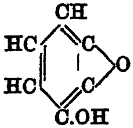
$$C_6H_4.OPCl_2.OH \text{ and } C_6H_4(OPCl_2)_2$$

is obtained, formed by the successive replacements of hydroxyl groupings by the $(OPCl_2)$ group thus:—

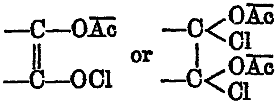
$$C_6H_4(OH)_2 + PCl_5 = C_6H_4(OH).OPCl_2 + HCl$$
$$\text{and } C_6H_4(OH).OPCl_2 + PCl_5 = C_6H_4(OPCl_2)_2 + HCl.$$

Quinol is reformed on decomposing the mixed product with water.

Acetic chloride acting on quinone or monochloroquinol produces monochlorodiacetylquinol, with evolution of hydrochloric acid, in accordance with the equation $C_6H_4O_2 + 2\overline{Ac}Cl = C_6H_3Cl(O\overline{Ac})_2 + HCl$. It would appear probable from the above reaction that quinone has an oxygen-atom combined with carbon only, whilst the other is combined with carbon and hydrogen (the hydroxyl-group). It would thus have the constitution of a glycide phenol, thus—



The other formulæ proposed for quinone, in which the oxygen is combined with the carbon as in a ketone, or the two oxygen-atoms are combined with another thus: $\equiv C—O—O—C\equiv$, would involve the intermediate formation of compounds—



and the subsequent interchange of hydrogen for chlorine in the hydrocarbon grouping.

By the action of acetic chloride or anhydride on quinol, diacetylquinol is also formed.

Quinone was also treated with potash, water, carbon oxychloride, and sulphuryl hydroxychloride, but the results were unsatisfactory.

V. H. V.

Quinone. By O. HESSE (*Annalen*, **220**, 365—367).—Scheid (*Annalen*, **218**, 217) contends that the evolution of hydrochloric acid by the action of acetic chloride on quinone proves the presence of a hydroxyl-group in the latter body. The author believes that this reaction is rather to be explained according to the equations:

$$\text{(i.)}\ C_6H_4O_2 + 2\overline{Ac}Cl = C_6H_4(O\overline{Ac})_2 + 2Cl$$
$$\text{(ii.)}\ C_6H_4(O\overline{Ac})_2 + Cl_2 = HCl + C_6H_3Cl(O\overline{Ac})_2,$$

and is thus similar to the production of chloroquinol from quinone and hydrochloric acid. He believes that the acetyl-derivatives of quinone said to have been obtained, are really derivatives of quinol formed by the decomposition of quinone. Acetic anhydride brings about this decomposition only at temperatures above 200°, but quinone, in an aqueous solution of sodium acetate, is slowly decomposed at ordinary temperatures, a part being converted into quinol; the acetate, however, remains unchanged. The decomposition takes place more rapidly if the solution is heated.

Trichloroquinone-chlorimide, Tri- and Tetra-chloroquinone. By M. ANDRESEN (*J. pr. Chem.* [2], 28, 422—436).—Former research has shown (Abstr., 1882, 400) that by the action of aniline on trichloroquinone, dichloroquinone-dianilide is formed, and not as Schultz and Knapp (*Annalen*, 210, 181) have stated, monochloroquinone-dianilide. By the action of aniline on tetrachloroquinone and trichloroquinone-chlorimide dichloroquinone-dianilide is also formed, along with the compound monochlorodianilide-phenylquinoneimide, (?)$C_6Cl(NHPh)_2ONPh$. This latter substance is obtained in quantity by adding aniline to dichloroquinone-chlorimide in the proportion of 5 mols. to 1. It crystallises from hot alcohol in long needles melting at 195°. Nitrous acid passed into the alcoholic solution converts it into a nitroso-compound crystallising in green plates, which in pure alcohol are immediately reconverted into the original substances. Unlike dichloroquinone-dianilide it is not decomposed by boiling with alkalis in aqueous solution, but on adding alcohol a reaction does take place, and it dissolves to a red-coloured solution of a disodium compound, $C_{24}H_{17}ClN_3ONa_2$. On evaporation, this sodium compound crystallises in red needles, which dissolve in pure alcohol with immediate separation of the original substance. By the action of hydrochloric acid in alcoholic solution, it is decomposed with separation of aniline into monochloroquinone-dianilide, which, however, differs from that obtained by Schultz and Knapp.

Hydrochloric and hydrobromic acids have a reducing action on trichloroquinone-chlorimide. On treating the substance dissolved in pure benzene with dry hydrochloric acid gas, trichloroquinonimide hydrochloride is formed, whilst chlorine is given off. This body is decomposed by water into ammonium chloride and trichloroquinone. On treating trichloroquinone-chlorimide directly with hydrochloric acid in aqueous solution, it is decomposed into trichloroquinone, ammonium chloride, and chlorine, part of the chlorine being given off and part converting some of the trichloroquinone into tetrachloroquinone. Hydrobromic acid acts in an analogous way, yielding trichloroquinone, ammonium chloride, bromine, and some bromotrichloroquinone.

A. B.

Diiodoquinone and Diiodoquinone-chlorimide. By R. SEIFERT (*J. pr. Chem.* [2], 28, 437—438).—Diiodoparanitrophenol (Körner, *ibid.*, 1868, 324) yields diiodoparamidophenol by reduction with tin and hydrochloric acid. If this is suspended in a slightly acid solution and treated with chloride of lime solution, it yields diiodoquinone-chlorimide, $C_6H_2I_2<\overset{O}{\underset{N}{}}>Cl$, melting at 123°, but decomposing at a higher temperature. With dimethylaniline it yields diiodoquinone-dimethylanilide, analogous to trichloroquinone-dimethylanilide (Abstr., 1882, 400). Chromic mixture oxidises diiodoparamidophenyl sulphate to diiodoquinone, $C_6H_2I_2O_2$, crystallising from hot alcohol in yellow prisms, and melting at 178°. By boiling with stannous chloride, it yields diiodoquinol, crystallising from hot aqueous solution in long white needles, and melting at 145°; ferric chloride reconverts it into the diiodoquinone. The author is continuing his research on these compounds.

A. B.

Arbutin. By H. Schiff (*Gazzetta*, **13**, 538—513; also *Annalen*, **221**, 365—379).—The author has already stated (*Gazzetta*, **11**, 99; Abstr., 1881, 610) that he did not succeed in separating methylarbutin from arbutin, either by the use of solvents or by partial fusion of the natural mixture of these two glucosides. Afterwards he obtained methylarbutin by the action of methyl iodide on a solution of natural arbutin in caustic potash (*Ber.*, **15**, 1841; and 1883, Abstr., 60); and in order to compare this methylarbutin with the natural compound and separate the latter from arbutin, he has endeavoured to introduce a higher alcohol-radicle into arbutin, and thereby transform it into a compound considerably less soluble than methylarbutin. The treatment of arbutin with isopentyl bromide (amyl bromide) did not yield the desired result, as oily bodies were formed at the same time, which impeded the crystallisation, and could not easily be removed. The isopentylarbutin produced in this reaction crystallised in needles and was resolvable into glucose and isopentylquinol, an oily liquid, convertible by cold dilute nitric acid into a nitro-derivative which crystallised in small yellow needles, melting at the heat of boiling water, and forming a dark orange-coloured crystalline compound with ammonia.

The separation of the methylarbutin was more easily effected by converting the arbutin into benzylarbutin, viz., by the action of benzyl bromide and potassium hydroxide on natural arbutin, whereby the benzylarbutin is precipitated almost completely in the form of a crystalline mass. The filtered solution is then evaporated and the methylarbutin is extracted from the residue with absolute alcohol, decolorised with animal charcoal, and purified by recrystallising it several times from water. Natural methylarbutin thus prepared, crystallises in long white needles, having, like the artificial compound, the formula $C_{13}H_{18}O_7,H_2O$, melting at 174°, and recrystallising at 120—125°. The artificially prepared compound, probably more free from impurities, melted at 175—176°. Natural methylarbutin does not give a blue colour with ferric chloride, does not reduce potassiocupric solutions, and behaves in every way like the artificial compound, with which it is doubtless identical.

Benzylarbutin, $C_{19}H_{22}O_7H_2O = C_6H_{11}O_5.O.C_6H_4.O.CH_2Ph,H_2O$, prepared as above, dissolves in 530 pts. water at 23°, much more freely in boiling water, and crystallises therefrom on cooling in branches of small colourless needles which melt at 161°, give off 1 mol. H_2O, and may be heated to 250° without alteration beyond a slight brown coloration. It does not reduce potassio-cupric solutions, unless previously heated with dilute sulphuric acid, in which case it is easily resolved into glucose and benzylquinol.

Benzylquinol, $HO.C_6H_4.OC_7H_7$, thus prepared, separates almost completely on cooling, being much less soluble in cold water than benzylarbutin. It dissolves readily in alcohol, ether, benzene, and boiling water, and separates from the latter in large scales, having a brilliant silvery lustre, melting at 121—122·5°, recrystallises at about 110°, and is identical in every respect with the compound which Pellizzari has obtained by the action of benzyl bromide on quinol (p. 437 of this volume).

Benzylnitroarbutin, $C_{19}H_{21}(NO_2)O_7$, is prepared by gradually adding finely pulverised benzylarbutin to strong colourless nitric acid, avoiding all rise of temperature. It then dissolves readily and in large quantity without emission of red vapours, and the solution after some hours deposits a crystalline mass, which by two crystallisations from water containing a little acetic acid, yields benzylnitroarbutin in yellowish needles, acquiring a somewhat darker colour when dried in the air, especially in the ammoniacal atmosphere of a laboratory. It is less soluble in cold water than benzylarbutin. The crystals contain 1 mol. water, which they give off at 110—115°, and the anhydrous compound melts at 142—143°, at the same time turning brown and decomposing.

Benzylnitroquinol, $HO.C_6H_3(NO_2).OC_7H_7$, is formed by heating an aqueous solution of benzylnitroarbutin with dilute sulphuric acid, and crystallises from boiling water in long gold-coloured needles, melting with complete decomposition at 156—158°. With ammonia it forms a compound which crystallises in shining scales having the colour of cinnabar. The potassium-compound forms red needles.

When benzylquinol is treated with nitric acid, without previous separation from benzylarbutin, the process being otherwise conducted exactly as above directed, gold-coloured needles are obtained, agreeing with those just described in every respect, excepting that they melt at 137° without decomposition, the fused mass recrystallising as it cools.

The nitro-derivatives of benzylquinol obtained by the author, and that of dibenzylquinol obtained by Pellizzari (p. 437), may be represented by the following constitutional formulæ:—

Benzylnitroquinol	$C_6.\overset{1}{O}H.\ \ \overset{2}{N}O_2.H.O\overset{4}{C}_7H_7.H.\overset{6}{H}$
Benzyldinitroquinol	$C_6.OH.\ \ NO_2.H.OC_7H_7.H.NO_2$
Dibenzylnitroquinol	$C_6.OC_7H_7.NO_2.H.OC_7H_7.H.H.$

Experiments on the Preparation of Nitrophenetoïl. By H. Kolbe (*J. pr. Chem.* [2], 28, 62—63).—In a previous paper on "A Simple Method for Preparing Phenetoïl" (Abstr., 1883, 1113), it was remarked that probably nitrophenetoïl might be obtained by heating a salt of hydrogen ethyl sulphate with sodium nitrophenate as easily as phenetoïl is prepared from potassium ethyl sulphate and sodium phenate. On making the experiment in open apparatus, it was found that but very little product was obtained, either from ortho- or from para-nitrophenol, and on employing sealed tubes, these exploded before the temperature had reached 150°. H. B.

Ethylene Ethers of the Nitrophenols and Hydroxybenzoic Acids. By E. Wagner (*J. pr. Chem.* [2], 27, 199—230).—Weddige (Abstr., 1881, 1136) has shown that when ethylene bromide acts on the sodium-derivative of mononitrophenol, two different compounds are produced, the ether, $(NO_2.C_6H_4O)_2C_2H_4$, and the bromhydrin, $NO_2.C_6H_4O.C_2H_4Br$. It is the former compound and some of its derivatives which form the subject of the first part of the author's paper.

Ethylene Amidophenyl Ethers.—The ethylene nitrophenyl ethers used in preparing these compounds were obtained by heating ethylene bromide (1 mol.) with the sodium nitrophenate (2 mols.) at 140°. The product is treated with alcohol, the insoluble residue washed with cold water to remove sodium bromide, and then with boiling alcohol to remove the last traces of the bromhydrin produced at the same time; the nearly pure nitro-ether, which remains as a white pulverulent mass, is sparingly soluble in benzene and almost insoluble in cold alcohol. The melting points of the three isomerides are as follows:—

Ethylene orthonitrophenyl ether	163°
Ethylene metanitrophenyl ether	139°
Ethylene paranitrophenyl ether	143°

The amido-ethers are obtained from the corresponding nitro-ethers by reduction with tin and hydrochloric acid; as the mixture cools, the tin double salt of the amido-ether separates in large colourless crystals, which are sparingly soluble in cold water, but easily in hot water acidified with hydrochloric acid. The dilute solution of the tin salt is decomposed by hydrogen sulphide, and filtered from the stannous sulphide, which must be well washed with boiling water to dissolve out adhering amido-hydrochloride, and the filtrate and washings concentrated as rapidly as possible, as the amido-compound is easily oxidised. As the dark solution cools, it deposits the hydrochloride of the ethylene amido-ether in tufts of long plates in the case of the ortho-, and needles in the case of the meta-compound. On adding sodium carbonate to the aqueous solution of the crude hydrochloride, the base is separated in the free state, and after being collected on a vacuum-filter and washed with a little water, it is purified by one or two crystallisations from hot absolute alcohol. *Ethylene orthamidophenyl ether*, $(NH_2.C_6H_4O)_2C_2H_4$, crystallises from hot alcohol or water in lustrous white or reddish rhombic plates which melt at 128°. It is insoluble in cold water, but easily soluble in most of the usual solvents. It is diacid, and dissolves easily in acids, forming crystalline salts. *Ethylene paramidophenyl ether* crystallises in needles which melt at 168—172°. It is easily soluble in benzene, but differs from its isomeride in being sparingly soluble in chloroform and ether. *Ethylene metamidophenyl ether* forms reddish prisms which melt at 135°, and resembles the para-compound. The reactions of these three bases with various reagents are given in the accompanying table.

	Ortho-ether.	Para-ether.	Meta-ether.
H_2SO_4, cold	Blue-black colour	Indigo-blue	Dark-brown coloration
H_2SO_4, hot	Dirty violet colour	Ditto	Dark-brown coloration
Fe_2Cl_6	Sepia brown	Cherry-red colour	Brownish-black
Chromic mixture	Alizarin-red colour	Intense blue-violet coloration and formation of quinone	Ditto

Ethylene orthamidophenyl ether hydrochloride is obtained pure by dissolving the base in warm dilute hydrochloric acid; on cooling, it crystallises out in stellate groups of silvery, flat needles, containing 2 mols. H_2O. When heated at 110—150°, part of the salt sublimes in woolly needles, but the greater part is destroyed. On adding platinic chloride to the aqueous solution of the hydrochloride, a golden-yellow crystalline precipitate of the platinochloride is produced, but it rapidly alters and decomposes. The other salts of the base may be prepared in a manner similar to the hydrochloride. Of these the sulphate is the least soluble in water, whilst the acetate is very soluble. The oxalate and nitrate were both prepared, and are crystalline. *Ethylene acetyl-orthamidophenyl ether*, $(NH\overline{Ac}.C_6H_4O)_2C_2H_4$, is formed by the action of acetic anhydride on the base; the brown crystalline product is treated with alcohol to remove unaltered base, and crystallised from boiling aniline. It forms long needles which melt at 226°. It may also be prepared by heating the base with excess of glacial acetic acid at 160° for some hours. When heated in a retort it is decomposed, a dark yellow oil passing over, whilst a carbonaceous residue is left. The distillate consists of the free base, and a yellow oil of penetrating odour and very high boiling point, but no anhydro-base is formed; attempts to obtain a body of this class by the action of benzaldehyde on the base and on its hydrochloride were also unsuccessful.

Ethylene paramidophenyl ether hydrochloride, prepared in a similar manner to the salt of the ortho-base, crystallises in long colourless slender needles, which contain no water of crystallisation; it is easily soluble in water. The *sulphate* is sparingly soluble; the nitrate and oxalate were also prepared.

Ethylene metamidophenyl ether hydrochloride closely resembles the para-salt. The sulphate, nitrate, and oxalate were also prepared. On adding a concentrated solution of the nitrate of the meta-base to a solution of diazobenzene nitrate, it becomes first yellow, then red, and after a time deposits a red amorphous substance analogous to chrysoidine in its properties, capable of dyeing silk orange-yellow. On adding sodium carbonate to a hot solution of the dye, a few dirty yellow flocks are thrown down, which, after recrystallisation from boiling water, form yellow scales melting at 133—136°; analysis, however, showed that they were merely the original metamidophenyl ether coloured by the yellow azo-dye.

Part II of the paper gives a description of ethylenephenol-oxybenzoic acids and some of their derivatives.

Ethylic ethylene-orthonitrophenol-orthoxybenzoate,*

$$NO_2.C_6H_4O.C_2H_4.OC_6H_4.COOEt,$$

is prepared by digesting ethylic potassium salicylate with bromethylene orthonitrophenyl ether in alcoholic solution for some days; the alcoholic solution is then poured off from the solid residue consisting of salicylethylene orthonitrophenol ether and potassium bromide, the alcohol removed by evaporation, and the residue freed from ethylic

---

* Ethylene-orthonitrophenol-orthoxybenzoic acid,

$$NO_2.C_6H_4O.C_2H_4.OC_6H_4.COOH,$$

might be more consistently named orthonitrophenoxethylene-orthoxybenzoic acid, and the nomenclature of the other acids changed in a similar manner.—C. E. G.

salicylate by steam-distillation; the yellow viscous oily residue contains the ether in small quantity; it may be extracted by warm dilute alcohol, but the author was unable to obtain it in a state of purity. It is a yellow powder, consisting of microscopic needles which melt at about 100°, insoluble in water, but soluble in most of the usual solvents. It is saponified by boiling with soda-solution, yielding a sodium salt of the corresponding acid, but the greater portion of the substance undergoes further decomposition. The acid may, however, be obtained from the yellow viscous oil previously mentioned by heating it for several days at 130—140° with concentrated hydrochloric acid (6—8 parts), repeating the treatment several times. On treating the oily product with soda, the acid is dissolved, and may be precipitated by acids in reddish-brown flocks, which crystallise from hot alcohol in small yellow needles melting at 142—148°. The yield, however, is very small.

When the solid residue of potassium bromide and *salicylethylene orthonitrophenol ether*, $OH.C_6H_4.COO.C_2H_4.C_6H_4.NO_2$, mentioned above, is washed with cold water, the ether is left behind, and may be purified by repeated crystallisation from boiling alcohol, when it is obtained in transparent yellow plates melting at 106°. It is decomposed by soda solution or when heated with concentrated hydrochloric acid, salicylic acid and an oily body being produced. When treated with tin and hydrochloric acid it dissolves easily, yielding salicylic acid and the hydrochloride of a base, $NH_2.C_6H_4O.C_2H_4.OH$. The free base forms small colourless plates which melt at 90°, and rapidly become brown on exposure to the air.

When ethylene-orthonitrophenol-oxybenzoic acid is reduced with tin and hydrochloric acid, it yields the salt of the corresponding amido-acid, from which the hydrochloride may be obtained in the usual way; this forms small colourless needles melting at 177°, whilst the free amido-acid crystallises in small thick colourless prisms melting at 110°.

Ethylic Ethylene-paranitrophenol-orthoxybenzoate, obtained from bromethylene paranitrophenol ether in a manner similar to the corresponding ortho-compound, crystallises in long thick pale yellow needles melting at 81°, whilst the free acid forms long colourless needles melting at 132°; its salts are colourless. The *salicylethylene paranitrophenyl ether*, corresponding in composition, mode of formation, and properties with the isomeric ortho-compound previously described, melts at 131°.

Ethylic potassium-parahydroxybenzoate reacts sharply with bromethylene ortho- and para-nitrophenyl ethers, yielding a series of compounds analogous to those obtained with salicylic acid.

Ethylic ethylene-orthonitrophenol-paroxybenzoate forms yellow lustrous plates melting at 103°; it yields orthonitraniline when heated with ammonia at 140°. The free acid obtained by heating the ethylic salt with hydrochloric acid crystallises in colourless needles melting at 205—207°. The amido-acid forms broad needles melting at 185°.

Ethylic ethylene-paranitrophenol-paroxybenzoate melts at 131°, and the free acid at 218°; it is reduced by tin and hydrochloric acid, but the corresponding amido-acid could not be isolated.

Ethylic ethylene-phenolparoxybenzoate, $OPh.C_2H_4.OC_6H_4.COOEt$, is formed by the action of bromethylene phenyl ether on ethylic potassium-parahydroxybenzoate; it crystallises in colourless shining plates which melt at 81°, and on saponification yields the potassium salt of the ethylene-phenolparoxybenzoic acid. The free acid crystallises from hot alcohol in long silky needles melting at about 196°, sparingly soluble in benzene and chloroform. The properties of the various isomerides described in the paper are there given in tabular form for comparison.
C. E. G.

Benzylic Ethers of the Dihydroxybenzenes. By G. Pellizzari (*Gazzetta*, **13**, 501—507; also *Annalen*, **221**, 365—379).—1. Benzylquinols.—These compounds, $C_6H_5(C_7H_7)O_2$ and $C_6H_4(C_7H_7)_2O_2$, are formed when quinol dissolved in a small quantity of alcohol, and benzyl bromide, in molecular proportions, are made to act on one another in presence of alcoholic potash. The action commences at ordinary temperatures, and is quickly completed on heating, the solution turning brown and depositing crystals of potassium bromide. When all the benzyl bromide is decomposed, a small quantity of sulphuric acid is added and then water, whereby a crystalline substance is thrown down, part of which is dissolved out by alcohol, together with the whole of the colouring matter, while a nearly white substance remains behind.

Monobenzylquinol, $C_6H_4(OC_7H_7).OH$ $[OC_7H_7 : OH = 1 : 4]$, is the portion of the product which dissolves in alcohol. It may be freed from colouring matter by recrystallisation from boiling alcohol, and is deposited therefrom on cooling in silvery laminæ melting at 122°, very soluble in alcohol, ether, chloroform, and benzene, slightly soluble in boiling water, extremely soluble in aqueous potash. The compound thus prepared agrees in every respect with the benzylquinol which H. Schiff obtained from benzylarbutin.

Dibenzylquinol, $C_6H_4(OC_7H_7)_2$, is the white crystalline substance above mentioned, sparingly soluble in alcohol. When dissolved in boiling alcohol, it separates on cooling in beautiful shining laminæ, melting at 130°, insoluble in water and in aqueous potash, moderately soluble in benzene, ether, and chloroform.

Benzyldinitroquinol, $C_6H_2(NO_2)_2(OC_7H_7).OH$, is prepared by throwing pulverised monobenzylquinol by small portions into cooled strong nitric acid, and crystallises from alcohol in splendid golden-yellow laminæ, soluble in ether, benzene, and boiling water, melting at 137°. When treated with potash, it forms red needles of a potassium derivative which, when left in a vacuum, give off 1 mol. crystal-water, their cinnabar-colour changing at the same time to a dark-red colour, with splendid metallic reflex. On exposure to the air, the compound recovers its molecule of water and its original colour. It detonates strongly when heated.

When dry ammonia-gas is passed over the dinitro-compound contained in a tube, the substance becomes heated and assumes a fine blood-red colour, which, if the passage of the gas be continued, slowly changes to a brick-red; but on subsequently passing a current of dry air over the product, the original blood-red colour is restored. These changes indicate the formation of two different compounds, and analysis shows that the brick-red substance has the composition

$$C_6H_2(NO_2)_2(OC_7H_7).OH,NH_3,$$

while the blood-red compound contains a double proportion of ammonia, being represented by the formula

$$C_6H_2(NO_2)_2(OC_7H_7).OH,2NH_3.$$

The monammonia compound is stable, and may be recrystallised withou[illegible]ion, whereas the diammonia compound is stable only in an atmosphere of ammonia.

Dibenzylnitroquinol, $C_6H_3(NO_2)(OC_7H_7)_2$, is formed on throwing finely pulverised dibenzylquinol into strong nitric acid, and applying a gentle heat, whereupon the mass assumes a lemon-yellow colour, and when crystallised from alcohol, yields long yellow needles of the dinitro-compound. This body does not contain a free hydroxyl-group, and consequently does not yield any metallic derivatives.

On treating the two nitro-compounds dissolved in acetic acid with stannous chloride, the formation of amido-compounds was indicated by the red colour which the products gave with furfural; but their stannochlorides were too soluble, and their hydrochlorides too unstable, to admit of quantitative determination.

BENZYL-RESORCINOLS.—*Dibenzylresorcinol*, $C_6H_4(OC_7H_7)_2$ [1 : 3], is prepared like the corresponding quinol derivative, and separates from solution in hydrochloric acid, on addition of water, as a very dense syrupy mass, which dissolves in alcohol, and is deposited therefrom in white shining scales melting, after purification, at 79°.

The product thus obtained did not appear to contain any monobenzylresorcinol, but this compound may be obtained, together with the dibenzyl-derivative, by leaving resorcinol and benzyl bromide in molecular proportion in contact with aqueous potash, and agitating the mixture at intervals for several days till all the benzyl bromide is decomposed.

In this manner, a semi-fluid mass is formed, containing dibenzylresorcinol and a supernatant alkaline liquid, from which acids throw down yellowish flakes of a compound having nearly the composition of *monobenzylresorcinol*, $C_6H_4(OC_7H_7).OH$. Analysis 78·55 C and 6·00 H; calc. 78·00 C and 6·00 H. This substance, after washing on a filter, forms a solid amorphous mass, soluble in alcohol, benzene, ether, acetic acid, and chloroform, but does not separate from these solutions in crystalline form. Both the benzylresorcinols become resinised on treatment with strong nitric acid.

DIBENZYLCATECHOL, $C_6H_4(OC_7H_7)_2$ [1 : 2], prepared like its analogues above described, crystallises from alcohol in needles having a very faint yellow colour, and melting at 61°. It dissolves in the ordinary solvents, and is converted by nitric acid into a nitro-derivative, which crystallises in opaque yellow needles melting at 98°.

The portion of the product which is soluble in aqueous potash separates therefrom, on addition of an acid, as a somewhat mobile liquid, which decomposes at about 200°, but may be distilled with steam. With ferric chloride, it gives a faint violet coloration, indicating the presence of a hydroxyphenol: hence it is probably monobenzylcatechol. Strong nitric acid converts it into a solid mass, which crystallises from alcohol in yellow shining needles melting at 129°. H. W.

Synthetical Researches in the Glucoside Group. By A. MICHAEL (*Amer. Chem. J.*, 5, 171—182; cf. Abstr., 1879, 1038).—*Tetracetylphenolglucoside*, $C_6H_7O(OPh)(O\overline{Ac})_4$, is prepared by heating a mixture of 1 part of phenolglucoside with 5 parts of acetic anhydride and 2 parts of fused sodium acetate on the water-bath for three hours. It crystallises in long white glistening needles, is insoluble in cold, sparingly soluble in hot water and in cold alcohol, readily soluble in hot alcohol. It seems to suffer slight decomposition when the alcoholic solution is boiled for a few minutes, as the odour of acetic ether becomes decidedly perceptible. It does not reduce Fehling's solution, except on long-continued boiling.

Synthesis of Salicin from Synthetical Helicin.—Lisensko having shown that helicin prepared from salicin is reconverted into the latter by the action of sodium-amalgam (*Zeitsch. Chem.*, 1864, 577), the author thought it advisable to repeat the experiment with helicin synthesised from sodium salicylaldehydye and acetochlorhydrose, and finds the product to be identical with natural helicin. This is the first known instance of the synthesis of a natural glucoside.

By the action of dipotassium salicylate on acetochlorhydrose there is obtained, not as was expected, the glucose of salicylic acid, but a body, $C_{26}H_{30}O_{15}$, standing to it in the relation of an anhydride or ether. It crystallises in long white needles, melts at 184—185°, is insoluble in cold, sparingly soluble in hot water or in cold alcohol, readily soluble in warm alcohol. It does not reduce Fehling's solution. It is insoluble in cold aqueous ammonia, but on boiling a gradual solution is effected; it is also soluble in aqueous potash; these solutions reduce Fehling's solution, and probably contain salicylglucoside. The acetyl-compound, $C_{26}H_{22}O_{15}\overline{Ac}_8$, forms long white needles, melts at 110—111°, is insoluble in water, soluble in alcohol.

Synthesis of Methylarbutin.—The potassium-derivative of quinolmonomethylin, $C_6H_4(OMe).OK$, was prepared by mixing equivalent quantities of potassium ethoxide and quinolmonomethylin in alcoholic solution and adding large excess of ether, when the potassium compound is precipitated as a white crystalline powder. This is dissolved in absolute alcohol, acetochlorhydrose added, and the solution allowed to stand for several days, the deposited potassium chloride filtered off, and the liquid allowed to evaporate spontaneously. *Methylarbutin*, $2C_{13}H_{18}O_7 + H_2O$, so obtained, crystallises in long, colourless, silky needles, melts at 168—169°, and resolidifies at 137—138°, is readily soluble in water and alcohol, insoluble in ether. It is not precipitated by basic lead acetate nor copper salts, and does not reduce Fehling's solution, but is rapidly decomposed into dextrose and quinol monomethylin on digestion with dilute acids. It is distinguished from arbutin by not giving a blue coloration with ferric chloride; this is in accordance with the formula $C_6H_{11}O_5.O.C_6H_4.OMe$, derived from its method of preparation, and shows the absence of hydroxyl in the aromatic group. A. J. G.

Hydrazine Compounds of Phenol and Anisoïl. By H. Reisenegger (*Annalen*, **221**, 314—332).—Attempts to prepare hydrazine phenols from the potassium salts of ortho- and para-hydrazinephenolsulphonic acids gave negative results. *Orthohydrazinanisoïl*, obtained from orthanisidine by a method analogous to that by which E. Fischer prepared phenylhydrazine, crystallises in white needles which decompose on exposure to the air. The crystals melting at 43° are soluble in alcohol, ether, and benzene. The *hydrochloride*,

$$OMe.C_6H_4.N_2H_3,HCl,$$

sulphate, and *oxalate* are crystalline salts, soluble in hot water. The *picrate* forms yellow plates which detonate when quickly heated. *Monacetic orthohydrazanisoïl* crystallises in white needles which melt at 125°. The compound *carbamide*, $OMe.C_6H_4.N_2H_2.CONHEt$, prepared by the direct union of ethyl isocyanate and hydrazineanisoïl, forms needle-shaped crystals, which melt at 110°. W. C. W.

Hydrazines of Cinnamic Acid. By E. Fischer and H. Kuzel (*Annalen*, **221**, 261—297).—Methods for preparing many of the compounds described in this paper have already appeared in this Journal (Abstr., 1881, 598; 1883, 812, 1132). *Ethylamidocinnamic acid*, melting at 125°, dissolves in alcohol, ether, and carbon bisulphide, forming a yellow solution which exhibits a green fluorescence. It unites with acids and alkalis, yielding crystalline salts which are very soluble in water.

Diethylamidocinnamic acid forms large crystalline plates of a pale lemon colour, and melts at 124°. It is freely soluble in alcohol, ether, and carbon bisulphide. This substance combines with alkalis, and also unites with acids to form colourless crystalline salts which dissolve easily in water.

Nitroso-orthoethylamidocinnamic acid, $NOEtN.C_6H_4,CH{:}CH.COOH$, forms pale-yellow plates, which melt at 150° with decomposition. It dissolves readily in ether, alcohol, chloroform, and in hot water, and also in solutions of alkalis or alkaline carbonates, but not in acids.

Friedländer and Wienberg have pointed out (*Ber.*, **15**, 2104) that an alkaline solution of orthoethylamidocinnamic acid is converted into the hydro-acid by sodium-amalgam. If the cold solution is cautiously neutralised with dilute sulphuric acid, ethylamidocinnamic acid is precipitated. The precipitate dissolves easily in excess of sulphuric acid, and is converted into ethylhydrocarbostyril by warming the solution. On adding sodium nitrite to the solution of ethylamidocinnamic acid in dilute sulphuric acid, the *nitroso*-compound, $NOEtN.C_6H_4.C_2H_4.COOH$, is obtained. It crystallises in colourless plates which melt at 78° and decompose at 150°. The crystals dissolve freely in ether, benzene, alcohol, and alkalis.

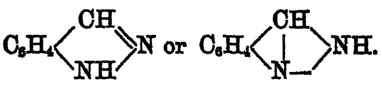
The hydrochloride of orthodiazocinnamic acid is a yellow crystalline powder, which detonates when heated. The nitrate, $C_9H_7O_2N_2.NO_3$, crystallises in colourless prisms resembling the hydrochloride. Both these salts dissolve in warm water, but on boiling the solutions nitrogen is evolved and orthocumaric acid is formed. The best yield of orthocumaric acid is obtained from the sulphate.

Hydrazinecinnamic acid, $NH_2.NH.C_6H_4.C_2H_2.COOH$, is best prepared by passing moist hydrochloric acid gas over sodium hydrazinesulphonate. When the salt acquires a brown colour, the excess of hydrochloric acid is expelled by a current of air and the residue is dissolved in warm water; on the addition of sodium acetate, a small quantity of resin separates, and is removed by filtration. Sodium acetate is again added, and the liquid evaporated to half its volume, when the acid is deposited in pale yellow crystals which are almost insoluble in alcohol, ether, and benzene. They are sparingly soluble in hot water, but the solution decomposes on evaporation. Hot glacial acetic acid dissolves hydrazinecinnamic acid, and the solution bleaches indigo and litmus.

Orthohydrazinecinnamic anhydride, which has been previously described (Abstr., 1881, 598), has not yet been directly prepared from the acid. The name "amidocarbostyril" proposed for this compound has been abandoned, since Friedländer has shown that carbostyril has the constitution  $C_6H_4\left<\begin{matrix}CH:CH\\ \text{———}N\end{matrix}\right>C.OH$, and the constitution of this anhydride is represented by the formula  $C_6H_4\left<\begin{matrix}CH:CH\\ N(NH_2)\end{matrix}\right>CO$.

Hydrazinecinnamic acid melts at 146°, and decomposes into acetic acid and *indazole*, $C_6H_4(NHNH_2).C_2H_4.COOH = C_7H_6N_2 + C_2H_4O_2$.

Indazole crystallises in colourless needles which melt at 146·5°, and sublime rapidly at 100°. It is soluble in alcohol, ether, hot water, and in dilute hydrochloric acid. It is precipitated from the acid solution by alkalis. Indazole yields a nitroso-compound. Its constitution may probably be represented as



Sodium hydrazinecinnamosulphonate is reduced by the action of sodium-amalgam to a salt of the hydro-acid, which forms colourless crystals freely soluble in water. On the addition of hydrochloric acid to the solution decomposition ensues, and *hydrazinehydrocinnamic anhydride* or *amidohydrocarbostyril*,  $C_6H_4\left<\begin{matrix}CH_2:CH_2\\ \text{-}N(NH_2)\text{-}\end{matrix}\right>CO$ is formed. It is deposited in colourless plates melting at 143°, on the addition of an alkali to the solution. Amidohydrocarbostyril is soluble in hot water and dilute acids. It combines with strong hydrochloric acid to form the hydrochloride $C_9H_{10}N_2O,HCl$, which crystallises in colourless prisms, soluble in water and alcohol. The base reduces alkaline silver solutions, but does not reduce Fehling's solution.

Hydrocarbostyril is precipitated on the addition of sodium nitrite to an acid solution of amidohydrocarbostyril.

Ethylamidohydrocarbostyril, $C_6H_4<\substack{CH_2.CH_2.CO\\ -N(NEtH)-}>$, prepared by the action of ethyl iodide on an alcoholic solution of amidohydrocarbostyril. forms colourless crystals melting at 74°, which are freely soluble in alcohol, ether, and chloroform. It unites with mineral acids to form salts which are very soluble in water. The nitrosamine is an oily liquid.

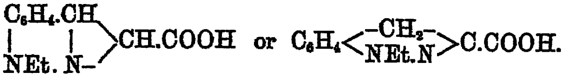
Ethylquinazolcarboxylic acid (Abstr., 1883, 812) is deposited from an aqueous solution in colourless plates which melt at 131°. On adding light petroleum to the solution of the acid in chloroform, it is precipitated in slender plates which melt at 126°. These crystals slowly change into the first modification.

Ethylquinazolcarboxylic acid forms crystalline compounds with bases and with acids. The crystalline hydrochloride, formed by passing hydrochloric acid gas into an ethereal solution of the carboxylic acid, is decomposed by water.

Monobromethylquinazolcarboxylic acid, $C_{11}H_{11}N_2O_2Br$, crystallises in colourless needles which melt at 173° with decomposition. It is freely soluble in alcohol and ether. The *dibromo-derivative*, melting at 196°, is less soluble in alcohol, ether, and chloroform than the preceding compound. The sodium salt is sparingly soluble in sodium hydroxide. It is deposited from a strongly alkaline solution in white plates. The bromine is eliminated by the action of sodium-amalgam.

Ethylquinazole (*loc. cit.*) unites with methyl iodide to form the compound $C_{10}H_{12}N_2MeI$, which is deposited from an alcoholic solution in highly refractive needle-shaped crystals melting at 192° with decomposition.

The constitution of ethylquinazole is probably



$$\begin{array}{l}C_6H_4.CH\\ \;|\qquad\;|\\ NEt.N-\end{array}\!\!>CH.COOH \quad\text{or}\quad C_6H_4<\substack{-CH_2-\\ NEt.N}>C.COOH.$$

Ethylhydrocarbazostyril, $C_6H_4<\substack{CH_2.CH_2\\ NEt.NH}>CO$, the isomeride of ethylamidohydrocarbostyril, has been previously described (Abstr., 1883, 1132).

Action of Benzaldehyde and Sulphuric Acid on a Mixture of Aniline and Nitrobenzene. By G. Mazzara (*Gazzetta*, 13, 527—529).

—By this reaction the author obtained a base, the composition of which he has not yet determined. Its hydrochloride forms garnet-red crystals, dissolving freely in alcohol, with violet coloration, and in water. The solutions, however, as well as those obtained with sulphuric acid, do not leave crystalline salts on evaporation. Picric acid produces in the hydrochloric solutions a reddish hydrated precipitate soluble in alcohol. The hydrochloric solution gives precipitates with mercuric chloride and potassium dichromate. Platinic chloride forms a reddish-yellow precipitate in concentrated solutions of the hydrochloride, and in aqueous solutions a brown precipitate containing water of crystallisation. H. W.

Reaction of Ethyl Acetoacetate with Aldehydes. By L. Claisen and F. E. Matthews (*Annalen*, **218**, 170—185).—A continuation and extension of former researches (Abstr., 1881, 405). The alkyl salts of acetoacetic acid react with aldehydes with elimination of water and substitution of the hydrogen-atom in the methylenic group by the hydrocarbon residue of the aldehyde, thus giving rise to substances of generic formula $CHR : C(COOEt).COMe$. Less generally a hydrogen-atom in the methyl-group is replaced, and compounds of formula $CR_2(COOEt).CO.CH : CHR$ are obtained. Further, all attempts to replace the hydrogen at once in the methyl and the methylenic group have been unsuccessful. *α-Ethyl acetocrotonate*, $CHMe : C\overline{Ac}.COOEt$, is easily obtained by passing hydrochloric acid into a mixture of ethaldehyde and ethyl acetoacetate, when the condensation-product separates out as a colourless oil boiling at 210° (sp. gr. = 1·0225); it resembles the crotonic derivatives in odour. It is easily reconverted into aldehyde and ethyl acetoacetate; it takes up a molecule of bromine to form a viscid *dibromide*, which cannot be distilled.

Ethyl acetisobutylideneacetate, $C_6H_8(C_4H_8)O_3$, from isobutaldehyde and ethyl acetoacetate, is a colourless liquid boiling at 219—222°, possessing a peppermint-like smell.

Ethyl acetisamylidineacetate, $C_6H_8(C_5H_{10})O_3$, from valeraldehyde and ethyl acetoacetate, is a colourless liquid boiling at 237—241°, sp. gr. 0·9612.

Ethyl acetotrichlorethylidineacetate, $C_6H_8(C_2HCl_3)O_3$, from chloral and ethyl acetoacetate, is a viscid colourless liquid, smelling faintly of chlorine; sp. gr. 1·342; it can be distilled in a vacuum, but under ordinary pressure is decomposed with evolution of hydrochloric acid.

Ethyl acetofurfuralacetate, $C_6H_8(C_5H_4O)O_3$, from furfuraldehyde and ethyl acetoacetate in presence of acetic anhydride, boils under a pressure of 30 mm. at 188°; it forms large glistening crystals melting at 62°, and easily soluble in alcohol, chloroform, and benzene.

Ethyl acetobenzilideneacetate, $CHPh : C\overline{Ac}.COOEt$, from benzaldehyde and ethyl acetoacetate, is a colourless tasteless strongly refractive oil, boiling at 295°; on standing it crystallises in four- or six-sided tables. It takes up a molecule of bromine to form a dibromide, $C_{13}H_{14}O_3Br_2$, which crystallises in short colourless needles. Under certain conditions, a mixture of two isomeric chlorhydrins of ethyl acetobenzylideneacetate can be obtained, the one crystallising in prisms melting at 41°, easily soluble in alcohol and ether; the other crystallising in rhombohedrons melting at 71°, and equally soluble in the same menstrua.

The formation of two isomeric products can be explained by supposing that at first an intermediate chlorhydrin is produced, $CHPhCl.CH\overline{Ac}.COOEt$, and then is decomposed into the abovementioned ethyl acetobenzylidenoacetate and hydrochloric acid, which subsequently recombine to form ethyl acetobenzylchloracetate, thus: $CHPh : C\overline{Ac}.COOEt + HCl = CH_2Ph.C\overline{Ac}Cl.COOEt$. From these results it is probable that in all cases an intermediate chlorhydrin is first produced.

Ethyl cinnamylethylacetate, CHPh : CH.CO.CHEt.COOEt, is formed when the mixture of benzaldehyde and ethyl acetoacetate, which has been saturated with hydrochloric acid, is allowed to stand for a week or more. As it could not be obtained in a satisfactory state of purity, it was converted into the analogous *diethyl-derivative*, CHPh : CH.CO.CEt$_2$.COOEt. This crystallises in triclinic prisms which melt at 101°; it is easily soluble in chloroform and ether, sparingly soluble in alcohol. It combines with bromine to form a dibromide, $C_{17}H_{12}O_3Br_2$, which crystallises in prisms melting at 55°, easily soluble in alcohol and petroleum. V. H. V.

Action of Benzaldehyde on Malonic Acid and its Ethylic Salt. By L. CLAISEN and L. CRISMER (*Annalen*, 218, 129—144).—In a preliminary notice, Claisen has described (Abstr., 1881, 405) a condensation-product of benzaldehyde and ethyl malonate, viz., ethyl benzalmalonate, CHPh : C(COOEt)$_2$. In the present communication a fuller account is given of this substance and of the corresponding carboxylic acid, CHPh : C(COOH)$_2$. This cinnamic and carboxylic acid resembles dicarbontetracarboxylic acid, and differs from other acids in which the two carboxyl-groups are attached to the same carbon-atom, in that it does not readily decompose into cinnamic acid and carbonic anhydride. Further, it readily takes up a molecule of water, with simultaneous decomposition into its two derived components, benzaldehyde and malonic acid. *Ethyl benzalmalonate*, CHPh : C(COOEt)$_2$, is readily obtained from a mixture of ethyl malonate and benzaldehyde, either by passing hydrochloric acid to saturation, or by heating them in a sealed tube with acetic anhydride. It is a colourless tasteless viscid and strongly refractive liquid, sp. gr. = 1·115, and boils at 215—217° under a pressure of 30 mm.; it is readily saponified by baryta-water, yielding *benzalmalonic acid*, CHPh : C(COOH)$_2$, which crystallises in short prisms melting at 195°, soluble in alcohol, insoluble in benzene and chloroform. By a protracted heating at its boiling point, it is gradually decomposed into cinnamic acid and carbonic anhydride. When boiled with water, it yields benzaldehyde and malonic acid, thus:

$$CHPh:C(COOH)_2 + H_2O = Ph.CHO + CH_2(COOH)_2.$$

The salts of benzalmalonic acid are crystalline substances, more stable in the presence of water than their parent acid; the ferric, lead, mercuric, and cadmium salts are sparingly soluble precipitates. By nascent hydrogen, benzalmalonic acid is converted into benzylmalonic acid, thus: $CHPh:C(COOH)_2 + H_2 = CH_2Ph.CH.(COOH)_2$. It does not, however, similarly take up a molecule of bromine, but is decomposed to form α-bromocinnamic acid, in accordance with the equation—

$$CHPh:C(COONa)_2 + Br_2 = CHPh:CBr.COONa + NaBr + CO_2.$$

A study of the reaction between benzaldehyde and the ethyl salt of ethylmalonic acid did not give satisfactory results.

It is remarked in a footnote that Culp has obtained from furfuraldehyde and ethyl malonate a condensation-product, ethyl furfuralmalonate, and its corresponding carboxylic acid. V. H. V.

Action of Aldehydes on Ketones, Ketonic Acids, and Malonic Acid. By L. CLAISEN (*Annalen*, **218**, 121—128).—In this paper some general remarks are offered on the reactions obtained between the aldehydes and ketones or their derivatives. The results of Chiozza, Schmidt, and the author's researches on the action of benz- and furfur-aldehyde on acetaldehyde have established that only such methyl or methylene-groups as are directly combined with the carbonyl residue, exchange their hydrogen for the hydrocarbon residue of the aldehyde. In this respect the condensation between aldehydes and ketones resembles that between the aromatic aldehydes and fatty acids (Perkin's reaction); for in this case only the CH_2 or CH residue attached to the carboxyl-groups enters into the reaction.

Further, either or both of the hydrocarbon residues attached to the carbonyl-group may take part in the condensation with formation of a mono- or a di-derivative. It seemed that a study of the action of aldehydes on malonic acid or its alkyl salts, as containing a methylene residue associated with two carbonyl-groups $CO—CH_2—CO$, would be a suitable extension of these general reactions. (The results of the experiments are detailed in the Abstracts, this vol., pp. 422, 443 and 444.) V. H. V.

The Three Nitracetophenones. By H. GEVEKOHT (*Annalen*, **221**, 323—335).—That portion of the paper which relates to the preparation of the three nitracetophenones has already appeared in this Journal (Abstr., 1883, 191). *Orthamidoacetophenone*, obtained by reducing the nitro-compound with tin and hydrochloric acid, is identical with the amidoacetophenone which Baeyer and Bloem (Abstr., 1883, 197) prepared from orthamidophenylpropiolic acid.

By the action of bromine on orthonitracetophenone dissolved in glacial acetic acid, mono- and di-bromo-derivatives are formed. The monobromo-derivative $C_6H_4(NO_2).CO.CH_2Br$ crystallises in colourless needles melting at 55°, which have a bitter taste. The dibromo-compound forms crystalline prisms which melt at 85°. *Dichlororthonitracetophenone* crystallises in colourless plates, melting at 73°. Each of these three compounds is freely soluble in alcohol, ether, and chloroform. On reducing their alcoholic solutions by ammonium sulphide, indigo-blue is produced. Orthonitracetophenone is attacked by phosphorus pentachloride at the ordinary temperature, and is converted into orthonitromonochlorostyrene.

The ethylic salt of nitrobenzoylacetic acid is decomposed when boiled with dilute sulphuric acid, and yields a mixture of nitrobenzoic acid and *orthonitrobenzoylacetone*, $NO_2.C_6H_4.CO.CH_2.COMe$. Nitrobenzoylacetone forms yellow crystals melting at 55°, soluble in alcohol and ether. It combines with alkalis to form soluble salts of a yellow colour, and it also unites with phenylhydrazine, forming a crystalline compound melting at 120°, which probably has the constitution $NO_2.C_6H_4.C(N_2HPh).CH_2.C(N_2HPh)Me$. W. C. W.

Transformation of the Fluobenzoic Acids in the Animal Organism. By F. Coppola (*Gazzetta*, 13, 521—525).—The experiments were made by giving to a middle-sized dog 5 grams of a fluobenzoic acid, in two doses daily, which did not affect him injuriously. The urine passed in the 48 hours was then evaporated to a syrup; this was treated with alcohol; the solution was filtered; and the residue left on distilling off the alcohol was decomposed with hydrochloric acid and digested with ether. On then distilling off the ether, there remained a strongly acid, oily mass, consisting of a fluohippuric acid, formed by combination of the fluobenzoic acid with the glycocine derived from the animal organism, and having the ortho-, meta-, or para-constitution according to the modification of fluobenzoic acid employed. The union was in all cases complete, no trace of free fluobenzoic acid being discovered in the urine.

The three fluohippuric acids, $C_9H_8FNO_3$, thus obtained are very similar in appearance, crystallising in radiate groups of needle-shaped prisms having a nacreous lustre. They are very soluble in ether, alcohol, and ethyl acetate, slightly soluble (the *p*-modification insoluble) in chloroform, insoluble in carbon bisulphide and in benzene. The *ortho*-modification melts at 121·5°, the *meta*- at 152°, and the *para*- at 161—161·5°. They are decomposed by boiling with hydrochloric acid into glycine and the corresponding fluobenzoic acids.

H. W.

New Synthesis of Cinnamic Acid. By A. Michael (*Amer. Chem. J.*, 5, 205—206).—A satisfactory yield of cinnamic acid is obtained by heating malonic acid and benzaldehyde in molecular proportions in a sealed tube at 140° for several hours. A. J. G.

Dry Distillation of Parahydroxybenzoic Acid. By A. Klepl (*J. pr. Chem.*, 28, 193—219).—Parahydroxybenzoic acid begins to decompose when heated above 300°, carbonic anhydride being evolved, whilst phenol and water distil over, and the acid becomes cloudy from separation of a white liquid which gradually collects at the bottom of the retort. When the temperature reaches 350°, the contents of the retort solidify, forming a yellowish-white amorphous mass, which closely resembles salicylide and glycollide, and which the author accordingly calls parahydroxybenzide.

Parahydroxybenzide, $C_7H_4O_2$, is obtained pure by repeatedly boiling the above-mentioned white residue with absolute alcohol. It is a white amorphous powder which does not dissolve in any of the ordinary solvents. It carbonises when heated above 350°. When boiled with potash, it is converted into parahydroxybenzoic acid. When heated on a water-bath with five times its weight of sulphuric acid, it yields *sulphoparahydroxybenzoic acid*, which crystallises from water in rhombic plates. The *barium salt*, which forms colourless prisms, loses 7 mols. H_2O when heated to 120—130°. The *silver salt* is obtained by treating the barium salt with silver sulphate; it crystallises in irregular brown prisms containing no water of crystallisation. The formation of a very insoluble acid potassium salt is highly characteristic of the sulphonic acid. Extremely dilute solutions of the acid yield a precipitate on addition of sulphuric acid and potash solution. The *acid salt*, $C_7H_5SO_6K + H_2O$, crystallises in quadratic prisms, or when formed in a very dilute solution, rectangular plates.

Phenyl phenylparahydroxybenzoate, $OPh.C_6H_4.COOPh$, is prepared by passing carbonic anhydride, heated to 170—200°, over parahydroxybenzide at 400°. After purification from absolute alcohol and glacial acetic acid, it crystallises in white scales which melt at 73—78°. When boiled with alcoholic potash or concentrated hydrochloric acid, it is decomposed into phenol and an acid of the composition $C_{13}H_{10}O_3$, which crystallises from chloroform in prisms melting at 159·5°. It forms a liquid ethyl salt. When the acid is distilled with baryta, the pure phenyl ether distils over as a colourless oily liquid, which solidifies in a freezing mixture, forming long needles melting at 27—28°. The compound, $C_{13}H_{10}O_3$, appears to be paraphenoxybenzoic acid, $C_6H_4(OPh).COOH$.

When parahydroxybenzide is distilled in a current of chlorine, a small quantity of an oil consisting of a mixture of chlorinated substances passes over, and in addition, long glittering needles melting at 222°, of a substance possessing all the characteristic properties of Julin's *carbon chloride*, C_6Cl_6.

Parahydroxybenzonitrile, $C_6H_4(OH).CN$, is formed when parahydroxybenzide is heated at 250° in a current of ammonia gas. It crystallises in large rhombic plates melting at 112—113°. When boiled with potash, it yields ammonia and parahydroxybenzoic acid.

Parahydroxybenzide is converted into parahydroxybenzoic acid by the action of superheated steam at 250°.

Parachlorobenzotrichloride, $C_6H_4Cl.CCl_3$, is obtained by heating parahydroxybenzide with five times its weight of phosphorus pentachloride in a sealed tube at 290—300°. It boils at 240—260°. Concentrated sulphuric acid converts it into chlorosalicylic acid.

Diparahydroxybenzoylparahydroxybenzoic Acid. — The solid cake which is obtained by distilling parahydroxybenzoic acid contains, in addition to parahydroxybenzide, two parahydroxybenzoylparahydroxybenzoic acids. They may be regarded as being parahydroxybenzoic acid in which the hydrogen of the phenolic hydroxyl-group is replaced by the radical parahydroxybenzoyl. In the case of diparahydroxybenzoylparahydroxybenzoic acid the substitution is carried further, by the introduction of a second parahydroxybenzoyl-group in the phenol of the first. The latter acid forms a white powder melting at 280°, very sparingly soluble in alcohol and ether, insoluble in water and in chloroform. It dissolves freely in soda-solution, carbonate of soda, and ammonia.

Parahydroxybenzoylparahydroxybenzoic acid,

$$C_6H_4(OH).COO.C_6H_4.COOH,$$

is best obtained by interrupting the distillation of parahydroxybenzoic acid when it has lost about 15 per cent. in weight. The residue is first treated with chloroform to remove resinous substances, then with water to dissolve undecomposed parahydroxybenzoic acid, and afterwards with 50 per cent. alcohol to dissolve the parahydroxybenzoylparahydroxybenzoic acid. The last crystallises in microscopic needles melting at 261°. It dissolves freely in alkalis; but such solutions quickly decompose, forming parahydroxybenzoic acid. It forms a sodium salt and two barium salts. When heated with acetic anhydride, it yields an acetyl-compound which crystallises in plates melting at 216·5°. The corresponding acetyl salt of diparahydroxybenzoylparahydroxybenzoic acid forms glittering plates melting at 185°. The author states that acids containing more parahydroxylbenzoyl-groups appear to exist.

III. *Phenyl parahydroxybenzoate*, $C_6H_4(OH).COOPh$.—The distillate from parahydroxybenzoic acid contains, in addition to phenol, water and phenyl parahydroxybenzoate. It forms rhombic plates melting at 176°. It is insoluble in water. When treated with acetic anhydride it yields an acetyl-compound which crystallises in long plates melting at 84°. J. I. W.

Action of Phthalic Anhydride on Secondary Monamines. By A. Piutti (*Gazzetta*, 13, 542—563).—The author has already shown (Abstr., 1883, p. 999) that phthalamidobenzoic acid reacts with primary amines in the manner shown by the equation:—

$$C_6H_4 : C_2O_2 : N.C_6H_4.COOH + NH_2.C_nH_m = C_6H_4 : C_2O_2 : N.C_nH_m + NH_2.C_6H_4.COOH,$$

whence it appears that this acid, so far as its phthalic component is concerned, behaves like phthalic anhydride, *i.e.*, it unites with the amine, forming the corresponding substituted phthalimide. The study of the action of phthalamidobenzoic acid on secondary monamines resolves itself therefore into that of the action of phthalic anhydride on the same bodies. The present paper describes the results obtained in this direction.

The action of phthalic anhydride on secondary monamines may be supposed to take place in two ways, yielding (1) a disubstituted phthalamic acid; and (2) a tetrasubstituted-derivative of a phthalic diamide:—

$$(1.)\ C_6H_4 : C_2O_2 : O + NH(C_nH_m)(C_{n'}H_{m'}) = (C_nH_m)(C_{n'}H_{m'}) : CON.C_6H_4.COOH.$$

$$(2.)\ C_8H_4O_3 + 2NH(C_nH_m)(C_{n'}H_{m'}) = H_2O + C_8H_4O_2[N(C_nH_m)(C_{n'}H_{m'})]_2.$$

With the bases on which the author has experimented, viz., ethylaniline, diphenylamine, piperidine, and conine, the action takes place in both these ways, the substituted phthalamic acid, as it forms, uniting with the base which has not yet entered into the reaction, and forming a salt, which, under the influence of heat, gives up a molecule of water, and yields a substituted diamide.

Action of Phthalic Anhydride on Ethylaniline.—The alkyl-derivatives of aniline prepared from commercial aniline, even after purification, cannot be separated from one another by fractional distillation, and moreover they frequently contain substituted ortho- and para-toluidines, together with unaltered toluidine and aniline. A sample of ethylaniline, after repeated fractional distillation, was divided into two portions, boiling respectively at 203—209° and 209—215°; and in order to obtain pure compounds from these fractions, they were treated with $\frac{1}{20}$ of the quantity of phthalic anhydride required to convert into an amide the entire quantity of ethylaniline present, supposing it to be pure. The liquid was then heated in a reflux apparatus; the first portion containing water was distilled off; and the last anhydrous distillate was again subjected to the action of $\frac{1}{20}$ phthalic anhydride, and so on. Each time there was left in the flask a residue, often crystalline, from which the small remainder of free base not removed by distillation was separated by hydrochloric acid. The hard residue then left was washed with water, dried, and dissolved in alcohol, and the several compounds separated from the solution by fractional crystallisation. In this manner the following products were obtained:—

From the portion of the ethylaniline boiling at 203—209°, by the action of $\frac{1}{20}$ phthalic anhydride:—

In the first treatment, *phenylphthalimide*, in the second, *phenylphthalimide* with a small quantity of *orthotolylphthalimide;* in the third, o-*tolylphthalimide* together with small quantities of *phenylphthalimide* and *ethylanilphthalein;* in the fourth, o-*tolylphthalamide* and *ethylanilphthalein;* in the fifth, sixth, and seventh, *ethylanilphthalein* and *ethyltoluidinephthalein.*

After the last treatment, the ethylaniline was separated by fractional distillation into two portions, one boiling at 204—205°, and consisting of nearly pure ethylaniline, while the other, which boiled at a higher temperature, consisted in great part of tertiary bases, and was therefore added to the following portion. This last portion of ethylaniline (209—215°) on treatment with $\frac{1}{20}$ phthalic anhydride yielded o-*tolylphthalimide*, and in the second and third treatments, *ethyltoluidinephthalein.* After these treatments, there remained diethylaniline boiling at 213—215°, which gave only a slight turbidity with œnanthal, and therefore contained only traces of secondary bases.

The author then proceeds to describe—first the products obtained by the action of phthalic anhydride on purified ethylaniline; then the substituted amides formed by treating the two portions of the mixed ethylanilines; and lastly orthotolylphthalimide.

Ethylphenylphthalamic acid, $C_{16}H_{15}NO_3 = NPhEt.CO.C_6H_4.COOH$, is formed on dissolving 1 mol. phthalic anhydride in 2 mols. ethylaniline, and remains on exhausting the product with ether, and evaporating the solvent, as a colourless oil, heavier than water, somewhat soluble therein, very easily soluble in alcohol, ether, and other ordinary solvents. Hydrochloric acid decomposes it, yielding phthalic acid and ethylaniline hydrochloride. It unites with all the alkaline bases, forming salts moderately soluble in water. The *copper salt*, $(C_{16}H_{14}NO_3)_2Cu$, is precipitated on adding cupric acetate to a moderately concentrated solution of the ammonium salt, and when dried forms a light blue powder somewhat soluble in cold water, melting in boiling water, and solidifying on cooling to a green resin. A similar deportment is exhibited by all the insoluble or slightly soluble salts of this acid, and in general of all the substituted phthalamic acids hitherto examined. The copper salt begins to give off ethylaniline at about 100°, and at higher temperatures melts and decomposes, yielding ethylaniline and phenylphthalimide. The *barium salt*, obtained by neutralisation, is moderately soluble in water, more freely in alcohol, but does not crystallise. On adding silver nitrate to the ammonium salt the *silver salt* is precipitated in clots which blacken quickly on exposure to light.

Ethylaniline Ethylphenylphthalamate,

$$NPhEt.CO.C_6H_4.COO.NH_2PhEt,$$

formed by direct combination, is uncrystallisable, and dries up in the exsiccator to a resinous mass which gradually becomes coloured. It is moderately soluble in alcohol, less in ether and in water, more soluble in cold than in hot water. Heated above 200°, it gives off 1 mol. water, and is converted into an amidated compound

$$C_8H_4O\ (NPhEt)\ ,$$

which is not a derivative of the normal diamide of phthalic acid, but, as will presently be shown, must be regarded as a derivative of an unsymmetrical diamide, *i.e.*, as a phthaleïn of ethylaniline.

Ethylanilphthalein, prepared in the manner just mentioned, is obtained, after a few crystallisations from ether, in very fine prismatic shining crystals melting at about 140°. They are identical with the product obtained in the final treatment of the ethylanilines boiling at 203—209° with phthalic anhydride. When this body is recrystallised from alcohol, it melts at 140·5° to 141·5°. It is insoluble in water, soluble in alcohol, especially when hot, also in ether and in benzene. The etheric solution yields it, on slow evaporation, in large crystals 2 cm. long, forming a characteristic twin-combination, and when isolated presenting the aspect of celestin. Ethylanilphthaleïn is insoluble in aqueous, but soluble in alcoholic potash, and does not decompose when boiled with that solvent, even for a long time. By fused potash, on the other hand, it is easily and completely resolved into ethylaniline and phthalic acid. It decomposes partially at 300°, but is reproduced and deposited in crystals on the cold sides of the containing vessel.

Ethyltoluidine-phthaleïn, $C_8H_4O_2(N.C_2H_5C_7H_7)_2$.—In the second and third treatments with phthalic acid of that portion of the mixed ethylanilines which boils at 209—215°, and from the alcoholic mother-liquors of ethylanilphthalein formed by the action of phthalic anhydride on the portions boiling at 203° to 209°, there is obtained an uncrystallisable substance, transparent, somewhat coloured, melting at a low temperature, insoluble in hydrochloric acid and in strong potash-ley. After purification by repeated extraction with these solvents, and drying in the exsiccator at about 90°, it gave by analysis numbers agreeing with the formula of *ethyltoluidinephthaleïn*. It appears to be the phthaleïn of ethyl-orthotoluidine, inasmuch as metatoluidine is not found in commercial aniline, and the author on treating with phthalic anhydride the first portion of the mixed ethylanilines, found orthotolylphthalimide quite free from the para-compound.

Diphenylphthalamic acid, $C_{20}H_{15}NO_3 = NPh_2.CO.C_6H_4.COOH$, is formed by heating diphenylamine and phthalic anhydride in molecular proportions, the heat being gradually raised to 250° and kept at that point for about an hour. The product on cooling solidifies to a brown-green mass of diphenylamine diphenylphthalamate containing needles of phthalic anhydride. On dissolving this mass in a small quantity of hot alcohol and adding aqueous ammonia, the diphenylamine is precipitated, while ammonium diphenylphthalamate and phthalate remain in solution. This solution gives off ammonia during concentration and deposits yellow needles of diphenylphthalamic acid, additional quantities of which may be obtained from the mother-liquors. This acid, after several recrystallisations from alcohol, forms large white hard mammellated groups intermixed with small shining prisms. It melts at 147° to 148°, is insoluble in water, slightly soluble in ether, very freely in alcohol. It dissolves in alkalis, and is precipitated by strong acids; also in cold sulphuric acid, but the solution on addition of nitric acid does not give the reaction of diphenylamine. Its *silver salt*, $C_{20}H_{14}NO_3Ag$, crystallises in white nodules, quickly blackened by light. The *copper salt* is a light sky-blue powder. The *lead* and *barium salts* are insoluble in water.

Diphenylamine diphenylphthalamate, formed by fusing the acid and base together in molecular proportion, is a coloured solid mass which dissolves in ether, but does not crystallise therefrom. Heated for some time above 300°, it gradually loses water, turns dark brown, and is converted into the corresponding phthaleïn, viz.,

Diphenylamine-phthaleïn, $C_{20}H_{14}N_2O_2 = (NPh_2)_2C{<}\begin{matrix}C_6H_4\\ O\end{matrix}{>}CO$, which may also be prepared directly by boiling in a reflux apparatus for several hours, a mixture of 1 mol. phthalic acid and 2 mols. diphenylamine, as long as water is given off. The product is a solid highly coloured mass soluble in ether, benzene, and alcohol, especially when hot, and separating from the concentrated etheric solution as a crust of transparent slightly coloured crystals. From alcohol, it crystallises in stellate groups of long, very white, shining needles melting at 238—238·5°. It is insoluble in aqueous potash, and is decomposed by very strong boiling or fused potash, into diphenylamine and phthalic acid. It dissolves in strong sulphuric acid, and on adding a drop of nitric acid, a splendid violet colour is developed, which disappears on addition of water, a brown substance being then deposited which redissolves in strong sulphuric acid with the coloration above mentioned. The solution of diphenylamine in sulphuric acid treated in the same manner gives, on the other hand, a deep blue coloration. Diphenylamine-phthaleïn is converted by strong nitric acid into a nitro-compound which dissolves in alcohol and crystallises therefrom in yellow leaflets, turning deep red on addition of ammonia. The potassium compound has a deep blood-red colour, but does not crystallise from alcoholic solution even highly concentratrd.

The diphenylamine-phthaleïn prepared as above is identical with that which Lellman obtained (*Ber.*, **15**, 830, and Abstr., 1382, 1060) by the action of phthalyl chloride on diphenylamine; and, admitting for this chloride the formula $C_6H_4<\genfrac{}{}{0pt}{}{CCl_2}{.CO.}>O$, proposed by Ador and demonstrated by v. Gerichten (Abstr., 1880, 470—473), it follows that diphenylamine-phenylphthaleïn must be represented by the formula $(NPh_2)_2C<\genfrac{}{}{0pt}{}{C_6H_4}{-O-}>CO$, the general formula of bodies of the same class being $[N(C_nH_m)(C_{n'}H_{m'})]_2\ C<\genfrac{}{}{0pt}{}{C_6H_4}{-O-}>CO$.

When a solution of diphenylphthalamic acid in a slight excess of ethylaniline is boiled for some time, diphenylamine ethyl-phenylphthalamate is formed, which is resolved by hydrochloric acid into ethylphenylphthalamic acid and diphenylamine. On heating the same salt at a higher temperature. coloured products were formed, the composition of which could not be determined.

Piperilene-phthalamic Acid,

$$C_{13}H_{15}NO_3 = C_5H_{10}:N.CO.C_6H_4.COOH.$$

—On gradually adding phthalic anhydride to piperidine in a cooled vessel, a white crystalline mass is formed containing piperilene-phthalamic acid, partly free, partly combined with the piperidine; and on adding a small quantity of water and agitating with ether, the phthalic acid formed by the action of the water on the excess of the anhydride separates the piperilene-phthalamic acid from its piperidine salt, and the ether removes the whole of this acid from the aqueous solution. On evaporating the etheric solution, an oily residue is left consisting almost wholly of piperilene-phthalamic acid, while the water retains in solution the acid phthalate of piperidine which does not crystallise even when left for a long time over sulphuric acid.

Piperilene-phthalamic acid is a thick colourless oil, somewhat soluble in water, abundantly in alcohol. It forms soluble salts with the alkalis, and is reprecipitated from the solutions by the stronger acids. By the prolonged action of hydrochloric acid, it is resolved into piperidine and phthalic acid. Its *copper salt*, $(C_{13}H_{14}NO_3)_2Cu$, formed by double decomposition, is a light-blue precipitate.

The acid phthalate of piperidine which is obtained in the preceding reaction, together with piperilene-phthalamic acid, loses a molecule of water when heated, being thereby converted into piperilene-phthalamic acid: $C_5H_{11}N,C_6H_4(COOH)_2 = H_2O + C_5H_{10}N.CO.C_6H_4.COOH$.

Piperylenamine-phthaleïn, $C_8H_4O_2(NC_5H_{10})_2$, is formed by heating the acid phthalate of piperidine at 210° as long as phthalic anhydride continues to sublime, treating the pasty and slightly coloured product with strong potash-lye, and cooling with ice: it then separates as a somewhat consistent mass, which may be purified from free phthalic acid by repetition of the treatment. On evaporating the etheric solution, the piperylenamine-phthaleïn remains as a nearly colourless oil, soluble in the ordinary solvents and in excess of cold aqueous potash, and partly precipitated from the last-mentioned solution on heating. The transformation of acid phthalate of piperidine into piperylenamine-phthaleïn is represented by the equation:

$$2[COOH.C_6H_4.COOH,NH(C_5H_{10})] = C_8H_4O_2(NC_5H_{10})_2 + C_6H_4:C_2O_2:O + 3H_2O.$$

The compound thus prepared is identical with that obtained by R. Schiff (Abstr., 1880, 127) by the action of 2 mols. piperidine on 1 mol. phthalic anhydride in alcoholic solution, and regarded by him as phthalyl-piperide.

Piperylenamine-phthaleïn dibromide, $C_8H_4O_2(NC_5H_{10})_2,Br_2$, is formed on dropping a dilute etheric solution of bromine into an etheric solution of the phthaleïn, whereupon a red heavy oil is first formed which, as the addition of bromine is continued, crystallises completely in groups of shining prisms. It gave by analysis 33·3 per cent. bromine, the formula requiring 34·7 per cent.

Conilene-phthalamic acid,

$$C_{16}H_{21}NO_3 = C_8H_{16} : N.CO.C_6H_4.COOH,$$

is prepared from phthalic anhydride and conine in the same manner as the corresponding piperylene-compound, and crystallises in mammellated groups of colourless needles, which after recrystallisation from hydrochloric acid melt at 155°. By keeping, they become brown and opaque. The compound is but slightly soluble in ether and in water, somewhat more freely in benzene, easily in aqueous ammonia, from which it crystallises on addition of hydrochloric acid. Its ammonium salt does not precipitate barium chloride, but forms with lead acetate and silver nitrate white precipitates slightly soluble or insoluble in water. The *copper salt*, $(C_{16}H_{20}NO_3)_2Cu$, is a light-green powder slightly soluble in water.

Conilenamine-phthaleïn, $C_8H_4O_2(NC_8H_{16})_2$, is formed on heating the conilene-phthalamate of conine at a temperature above 210°. The product thus obtained is coloured, but may be purified by dissolving it in strong potash-lye, extracting with ether, washing with hydrochloric acid, again extracting with ether, and removing the hydrochloric acid from the etheric solution by agitation with dilute potash. On evaporating the ether, the conilenamine-phthaleïn remains as a thick nearly colourless oil, having a faint odour of conine. When quite dry, it forms an amorphous faintly fluorescent mass. It is moderately soluble in the ordinary solvents, and resists the action of hot strong potash-lye, but is resolved by fusion with potash into conine and phthalic acid. By treatment with bromine in etheric solution, it is converted into a red noncrystalline compound, which gradually gives off bromine, and appears to be analogous in composition to the compound similarly formed from piperylenamine-phthaleïn.

Orthotolylphthalimide, $C_{15}H_{11}NO_2 = C_6H_4 : C_2O_2 : N.C_6H_4Me$, is obtained, together with phenylphthalimide, by the action of phthalic anhydride on the first portion of the mixed ethylanilines (p. 449) boiling at 203—209°, and separates in mammellated groups of nearly white crystals, melting at 179°, and more soluble in alcohol than phenylphthalimide. With potash, it reacts like other substituted phthalimides, yielding phthalic acid and a volatile base. H. W.

Orthamidotolueneparathiosulphonic Acid. By W. Paysan (*Annalen*, 221, 360—364).—*Orthamidotolueneparathiosulphonic acid*, $C_7H_6(NH_2)SO_2.HS$, resembles paramidotolueneorthothiosulphonic acid in its properties and mode of preparation. It crystallises in four-sided prisms, soluble in hot water; it decomposes at 115° without melting. The salts which this acid forms with the alkalis and alkaline earths are very soluble in water. The lead, silver, and copper salts are insoluble. Orthamidotolueneparasulphinic acid crystallises in large plates soluble in hot water. It decomposes at 160° without melting. The crystals of the barium salt, $(NH_2.C_7H_6.SO_2)_2Ba + 2H_2O$, and the anhydrous potassium salt are freely soluble; the crystalline silver salt and the amorphous lead salt are sparingly soluble in water. By decomposing the diazo-compound with alcohol, an ethoxytoluenesulphonic acid is obtained which appears to be identical with that described by Hayduck (*Annalen*, **172**, 215).

Toluenesulphamine, $C_7H_6SO_2H.NH_2$, prepared by boiling the sulphinic acid with hydrochloric acid, is deposited from alcohol in needle-shaped crystals melting at 175°, soluble in ether. The hydrochloride, $C_7H_6SO_2H.NH_2,HCl$, crystallises in slender needles, soluble in water. It decomposes at 100° without melting. W. C. W.

Paramidotoluene-orthothiosulphonic Acid. By A. HEFFTER (*Annalen*, **221**, 345—359).—Paranitrotoluene-orthosulphonic chloride is added to a well-cooled solution of ammonium sulphide. After removing the precipitated sulphur by filtration, acetic acid is added, when the *amidotoluenethiosulphonic acid*, $C_7H_6(NH_2).SO_2.SH$, is deposited. This acid forms yellow prisms, which are sparingly soluble in water, and insoluble in alcohol and ether. It is decomposed by acids at the ordinary temperature, and also by boiling with water. The barium, $(NH_2.C_7H_6.SO_2.S)_2Ba + 2H_2O$, mercuric, and copper salts are crystalline; the silver and lead salts are amorphous. Sodium-amalgam converts the thiosulphonic acid into *paramidotoluene-orthosulphinic acid*, $NH_2.C_7H_6.SO_2H$, which crystallises in colourless needles or prisms soluble in hot water. The salts of this acid are freely soluble in alcohol and water. The potassium salt crystallises in prisms, and the barium salt in needles, which are very deliquescent. Bromine-water converts the sulphinic acid into amidotoluenesulphonic acid and toluenesulphamine. By the action of nitrous acid on an alcoholic solution of amidotoluene-sulphinic acid, the diazo-compound is obtained, but if the acid is dissolved in hydrobromic acid instead of alcohol, Jenfsen's parabromotoluene-orthosulphonic acid (*Annalen*, **172**, 230) is produced. The diazo-compound crystallises in yellowish-brown needles. It is decomposed by alcohol, forming *ethoxytoluenesulphonic acid*, $EtO.C_7H_6.SO_3H$, which bears a close resemblance to the isomeride which Hayduck (*Annalen*, **172**, 215) obtained from the diazo-compound of orthamidotolueneparasulphonic acid. The barium salt, $(OEt.C_7H_6.SO_3)_2Ba + 3\frac{1}{2}H_2O$, forms glistening plates, soluble in alcohol and water. The potassium salt is deposited from alcoholic solutions in yellow plates. The chloride is a thick yellow oil, and the amide, $OEt.C_7H_6.SO_2NH_2$, forms white needles melting at 136°, and dissolving freely in alcohol, ether, and hot water. *Methoxytoluenesulphonic acid*, $MeO.C_7H_6.SO_3H$, yields very soluble potassium and barium salts, which crystallise with difficulty. The chloride is an oily liquid. The amide crystallises in prisms which melt at 150°.

Strong acids convert amidotoluenesulphinic acid into a base which the author calls *toluenesulphamine*, $C_7H_6SO_2H.NH_2$. The base melts at 132°, and dissolves readily in alcohol and ether. It unites with acids to form a series of crystalline salts, *e.g.*, $C_7H_6SO_2H.NH_3,HCl$. Toluenesulphamine is converted into amidotoluenethiosulphonic acid by yellow ammonium sulphide, and into the sulphinic acid by the action of sodium-amalgam. W. C. W.

Metamidobenzamide. By H. Schiff (*Annalen*, 218, 185—194). —The difference in chemical function of the two amido-groups in amidobenzamide, $NH_2.C_6H_4.CO_2NH_2$, is shown most markedly in its reaction with aldehydes, for the amido-group in the benzene nucleus combines with the hydrocarbon residue of the aldehyde far more readily than does the acid amido-group. For example, acetaldehyde and metamidobenzamide react in accordance with the equation $Me.CHO + 2NH_2.C_6H_4.CONH_2 = CHMe(NH.C_6H_4.CONH_2)_2$. The resultant substance is an amorphous powder, turning gold-coloured and finally red on exposure to air. When heated in sealed tubes at 100—120° a further separation of water takes place, the aldehydic residue being introduced into the acid amido-group. Similarly on mixing aqueous solutions of salicylaldehyde and metamidobenzamide, glistening golden needles of *orthohydroxybenzyleneamidobenzamide*,

$$OH.C_6H_4.CH : N.C_6H_4.CONH_2,$$

separate out. This compound melts at 186°, and is readily soluble in hot water and alcohol. By prolonged boiling with water, it is decomposed into its components, salicylaldehyde and metamidobenzamide. When the salicyl-derivative is heated with benzaldehyde, a further substitution-product is formed,

$$C_7H_6(NH.CO.C_6H_4.N : CH.C_6H_4.OH)_2,$$

a crystalline substance which cannot be melted without decomposition. Its diacetyl-derivative crystallises in small needles, and decomposes at 220° with partial liquefaction.

A glucoside of the above monosalicyl-derivative of metamidobenzamide can be prepared by dissolving in warm water metamidobenzamide and helicine (glucosalicylaldehyde). It crystallises in colourless crystals melting at 113° to form a golden glass. Its composition is expressible by a formula—

$$NH_2CO.C_6H_4.N : CH.C_6H_4.O.C_6H_{11}O_5 + 2H_2O.$$

On warming with dilute hydrochloric acid, it is decomposed into salicylaldehyde, metamidobenzamide, and glucose.

Again metamidobenzamide combines with isatin, producing a compound, *isatomidobenzamide*, $NH_2.CO.C_6H_4.N :$  $C{<}{\genfrac{}{}{0pt}{}{C_6H_4}{\text{-}CO\text{-}}}{>}NH$, forming large golden crystals, which begin to melt at 280, turning brown and evolving gas.

If the aldehyde- or helicin-derivatives of amidobenzamide be warmed with aniline, the aldehydic grouping combines with the aniline, with regeneration of amidobenzamide, thus—

$$NH_2.CO.C_6H_4.N:C_nH_m + NH_2Ph = NH_2.C_6H_4.CONH_2 + NPh:C_nH_m.$$

Similarly phthalamidobenzamide with aniline forms phenylphthalimide.

V. H. V.

Oxidation of Substitution-products of Aromatic Hydrocarbons. XV.—Oxidation of β-Cymenesulphonamide. By I. Remsen and W. C. Day (*Amer. Chem. J.*, 5, 149—161).—In this series of researches it has already been shown in the oxidation of paradiethylbenzenesulphonamide, [$Et : SO_2NH_2 : Et = 1 : 2 : 4$], and of α-cymenesulphonamide, [$Me : SO_2NH_2 : Pr^a = 1 : 2 : 4$], that the sulphonamide-group exerts a protecting influence on that hydrocarbon-group which occupies the ortho-position relatively to it. To ascertain the general nature of the rule, the authors now investigate the oxidation of β-cymenesulphonamide, [$Pr : SO_2NH_2 : Me = 1 : 2 : 4$], and find that the propyl-group is protected and the methyl-group oxidised.

Monobromcymene, [$Me : Br : Pr^a = 1 : 2 : 4$], is converted into the *sulphonic acid* by treatment with a mixture of ordinary and fuming sulphuric acids; the liquid solidifies on cooling to a mass of dark purple crystals; these are dissolved in water, the solution neutralised with chalk, and the resulting calcium salt obtained on evaporation in long needles of the formula $(C_{10}H_{12}Br.SO_3)_2Ca + 9\frac{1}{2}H_2O$. The barium salt, $(C_{10}H_{12}Br.SO_3)_2Ba + 9\frac{1}{2}H_2O$, the zinc salt, $(C_{10}H_{12}Br.SO_3)_2Zn + 8H_2O$, and the magnesium salt, $(C_{10}H_{12}Br.SO_3)_2Mg + 9\frac{1}{2}H_2O$, all crystallise in long needles. The sodium salt, $C_{10}H_{12}Br.SO_3Na + 4\frac{1}{2}H_2O$, crystallises in slender needles. *Bromocymenesulphonamide*, $C_{10}H_{12}Br.SO_2NH_2$, crystallises in slender needles, melts at 197° (corr.), and is sparingly soluble in hot water, but readily in alcohol.

β-Cymenesulphonamide, $C_{10}H_{13}.SO_2NH_2$, is prepared by treating a solution of sodium bromocymenesulphonate with sodium-amalgam until all the bromine is removed, the alkaline solution then being neutralised with sulphuric acid, the sodium sulphate crystallised out as far as possible, the mother-liquor evaporated to dryness, heated for some time at 110°, then treated with an equal weight of phosphorus pentachloride, the mixture being gently heated to complete the reaction. After cooling, the mass is treated with aqueous ammonia, and the mixture allowed to stand for 12 hours, when the sulphonamide separates in great part. After purification, β-cymenesulphonamide crystallises in glistening scales, melts at 151° (corr.), is insoluble in cold, sparingly soluble in hot water, readily soluble in hot alcohol. (Although from its method of formation this substance should have the constitution [$Pr^a : SO_2NH_2 : Me = 1 : 2 : 4$], yet the results obtained by the oxidation of paradipropylbenzenesulphonamide seem to throw some doubt on its really possessing that constitution. See next Abstract.) On fusion with potash, a strong odour of thymol was perceptible, but as the quantity of material employed was small, thymol could not be isolated from the product of the reaction. On oxidation with chromic mixture, it yields an acid of the formula $C_{10}H_{13}O_4SN$, *sulphamineparapropylbenzoic acid*, $C_6H_3Pr(SO_2NH_2)COOH$ [1 : 2 : 4], which melts at 244° (corr.), and crystallises in long needles. The barium salt crystallises with $2\frac{1}{2}H_2O$, and is very soluble in water. The result of the oxidation confirms the rule that the sulphonamide group protects that hydrocarbon group occupying the ortho-position relatively to it. A. J. G.

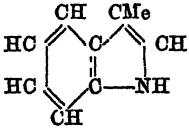
Oxidation of Substitution-derivatives of Aromatic Hydrocarbons. XVI.—Oxidation of Paradipropylsulphonamide. By I. Remsen and E. H. Keiser (*Amer. Chem. J.*, **5**, 161—171).—Paradipropylbenzene, prepared according to Körner's directions, is dissolved in fuming sulphuric acid, gently heated on the water-bath to complete the reaction, the liquid then being diluted and neutralised with barium carbonate. On evaporation, barium paradipropylbenzenesulphonate, $(C_{12}H_{17}.SO_3)_2Ba + 2H_2O$, crystallises out in minute needles, which effloresce on exposure to air. The potassium salt, $C_{12}H_{17}.SO_3K + 4H_2O$, crystallises in large transparent plates. By successive treatment with phosphorus pentachloride and ammonia, the potassium salt is converted into *paradipropylbenzenesulphonamide*, $C_{12}H_{17}.SO_2NH_2$. This crystallises in rhombohedrons having the axial ratios $a : c = 1 : 0·85592$; it melts at 103°, is sparingly soluble in boiling water, but readily in alcohol. On oxidation with chromic mixture, it yields a small quantity of sulphoterephthalic acid and a sulphaminepropylbenzoic acid, $C_{10}H_{13}SO_4N$, crystallising in long lustrous needles, and melting at 212—213° (corr.). The barium salt is not crystalline, the calcium salt, $(C_{10}H_{12}SO_4N)_2Ca + 6H_2O$, does not crystallise well; a hydrogen copper salt, $(C_{10}H_{12}SO_4N)_2Cu = C_{10}H_{13}SO_4N + 2H_2O$, is obtained in minute blue crystals by boiling the acid with copper oxide; the silver salt, $C_{10}H_{12}SO_4NAg$, is non-crystalline. Being derived from paradipropylbenzene, the acid must have the constitution $C_6H_3Pr^\alpha(SO_2NH_2).COOH$ [$Pr^\alpha : SO_2NH_2 : COOH = 1 : 2 : 4$]. The acid obtained by the oxidation of β-cymenesulphonamide (see preceding Abstract) should be identical with this, but the differences in the melting points of the acids and in the properties of their barium salts show that the acids are isomeric. Pending further investigation, the authors suggest the probability that during some of the operations employed in the preparation of β-cymenesulphonamide, the normal propyl-group must have undergone transformation into the isopropyl-group, a transformation of which many instances have been noted recently. A. J. G.

Decolorising Action of Ferric Salts on Indigo. By L. Margary (*Gazzetta*, **13**, 374—375).—In experiments on certain iron mordants for silk containing ferric sulphate and nitric acid, it was necessary to determine the amount of nitric acid present. This was done by means of indigo solution, and the author observed that the results were invariably too high. This he attributed to the oxidising action of the ferric salt, and found on heating the indigo solution with pure ferric sulphate that it was rapidly and completely decolorised, the ferric being reduced to a ferrous salt. C. E. G.

Transformation of Scatole into Indole, and Preparation of Indole. By M. Fileti (*Gazzetta*, **13**, 378—381).—The author found that the vapour of scatole is decomposed when passed through a red-hot tube, a combustible gas being given off, whilst indole is found in the distillate. On this reaction he founds a new and advantageous method for preparing indole. If the vapour of cumidine, prepared by the distillation of barium amidocumate with excess of baryta, be passed over oxide of lead at a red heat, gas is evolved in abundance, and a black liquid condenses in the receiver, consisting of indole mixed with some unaltered cumidine and resinous substances. The product is first treated with hydrochloric acid to remove cumidine, distilled in a current of steam, the distillate acidified with hydrochloric acid, and the indole precipitated with picric acid. The precipitate, after being dried and washed with light petroleum, is distilled with ammonia, when the indole passes over with the aqueous vapour, and forms oily drops, which soon solidify; that which remains dissolved in the aqueous distillate may be extracted by agitation with ether and purified by crystallisation from water. It is necessary carefully to regulate the temperature of the lead oxide in order to obtain good results: if the temperature is too high, most of the material is carbonised: if too low, the cumidine passes over unchanged. In a successful operation cumidine gives 24 per cent. of its weight of the crude picrate. The gas given off contains ethane, ethylene, and propylene. This method of formation is interesting, as it confirms the author's opinion that indole is methyl scatole (see next Abstract), and is moreover the best method for preparing indole. C. E. G.

Synthesis of Scatole. By M. Fileti (*Gazzetta*, **13**, 358—363).—When barium nitrocumate is distilled with barium hydroxide and zinc powder—or better metallic iron—a dark coloured distillate is obtained of disagreeable odour, consisting of cumidine, scatole, and resinous substances: the yield of crude scatole picrate obtained when iron is used is about 10 per cent. A better result is obtained by reducing a portion of the nitrocumic acid (4 parts) to amidocumic acid, mixing it with the rest of the nitrocumic acid (6), and excess of crystallised barium hydroxide (10), drying at 120°, mixing it with twice its weight of dry barium hydroxide, and distilling in small portions of 50 grams at a time. Although the reaction is more regular than when the nitro-acid is used alone, care must be taken or the result will be unsatisfactory. The distillate is treated with dilute hydrochloric acid to remove cumidine, and then distilled in a current of steam, when some of the scatole collects in the condenser in snow-white plates, and the remainder may be recovered from the distillate by acidifying it with hydrochloric acid and precipitating with picric acid. After purifying the picric acid compound by crystallisation from benzene, it is decomposed with ammonia.

It would seem that in this reaction traces of indole are formed, but no methylketole. In reference to Baeyer's statement (*Ber.*, **13**, 2340) that pure scatole gives no coloration with fir wood moistened with hydrochloric acid, the author has been unable by any method of purification to obtain scatole which does not give this coloration. When pure it has no fæcal odour, but a characteristic one recalling that of naphthylamine. Considering its mode of formation, its constitution may be graphically expressed as—



(See preceding Abstract.) C. E. G.

Oil of Hops obtained from Commercial Lupulin. By J. Ossipoff (*J. pr. Chem.* [2], **28**, 447—448).—Personne found oil of hops to consist of a hydrocarbon, $C_{10}H_{16}$, and an oxygenated compound, $C_{10}H_{16}O$. The first is possibly a terpene, but the nature of the second is unknown. The author has undertaken the study of these substances, and in this preliminary notice he states that bromine, sulphuric acid, chromic acid, and sodium act on the purified oil.

A. B.

Oil of Birch. By H. P. Pettigrew (*Pharm. J. Trans.* [3], **14**, 167—168).—A thorough chemical investigation of the composition of this volatile oil has never been made, although Procter found that it contained salicylic acid and had similar properties to the oil of gaultheria; whilst Kennedy quite recently confirmed this result, and thus supported the presumed identity of the oil of birch with the oil of gaultheria. The author has now examined a perfectly pure sample of oil of birch, sp. gr. 1·180 at 15°, boiling point 218°, and finds that it consists of methyl salicylate only, and therefore differs from oil of gaultheria, which contains a terpene, and has a sp. gr. = 1·0318 at 22°, and not 1·180 as given in the United States Pharmacopœia.

D. A. L.

Terebic Acid. By W. Roser (*Annalen*, **220**, 254—271).—A great part of this paper has already appeared (Abstr., 1882, 716). *Sodium ethyl teraconate* crystallises in small white hygroscopic needles of the formula $C_9H_{13}O_4Na$. With silver nitrate this salt gives a crystalline silver salt; with copper acetate, a bluish-green amorphous precipitate. Mineral acids separate *hydrogen ethyl teraconate*, $C_9H_{14}O_4$, an acid liquid, slightly soluble in water. Its solutions decompose carbonates. It is easily saponified to teraconic acid, identical with that obtained by Geissler. On distilling terebilic acid, partial decomposition ensues, carbonic acid is evolved, and a neutral body produced, which distils in a current of steam, and has the properties of a lactone. Terebilic acid boiled with a large excess of potash yields potassium diaterebilate, $C_7H_8O_5K_2$, but the latter, when in a neutral solution, is very unstable, becoming alkaline on warming by the reformation of potassium terebilate, $C_7H_7O_4K$. A solution of α-chloroterebic acid boiled with calcium or alkaline carbonates yields salts of hydroxyterebic acid. *Calcium hydroxyterebate*, $(C_7H_9O_5)_2Ca$, crystallises in microscopic tables; the *silver* salt forms easily soluble needles. The free acid was not obtained in a pure state, but fuses above 100°. From the mother-liquors obtained in the preparation of α-chloroterebic acid, another acid was isolated which appeared to be isomeric with the latter acid. α-Chloroterebic acid, treated with phosphoric pentachloride at 130—140°, yields *chloroterebilic acid*, $C_7H_7ClO_4$, which is easily soluble in water, and crystallises in small prisms melting at 200—203°. It is much more stable than α-chloroterebic acid, and is not decomposed by boiling with water or silver oxide. Its *calcium* salt, $(C_7H_6ClO_4)_2Ca + H_2O$, crystallises in tables or prisms, and loses its water at 170°. The *silver* salt crystallises from water in long needles. Chloroterebilic acid could not be obtained by the action of phosphoric chloride on terebilic acid. The author gives the following formulæ as most probably correct:—

$CMe_2(OH).CH(COOH).CH_2.COOH$

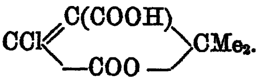
Diaterebic acid (hydroxypropylsuccinic acid).

$$CH_2 < \substack{CNa(COOEt) \\ \text{——} COO \text{——}} > CMe_2.$$

Hypothetical sodiumterebic ether.

$CMe_2 : C(COOEt).CH_2.COONa$

Sodium ethyl teraconate.



Chloroterebilic acid.

L. T. T.

Thapsia Resin. By F. CANZONERI (*Gazzetta*, 13, 514—521).—The root of *Thapsia Garganica*, a plant known for its vesicating properties, yields to boiling alcohol a white amorphous waxy substance, slightly soluble in ether and carbon bisulphide, and melting, after purification, at 90°. This substance however forms but a small part of the thapsia root. More abundant and important constituents are obtained by treating the dried and chopped root in a percolator with ether, whereby a yellow solution is obtained, which, on distilling off the ether, yields an amber-coloured syrupy resin possessing strong vesicating properties. This acid dissolves in strong aqueous potash at ordinary temperatures and in dilute potash when heated—in both cases with great rise of temperature,—and on neutralising the resulting solution with hydrochloric acid, a yellow curdy precipitate is formed, having an unpleasant odour, and consisting of a mixture of liquid and solid ethers and fatty acids, together with resinous substances. From this mixture of products, the author has obtained: (1.) An octoic or caprylic acid, $C_8H_{16}O_2$. (2.) A new acid of the series $C_nH_{2n-2}O_4$, which he designates as **thapsic acid**. (3.) A non-azotised neutral vesicating substance.

This last constituent was obtained in very small quantity only, and in some preparations was altogether absent; it is moreover very difficult to purify from resinous substances and wax, by which it is generally accompanied. It dissolves in hot alcohol, and separates on cooling in shining needles melting at 87°; also in ether and in carbon bisulphide; all its solutions possess vesicating properties. Heated with strong potash-lye, it dissolves partially and is precipitated in the crystalline state on diluting the solution with water. It is not altered by boiling with strong acids. Heated on platinum foil, it burns away without residue, emitting a pleasant odour.

Thapsic Acid, $C_{16}H_{30}O_4$, is obtained by pressing between paper the curdy precipitate formed on adding hydrochloric acid to the solution of the resin in aqueous potash, and crystallising it several times from boiling alcohol with addition of animal charcoal. It forms white shining scales melting at 123—124°, nearly insoluble in water, benzene, and carbon bisulphide, soluble in alcohol, less soluble in ether. When strongly heated, it distils without alteration; ignited on platinum foil, it burns with an odour of burnt wax. It is but slowly attacked by bromine or by strong nitric acid. It is a bibasic acid. Its *potassium salt*, $C_{16}H_{28}O_4K_2$, forms shining anhydrous prisms. The *barium salt*, $C_{16}H_{28}O_4Ba$, obtained by precipitation from the potassium salt, is a white amorphous powder insoluble in water and very slightly soluble in boiling alcohol. The *silver salt*, $C_{16}H_{28}O_4Ag_2$, is a white insoluble precipitate which blackens when heated or exposed to light.

Thapsic acid dissolves at boiling heat in aqueous ammonia, and the solution on cooling deposits a crystalline substance probably consisting of the corresponding amide. The acid heated with aniline at 170—180° in sealed tubes, is converted into the anilide, $C_{16}H_{28}O_2(NHPh)_2$, which forms a white crystalline powder melting at 162—163°, and acquiring a faint violet colour when exposed to the air.

The barium salt of thapsic acid distilled at a moderate heat with excess of barium hydroxide, yields a small quantity of hydrocarbons, saturated and non-saturated, having a musky odour, combining for the greater part with bromine, and forming a solid body which when dried between bibulous paper and crystallised from alcohol, forms white needles melting at 73°.

Octoic or Caprylic Acid, $C_8H_{16}O_2$.—On distilling with steam the oily precipitate obtained by neutralising with hydrochloric acid the potash-solution of the ethereal extract of the resin, after removal of potassium thapsate and dilution with water, there passes over a yellow transparent oil, lighter than water. On exhausting this oil with ether, drying the etheric solution with calcium chloride and distilling, the greater part goes over at 220—236°; and on fractioning this portion at intervals of 5—5°, three other fractions are obtained, the most abundant of which is a colourless liquid soluble in alcohol and ether, and solidifying when cooled with snow, in flexible laminæ melting at ordinary temperatures. The product thus obtained is shown by analysis to have the composition of an octoic acid, and in its melting and boiling points it agrees nearly with the octoic acid obtained by saponification of cocoanut oil, and by oxidation of the octyl alcohol from heracleum oil. melting at 16°, boiling at 236—237°, which agreement the author has further confirmed by examination of the sodium, barium, and zinc salts.*

---

* The author, in accordance with the view hitherto generally entertained, regards this acid as normal octoic acid $CH_3(CH_2)_6COOH$, but recent investigations have shown that the primary octyl alcohol of heracleum oil is an iso-alcohol,

$$CHMe_2(CH_2)_4.CH_2OH,$$

and consequently that the acid obtained from it by oxidation must be an iso-acid, $CHMe_2(CH_2)_4.COOH$. (See Watts's *Dictionary of Chemistry*, 8, 879.)—H. W.

The author suggests that thapsic acid may be a *dioctoic acid*, $C_8H_{15}O_2.C_8H_{15}O_2 = 2C_8H_{16}O_2 - H_2$, formed from the octoic acid by slow oxidation in the body of the plant. H. W.

Red Resins known as Dragon's Blood. By J. J. Dobbie and G. G. Henderson (*Pharm. J. Trans.* [3], **14**, 361—364).—Besides the red resins from *Pterocarpus Draco* and *Croton Draco*, there are three different recognised kinds of dragon's blood, one from the East Indies, *Calamus Draco*; one from Socotra, and one from the Canary Islands, *Dracæna Draco*. The first of these is the only one that has been fully described, but the results are not concordant; this is due apparently to the researches having been carried out on different substances. The authors have now investigated this subject, and have examined several varieties of the so-called dragon's blood, which they find can be arranged in four distinct groups: 1. Those which dissolve completely in chloroform, carbon bisulphide, and benzene; 2. Those soluble in chloroform, but insoluble in carbon bisulphide and benzene; 3. Those soluble in chloroform and benzene, and partly in carbon bisulphide; and 4. Those which are insoluble in all three reagents. The accuracy of this classification is supported by the physical properties of the resins and their behaviour towards reagents, and it is evident therefore that there were four different kinds of resins under examination. All the resins dissolve to a small extent in boiling water, those of Class 4 being rather more soluble than the others; they are all freely soluble in alcohol, ether, oil of cloves, and glacial acetic acid, leaving a variable amount of insoluble matter, which usually consists of vegetable tissue, sand, &c. They are all slightly soluble also in hydrochloric acid, those of Class 2 being the most soluble; ammonia reprecipitates them from this solution. The aqueous and alcoholic solutions have an acid reaction. When treated with sodium hydroxide, the resins effervesce and emit an odour like that of rhubarb. Ammonia forms a clear mixture with the alcoholic solutions. The resins were carefully purified by means of ether, and then powdered; the results of the individual class examinations may be thus summed up: Resin, 1, brick-red, melting at about 80°, when decomposed by heat gives off very irritating red fumes. It dissolves readily with an orange-red colour in alcohol, ether, chloroform, carbon bisulphide, and benzene, but with difficulty in boiling caustic soda, ammonia, sodium carbonate, and with great difficulty in lime-water, whilst, in the cold, it is scarcely soluble in the first two and insoluble in the last two of the latter reagents. The ammonia solution is reddish-yellow, and a portion of the resin is not dissolved. The alcoholic solution gives a brown-red precipitate with lead acetate. Analysis (combustion and lead estimation) suggests the formula $C_{18}H_{18}O_4$. This variety is derived from *Calamus Draco*. Resin 2, $C_{17}H_{19}O_5$, origin uncertain, is carmine-red, melting at about 100°; when heated it gives off non-irritating fumes. It dissolves freely in alcohol, ether, and chloroform with a pink colour, and in cold caustic soda, ammonia, sodium carbonate, and lime-water with purple colour changing to orange-red or yellow on boiling, whilst it is insoluble in carbon bisulphide and benzene. The alcoholic solution gives a lilac-coloured precipitate with lead acetate. Resin 3, $C_{18}H_{18}O_4$, from *Dracœna*, is vermilion, melting at about 80°; when heated it evolves aromatic irritating red fumes. It dissolves with a blood-red colour in alcohol and ether, and in cold caustic soda, ammonia, lime-water, and sodium carbonate, but is insoluble in chloroform, carbon bisulphide, and benzene. Its alcoholic solution gives a mauve-coloured precipitate with lead acetate. Resin 4, is a mixture of a reddish-brown resin, freely soluble in carbon bisulphide, and a light brick-red resin, nearly insoluble in that menstruum. The two portions differ considerably with regard to their solubility in ether, benzene, and other reagents, the dark portion being the less soluble of the two. Cinnamic acid was detected in the first and third varieties (comp. Abstr., 1882, 209), but not in the others. Johnstone found two resins in one kind of dragon's blood, to the one he gave the formula, $C_{20}H_{24}O_4$, and to the other, $C_{20}H_{21}O_4$. D. A. L.

Saponin. By E. Stütz (*Annalen*, **218**, 231—256).—At the commencement of this paper, an historical account is given of saponin, a drug obtained from the *Saponaria rubra* and its allied species. The formulæ proposed for this substance, deduced from the percentage proportions of carbon and hydrogen found in it, are various, but most experimenters are agreed in proving that it is decomposed on boiling with acids, yielding a carbohydrate among other products.

The source of the saponine studied in this paper was the bark of the *Quilbaja saponaria*, a member of the Spireæa family, indigenous in Chili and Peru. This was digested with water, the extract evaporated down, and hot alcohol of 90 per cent. added; on cooling, white flocks of saponin separated, which were then frequently recrystallised from alcohol, and finally purified by animal charcoal.

Saponin thus obtained is a white, amorphous, neutral powder, generally possessing an astringent taste, due to traces of impurities; it is soluble in water, insoluble in absolute alcohol and ether; its aqueous solution forms a lather like soap. When heated to 195° it turns brown, and at a higher temperature evolves a vapour resembling caramel in odour.

The author was unable to obtain saponin free from inorganic impurities; and from the properties of its barium compound it would appear probable that the impurities, principally consisting of calcium, were intimately associated with the saponin. From the mean of four concordant analyses the formula $C_{19}H_{30}O_{10}$ is deduced.

A concentrated aqueous solution of saponin is precipitated by baryta-water; a substance of composition $2C_{19}H_{30}O_{10} + Ba(OH)_2$ being formed, from which the barium is not readily separated by carbonic anhydride. In order to determine the number of alcoholic hydroxyl-groupings present in saponin, it was heated with acetic or butyric anhydride under various conditions. A series of acetyl-derivatives was thus obtained; amongst which are enumerated a tetracetyl, $C_{19}H_{26}\overline{Ac}_4O_{10}$, and a pentacetyl, $C_{19}H_{25}\overline{Ac}_5O_{10}$, derivative, and two compounds formed by the addition of acetic anhydride to the latter substance, viz., $C_{19}H_{25}\overline{Ac}_5.O_8(O\overline{Ac})_2$, and $C_{19}H_{25}\overline{Ac}_5O_8(O\overline{Ac})_4$. From these results it follows that the saponine contains five hydroxyl-groups, and two oxygen-atoms combined only with carbon; its constitutional formula will thus be: $C_{19}H_{25}(OH)_5.O_2.O_3$. From the acetyl-derivatives saponine can be regenerated. V. H. V.

Specific Rotatory Power of Photosantonic Acid. By R. Nasini (*Gazzetta*, **13**, 375—378).—The only one of the five isomeric acids $C_{15}H_{20}O_4$ which has not as yet been examined optically is the photosantonic acid produced by the action of sunlight on an alcoholic solution of santonin. A Cornu's apparatus was employed with sodium flame, and a temperature of 20°. The results obtained with chloroform and alcoholic solutions are given in the Tables I and II, where c is the concentration, that is, the weight of substance dissolved in 100 c.c. of the solvent; $L = 219{\cdot}65$ the length of the tube in millimetres; α the angle of deviation; $[\alpha]_D$ the specific rotatory power with respect to the line $D = \frac{\alpha\, 10^4}{L \cdot c}$.

Table I.

c.	α.	$[\alpha]_D$.
1·259	−3·30	−119·3
2·057	−5·10	−112·9
5·758	−14·30	−113·1

Table II.

c.	α.	$[\alpha]_D$.
0·536	−1·40	−118·9
0·968	−2·50	−117·6
3·285	−9·05	−125·4
4·774	−13·13	−125·2

The following gives the rotatory power of the five acids:—

Santoninic acid	(alcohcl,	$c = 1$ to 3)	$[\alpha]_D =$	−25
Santonic acid	(chloroform,	$c = 4{\cdot}476$)	„ =	−70·31
Parasantonic acid	„	$c = 4{\cdot}470$)	„ =	−98·51
Metasantonic acid	„	$c = 4{\cdot}127$)	„ =	−92·8
Photosantonic acid	„	$c = 1{\cdot}259$ to 5·758)	„ =	−119·3 to 113·1
„	(alcohol,	$c = 0{\cdot}536$ to 4·774)	„ =	−119 to 125

C. E. G.

Hydronicotine and Oxytrinicotine. By A. Étard (*Compt. rend.*, **97**, 1218—1221).—5 grams of nicotine, 5 grams of red phosphorus, and 60 grams of fuming hydriodic acid were heated in sealed tubes at 260—270° for 10 hours. Hydrogen was liberated and the crystalline contents of the tube, consisting probably of a periodide, were treated with potash, and the liberated oily bases fractionated. The products thus obtained are a small quantity of hydrocollidine, boiling at 205°, nicotine boiling at 244°, and hydronicotine, $C_{10}H_{16}N_2$, an oily liquid which boils at 263—264°; sp. gr. at 17° = 0·993. It has a faint odour and dissolves in water, alcohol, and ether in all proportions. Hydronicotine is lævogyrate, its specific rotatory power being $[\alpha]_D = -15° 40'$. The specific rotatory power of nicotine in solutions of the same strength (13·7 per cent.) is 73° 6′, but diminishes with dilution. Acids dissolve hydronicotine with development of heat, but alkalis precipitate the base from its solutions. Hydronicotine platinochloride, $C_{10}H_{16}N_{27}H_2PtCl_6 + H_2O$, forms pale yellow crystals which separate out even from very dilute solutions, and are thus distinguished from nicotine platinochloride. They lose their water in dry air. Hydronicotine hydrochloride gives no precipitate with gold chloride, and is not acted on by dilute solutions of mercuric chloride, potassium dichromate, or ferrous or ferric salts in the cold.

Hydriodic acid under pressure is the only substance with which the author has been able to obtain hydronicotine.

Oxytrinicotine.—Nicotine is heated to 240° and mercuric oxide is added in small quantities at a time until the liquid becomes thick and brown. Each addition of the oxide produces an energetic reaction; water is given off and metallic mercury separates out. The product of the reaction is allowed to cool, dissolved in dilute hydrochloric acid, and the solution filtered. The filtrate is treated with hydrogen sulphide, filtered from the mercuric sulphide, and the dark brownish-black filtrate is mixed with an alkali, which produces a flocculent brown precipitate of the composition $C_{30}H_{27}N_6O_2$ or $(C_{10}H_9N_2)_3O_2$, analogous to thiotetrapyridine, $(C_{10}H_9N_2)_2S$. This substance may be regarded as formed in a similar manner to thiotetrapyridine, the mercuric oxide giving up its oxygen at 240° in presence of the organic compound, and the author proposes to call it oxytrinicotine. Oxytrinicotine hydrochloride does not crystallise, and, like thiotetrapyridine hydrochloride, has an astringent taste. With platinum chloride its solution yields a brownish-yellow precipitate of the composition $(C_{10}H_9N_2)_3O_2,2H_2PtCl_6 + 6H_2O$. C. H. B.

Mono- and Di-chloracetate of Quinine. By G. MAZZARA (*Gazzetta,* 13, 525—527).—These salts, $CH_2Cl.COOH,C_{20}H_{24}N_2O_2,2\frac{1}{2}H_2O$ and $CHCl_2.COOH,C_{20}H_{24}N_2O_2,2H_2O$, are prepared by adding the requisite quantities of quinine dissolved in alcohol to mono- and dichloracetic acid respectively, and gently heating the mixtures. They crystallise in white silky needles, and dissolve in water; the monochloracetate in 62·43 parts at 20·9°, the dichloracetate in 41·4 parts at 22°. H. W.

Action of Benzyl Chloride on Quinine. By G. MAZZARA and G. POSSETTO (*Gazzetta,* 13, 529—532).—When these two bodies are heated together in alcoholic solution, a deep red liquid is formed, leaving on evaporation a residue of similar colour, which dissolves partially in water, leaving a resinous substance. The solution thus obtained is dichroic, yellow by transmitted, red by reflected light, and yields with platinic chloride a precipitate which dissolves in dilute alcohol, and separates therefrom as a micro-crystalline mass, having the composition $C_{20}H_{24}N_2O_2,C_7H_7Cl,HCl,PtCl_4 + 2H_2O$.

The concentrated solution of the compound of benzyl chloride and quinine gives with caustic soda a greenish-yellow precipitate; the dilute solution, a yellow crystalline precipitate of a compound of quinine with benzyl alcohol, which melts and blackens at 75°, dissolves in cold alcohol and ether, and melts to a resin when heated with water or alcohol.

The aqueous solution of the compound of benzyl chloride and quinine leaves on evaporation a yellowish semi-solid residue, and on heating this substance (8 g.) dissolved in alcohol with an equimolecular quantity of benzyl chloride (2·2 g.), and evaporating the alcohol, a deep red viscid residue is left, which dissolves partly in water, forming a solution green by transparent, red by reflected light. This solution, treated with platinic chloride, forms a yellow precipitate soluble in dilute alcohol, from which it is deposited in the form of a light friable powder, having the composition

$$C_{20}H_{24}N_2O_2,(C_7H_7Cl)_2,HCl,PtCl_4.$$

The solution of the compound of benzyl chloride and quinine, mixed with excess of water and caustic soda, yields a deep yellow precipitate which melts at 85° and decomposes at 130°, with emission of gas-bubbles.

A mixture of benzyl chloride and *benzylquinine hydrate*, in molecular proportion, dissolved in alcohol and treated as above, yielded a product which, when freed from alcohol and treated with water, formed a deep red solution, giving with platinic chloride a brick-red precipitate having the composition $C_{20}H_{24}(C_7H_7)N_2O_2,C_7H_7Cl,HCl,PtCl_4$.

H. W.

Action of Aromatic Aldehydes on Quinine. By G. MAZZARA (*Gazzetta*, 13, 367—369).—After referring to his former experiments on aldehydic compounds of quinine (this vol., 186), the author states that whilst nitrobenzaldehyde gives comparatively stable compounds with quinine, the results obtained with paraldehyde benzaldehyde and anisaldehyde are unsatisfactory.

When quinine and nitrobenzaldehyde in molecular proportions are boiled together in chloroform solution, and ether is added to the product, a yellow gelatinous precipitate is obtained resembling alumina in appearance. When dried, it is a yellow powder which melts at 113—118°. It has the composition $C_{22}H_{24}N_2O_2.C_6H_4(NO_2).CHO$. It is easily decomposed by acids into a salt of quinine and nitrobenzaldehyde.

If the chloroform solution of quinine and nitrobenzaldehyde is allowed to evaporate spontaneously instead of being precipitated with ether, a yellowish viscid residue is left which turns brown on exposure to the air.

C. E. G.

Caffeine, Xanthine, and Guanine. Part II. By E. FISCHER and L. REESE (*Annalen*, 221, 336—344).—*Chlorocaffeine* is best prepared by passing chlorine gas which has been dried by means of sulphuric acid and phosphoric anhydride, into a boiling solution of caffeine (dried at 120°) in chloroform. The operation is ended when the evolution of hydrochloric acid ceases. Chlorocaffeine may with great advantage be substituted for bromocaffeine in the preparation of the compounds described in Part I (Abstr., 1883, 354).

Diethoxyhydroxycaffeine, $C_8H_9N_4O_2(OH)(OEt)_2$, is decomposed by hydriodic acid, yielding hydroxycaffeine. The reaction takes place most favourably in a chloroform solution. Diethoxyhydroxycaffeine dissolves in phosphorus oxychloride, forming the compound

$$C_8H_9N_4O(OH)(OEt)Cl.$$

This derivative is reconverted by alcohol into diethoxyhydroxycaffeine. It is completely decomposed by water, with the formation of a considerable quantity of dimethylalloxan.

The decomposition of *Amalic acid*, $C_{12}H_{14}N_4O_8$, by heat is very complicated. One of the products of decomposition is *deoxyamalic acid*, $C_{12}H_{14}N_4O_6$. It is a colourless crystalline body, freely soluble in chloroform and strong acetic acid. It melts at 260° and sublimes at the same temperature. At a higher temperature, it distils with partial decomposition. On evaporation with nitric acid, dimethylalloxan is formed. Since prolonged boiling with chromic mixture converts deoxyamalic acid into dimethylparabanic acid, this acid is probably a derivative of malonyldimethylcarbamide.

Bromoguanine, $C_5H_4N_5OBr$, obtained by the method adopted for the preparation of bromocaffeine, is a white crystalline powder, almost insoluble in alcohol, ether, and cold water. It unites with acids to form crystalline salts, *e.g.*, $C_5H_4N_5O.Br,HCl$, and also with lead and silver to yield crystalline compounds. A complicated reaction takes place when the silver or lead salt is heated with methyl iodide at 100°. No methyl-derivative is obtained, but a considerable quantity of bromocaffeine is produced. Nitrous acid converts bromoguanine into *bromoxanthine*. This crystalline compound is decomposed by heat without melting. It is soluble in hot water, hot alcohol, and in mineral acids, but it is insoluble in alkalis. W. C. W.

Piperylhydrazine. By L. KNORR (*Annalen*, **221**, 297—313).— The preparation of *piperylhydrazine* by the action of zinc-dust and acetic acid on nitroso-piperidine has been previously described by the author (Abstr., 1882, 1115). It is a colourless refractive oil of ammoniacal odour. It boils at 146°, and has a sp. gr. 0·928 at 14·6° compared with water at the same temperature. Piperylhydrazine is very hygroscopic. It is miscible in all proportions with water, alcohol, ether, and benzene, but is sparingly soluble in concentrated solutions of the alkalis. It precipitates metallic oxides from their solutions, and expels ammonia from hot solutions of its salts. With chloroform and potash, it exhibits the isonitrile reaction, and it reduces cold ammoniacal solutions of silver, and also Fehling's solution on warming. Mercuric oxide, potassium permanganate, and bromine-water oxidise piperylhydrazine, and convert it into the corresponding tetrazone. *Piperylhydrazine hydrochloride*, $C_5H_{10}N.NH_2,HCl$, is deposited from alcohol in plates melting at 162°, which are freely soluble in hot water and chloroform. The platinochloride is insoluble in alcohol and ether. The picrate forms golden-yellow needles.

Monobenzoylpiperylhydrazine, $C_5H_{10}N.NH\overline{Bz}$, is deposited in white scales on mixing together ethereal solutions of benzoic chloride and piperylhydrazine. The crystals melt at 195°, and distil at a higher temperature without decomposition. When benzaldehyde and piperylhydrazine are brought together, *benzylidenepiperylhydrazine*,

$$C_5H_{10}N_2.CHPh,$$

melting at 62°, is produced. It is deposited from a hot alcoholic solution in crystalline plates, soluble in alcohol and ether.

Piperylsemicarbazide, $C_5H_{10}N.NH.CONH_2$, prepared by the action of potassium cyanate on piperylhydrazine hydrochloride, forms rhombic crystals melting at 136°, which dissolve freely in alcohol and in hot water.

Piperylthiosemicarbazide, $C_5H_{10}N.NH.CSNH_2$, is prepared from piperylhydrazine hydrochloride and ammonium thiocyanate by Fischer and Besthorn's method (*Annalen*, **212**, 325). It crystallises in prisms melting at 167°, and soluble in alcohol.

Carbon bisulphide acts energetically on piperylhydrazine; in presence of alcohol, *piperylthiocarbazide*, $CS(NH.NC_5H_{10})_2$, is the result of the reaction. This compound crystallises in transparent rhombic plates melting at 181°, which are freely soluble in alcohol and benzene. A *dipiperylthiosemicarbazide*, $C_5H_{10}N.CS.NH.NC_5H_{10}$, was also obtained crystallising in the triclinic system. It melts at 85·5°, and decomposes at a higher temperature.

Piperylhydrazine is decomposed by nitrous acid into nitrosopiperidine and nitric oxide. It unites with methyl iodide to form *methylpiperylazonium iodide*, $C_5H_{10}N.NH_2MeI$, which crystallises in needles, soluble in water, chloroform, and hot alcohol. The compound begins to decompose at 150°. The iodide is converted into *methylpiperylazonium hydroxide* on treatment with silver oxide. This base is decomposed by heat, yielding dimethylpiperylammonium iodide, piperidine, ammonia, and other products.

The preparation of the *tetrazone* has been previously described (*loc. cit.*). Acid solutions of the tetrazone are very unstable; they are decomposed by heat, half the nitrogen is evolved, and piperidine is formed. The *hydrochloride* is obtained as a heavy oil on mixing ethereal solutions of hydrochloric acid and the tetrazone. The *platinochloride*, $(C_{10}H_{20}N_4)_2,H_2PtCl_6$, is an amorphous powder, decomposing with detonation at 70°. W. C. W.

Action of Bromine on Pilocarpine. By CHASTAING (*Compt. rend.*, **97**, 1435—1437).—When bromine is added to a solution of pilocarpine in chloroform, there is development of heat, the mixture becomes acid, and a heavy oily liquid separates. The supernatant chloroform retains the excess of bromine together with a small quantity of the bromo-derivative, which gradually crystallises out. The oily liquid is rapidly evaporated, and forms a deep golden-yellow resinous mass, which is then dissolved in chloroform, from which it separates in a mass of minute prismatic crystals. These crystals have the composition $C_{11}H_{15}N_2O_2Br_5$, and consist of a *dibromide of dibromopilocarpine hydrobromide*, $C_{11}H_{14}Br_2N_2O_2,HBr,Br_2$. This substance is inodorous, but when exposed to air it absorbs moisture and gives off ethyl bromide, undergoing some alteration which results in the formation of a compound containing less carbon than the original substance. In contact with copper, dibromide of dibromopilocarpine hydrobromide gives up part of its bromine, and when treated with silver oxide in presence of water and chloroform, it loses Br_3 and yields dibromopilocarpine, $C_{11}H_{14}Br_2N_2O_2$, which resembles pilocarpine in appearance, but is less mobile and less strongly alkaline; it is precipitated by platinum chloride.

The action of bromine on pilocarpine in presence of a small quantity of water does not yield dibromide of dibromopilocarpine hydrobromide, but the corresponding derivative of a feebler base which contains an atom of carbon less than pilocarpine. This carbon is given off as carbonic anhydride, and the compound formed should be represented by the formula $C_{10}H_{14}N_2O_3,HBr,Br_2$. C. H. B.

Ptomaïnes and their Significance in Toxicology. By T. HUSEMANN (*Arch. Pharm.* [3], **21**, 401—417).—The commencement of a history of the ptomaïnes, and the methods of detecting them and distinguishing them from vegetable alkaloïds, compiled from the papers of recent investigators. W. R. D.

Ptomaïnes and Similar Bodies. By C. ARNOLD (*Arch. Pharm.* [3], **21**, 435—437).—In the course of a toxicological examination of the stomach and intestines of five dogs and two horses by the Stas-Otto method, the author isolated a brown viscous liquid having a strongly alkaline reaction, an aromatic smell, and a bitter taste. When neutralised with hydrochloric acid, it yielded a distinctly crystalline salt. The contents of the stomachs of seven dogs recently killed with hydrocyanic acid were examined for the same substance, and in four instances it was obtained. The weight of the product was two or three centigrams. It yielded precipitates with all the usual alkaloïd reagents, and when neutralised with hydrochloric acid and subcutaneously injected in frogs, it caused temporary paralysis. Rabbits were not affected when similarly treated. The alkaloïd could not be extracted from the brains, spleen, liver, or other organs of the animals; but in two cases when the fresh urine was treated by the Stas-Otto process, a residue which gave the general reactions for alkaloïds was isolated. An attempt was now made to produce the same alkaloïdal substance by a process of artificial digestion. 5 grams of pepsin and 100 grams of freshly prepared fibrin were mixed with 2·5 litres of water, to which had been added 25 grams of hydrochloric acid (sp. gr. 1·125). The mixture was allowed to stand for 30 hours at 37—38°, after which it was treated by the Stas-Otto method, and 0·4 gram of a body was obtained which had the same chemical, physical, and physiological properties as that which had been extracted from the actual contents of the stomach. The author has been easily able to isolate ptomaïnes from putrefying animal corpses. From 500 grams of the muscular tissue of a dog, in a high state of decomposition, 1·6 grams of a volatile alkaloïd was obtained by the Stas-Otto method; when it was subcutaneously injected in a rabbit, tetanus and death ensued. From 500 grams of putrefying horseflesh 0·5 gram of the same substance was obtained. W. R. D.

Physiological Chemistry.

Effects of Rarefied Air on the Animal Organism. By A. FRANKEL and J. GEPPERT (*Bied. Centr.*, 1883, 599—601) —Dogs were the animals experimented on; the general appearance of respiration under continuously reduced pressure coincides with the observations of Bert and with the experience of aëronauts at high elevations. It is remarked that the organs of the animals which were usually experimented on showed symptoms of gradually adapting themselves to their conditions, so that to obtain trustworthy results they should be allowed intervals of days, and even a week, and that those animals would bear with impunity increase and diminution of atmospheric pressure which a newly employed animal would not. A rarefaction equal to an elevation of 3800—4900 meters showed no perceptible diminution in the oxygen contained in the blood of three dogs, and with five others the loss was very small. At a pressure diminished to half an atmosphere the oxygen began to vary, but still very nearly within normal limits, so that probably the diminution of oxygen in the rarefied air was compensated by the rapidity of respiration. A reduction of pressure to one-third of an atmosphere impoverished the blood rapidly, and at one-fourth of an atmosphere death followed; at one-third, arterial blood contains only one-half its normal proportion of oxygen. The authors' experience confirms Bert's opinion that the effect of diminished barometrical pressure on the animal economy is within certain limits of a chemical rather than mechanical nature, and that even the bleeding which takes place from thin membranes is due to their having been weakened by abstraction of oxygen. A considerable increase in the nitrogen voided by the animals in their urine under diminished pressure was also noted.

J. F.

Experiments on the Time Required for Digestion of Meat and Milk. By E. JESSEN (*Bied. Centr.*, 1883, 602—604).—These experiments were of three classes; with an artificial digestive solution the substances introduced into the stomach of a dog and of a man.

The meat employed was separated from sinews and chopped small; it was used raw, half boiled, and well boiled, half and well roasted, the latter with 5 grams of butter to 100 grams of meat. Two strengths of pepsin solution were used, one containing 0·1 per cent. pepsin and 2½ per cent. hydrochloric acid, the other double the strength, both appeared to have the same amount of digestive power; the solutions were left in contact with the meat for 24 hours at a temperature of 35—40°. The undigested portion of the meat was then separated by filtration, dried at 110°, and weighed; the residues from 25 grams were—

Raw flesh	5·67
Half boiled	9·49
Well boiled	17·95
Half roasted	9·76
Well roasted	17·07

The experiment on the dog was made by introducing the meat sewn in a netting bag through a fistula into the stomach; 2 grams were used, the digestive power being previously excited by a ration of bread and milk. Owing to the meat not being freely accessible, the time of digestion was long, but conditions being the same, the results are useful for comparison. The time occupied in digestion of 2 grams—

	Hours.
Raw beef	5·58
Half boiled	6·83
Well boiled	5·79
Half roasted	7·42
Well roasted	7·54
Frog's flesh	4·46
Veal	6·63
Pork	6·25

A man, 30 years old, in normal health, was the subject of the next experiment. When his stomach was pumped empty he was fed with 100 grams meat and 300 c.c. water. The experiment was considered at an end when the stomach-pump brought up no particles of fibrine. The time required for digestion of the different substances:—

	Hours.
Raw beef	2
Half boiled	2½
Well boiled	3
Half roasted	3
Well roasted	4
Raw mutton	2
Raw veal	2½
Raw pork	3

The same person was fed with milk, the nitrogenous contents of which equalled those of 100 grams beef—

	Hours.
602 c.c. raw cows' milk	3½
602 „ boiled „	4
602 „ sour „	3
675 „ skimmed „	3½
656 „ raw goat's milk	3½

J. F.

Digestive Power of Commercial Pepsin. By C. M. Dana (*Bied. Centr.*, 1883, 644).—A number of samples of American and German preparations of pepsin dissolved on an average 10—12 times their weight of coagulated albumin, but were almost without result on larger pieces. To prove that this does not resemble the natural action of the stomach, the author experimented on dogs. The animals were fed with hard boiled eggs and meat, with and without pepsin; in the latter case (15 dogs) but one-third of the albumin dissolved; whilst with 21 dogs which had received pepsin, but one-fifth remained undissolved, and some which had got a better pepsin, only one-eighth remained undissolved. The duration of digestion was $1\frac{3}{4}$ to $3\frac{1}{2}$ hours: the operations in the stomach were therefore better than outside.

J. F.

Behaviour of Amides in Animal Nutrition. By N. ZUNTZ (*Bied. Centr.*, 1883, 602).—The experiments undertaken to verify those of Weiske (Abstr., 1882, 986) were performed on rabbits, which received as food 13 grams rice-starch freed from albumin by pepsin and hydrochloric acid, 2 grams sugar-candy, 2 grams olive oil, and 0·33 gram of the neutral ash of hay and wheat with 0·09 of common salt. When to this food, free from nitrogen, was added 1·5 gram of asparagine, there was an immediate reduction of the loss of nitrogen from the body amounting to from 71 to 72 per cent.; when in addition 0·1 gram tyrosine, 0·05 gram taurine, and 0·05 gram of guanidine thiocyanate were given, the waste of albumin *increased* by 156 per cent. above that of non-nitrogenous food. If a part of the asparagine is replaced by a strong ammonium body, produced by the action of pancreatic fluid on meat, the waste of nitrogen became 1·7 per cent. higher than when non-nitrogenous food was given. J. F.

Experiments with Stall-fed Cattle. By VOSSLER (*Bied. Centr.*, 1883, 512—614).—The experiments were made to ascertain if well fattened cattle could be maintained in that state for a lengthened period on moderate rations, if kept in a state of rest as nearly perfect as possible. Ewes and oxen were so treated, and with success; although the fattening was finished previous to the experiment, they did not lose but in some cases gained weight. J. F.

Further Experiments on the Digestive Powers of the Horse. By v. ELLENBERGER and V. HOFMEISTER (*Bied. Centr.*, 1883, 604—606).—In continuation of his researches (Abstr., 1883, 487, and this vol. 92), the authors submitted the mucous membrane of the horse's stomach to a complete histological examination. The gullet end of the stomach forms a receptacle in which the saliva has time to act on the large quantities of starchy matter which constitute the food of the horse, not being furnished with the glands which secrete the acid gastric juice; the posterior portion being furnished with those glands; the stomach is comparatively small but very elastic, and surrounded by strong and elastic integuments, its walls contain intercellular and intermuscular ganglia, and at least three kinds of cells, the peculiarities of which have not been fully examined. The cells of the pylorus glands, too, differ from those of the intestine.

The pepsin present in the mucous membrane of the stomach is partly extracted by glycerol and partly by treatment with hydrochloric acid. That part of the stomach which produces pepsin is small in extent, but very thick and has long capillaries. The surface of the pylorus contains very little trace of pepsin in the first hours of digestion, and not much at any period, but it is very abundantly produced in the proper part of the stomach, and possesses stronger fermentative qualities in those glands which lie deepest beneath the surface, and its greatest strength is about the end of the digestive process.

J. F.

Feeding Experiments on Pigeons. By ASSMUS (*Bied. Centr.*, 1883, 857).—A cock and a hen pigeon which originally weighed 200 and 250 grams respectively, after eating 75 grams daily of a mixture of 1 flesh meal and 10 potatoes for 20 days, were found to have increased in weight by 80 and 70 grams. E. W. P.

"Champion Spice." By C. LEHMANN and others (*Bied. Centr.*, 1883, 826).—A spice is much sold which is supposed greatly to increase the flow of milk when added to ordinary food. The authors state that such is not the case, but rather that the yield is reduced; they state that this spice consists of the waste from the grinding of *Fœnum græcum*, coriander, cumin, and aniseed, which is mixed with a little palm-nut cake.

The following figures show the difference between the guaranteed analysis and that made by one of the authors:—

	Guaranteed.	Siewert.
Fat	3·64	2·54
Albumin	10·76	4·55
Fibre and carbohydrates	70·24	60·61
Water	10·25	9·74
Sand and ash	5·11	9·16

E. W. P.

Cattle Plague and Pasteur's Protective Inoculation. By MÜLLER and others (*Bied. Centr.*, 1883, 614—618).—The first part of this paper is a report on certain herds of oxen and sheep which had been inoculated with Pasteur's so-called vaccine; it shows that the loss by death from the disease was very much less than amongst unprotected animals.

Archangelske describes his researches on the development of the bacteria of splenic fever. From the moment of the infection, the blood of the animal (using every possible caution in the examination) contained small round shining spherical organisms, about the size of ordinary micrococci; a little of this blood added to chicken broth caused cloudiness next day from presence of the bacteria. In the second stage of culture, bacteria and thread-like bodies were present, the latter developed themselves on potatoes, and mice died when they were introduced into their system; all the animals from which the blood was drawn died of splenic fever, with bacteria in the blood, spleen, and other organs. The author thinks these globular bodies are the spores of the bacteria, which multiply in the earlier stages and develop bacteria at the end of the sickness; the development in the earlier stages can be ascribed only to a splitting up similar to that of micrococci. As death sometimes occurs previous to the development of the spores, it accounts for some observers not having found bacteria after death; the author mentions a theory of Lemmers that the two forms are those of two different organisms, one of which being numerous while the other is few, and the reverse.

Feltz has investigated the part which earthworms are said to play in the spread of the disease; infected blood from artificial culture, and from guinea-pigs which died of the disease, was mixed with earth and placed in a flower-pot, in which were also placed worms; at intervals during 22—52 days worms were withdrawn and washed repeatedly in distilled water. Guinea-pigs were then inoculated with matter from the cut-up worms, and also the water in which they had been washed; the contents of the worms and the first washings produced the disease, but the last wash-water did not. Feltz also made experiments on rabbits in order to weaken the infection, but the results were unsatisfactory. He says that a long contact with the soil weakens the germs, and that a milder form of fever follows when derived from such a source. J. F.

Effects of Copper on the Organism of Ruminants. By v. ELLENBERGER and V. HOFMEISTER (*Bied. Centr.*, 1883, 606—609).—The action of solutions of salts of copper on animal membranes has long been known and investigated, but much remains to be learned, especially about chronic copper poisoning. The authors limit their work to a record of observations on the effects of small doses of the salts regularly administered. The subjects of the experiment were sheep, and the dose of from half a gram to 3 grams. Amongst the negative results were no alteration of muscular structure, no acceleration of the motion of the heart, no uniform alteration in the microscopic appearance of the blood corpuscles, no alteration of the respiration nor of the secretion of urine. Amongst the positive results, the presence of albumin, bile, and blood in the urine, flaccidity of muscles, weakness, and loss of appetite. The excretion of copper from the system is chiefly by means of the bile, partly by the urine, but in lesser degree.

The principal part of the body which retains copper is the liver, which holds it with very great tenacity, having been found 41 days after a dose had been given; the pancreatic glands retain it with almost equal strength; the kidneys do not contain so much as the other two organs. The deposit of copper is proportionally much greater if it has been administered in numerous small doses, the cells having time to absorb it, which is not the case with large doses, owing to their rapid action. The deposits in the nervous system are small, and still smaller in the muscular, not enough to interfere with their action, but sufficient to be found in the flesh after administration of medicines containing copper. J. F.

Kairine and Kairoline—Hydroxyquinolinemethyl Hydride and Quinolinemethyl Hydride. By FILEHNE (*Pharm. J. Trans.* [3], 14, 383—384).—The present paper treats of the physiological properties of these bodies. They are both, as well as some other compounds of the quinoline series, very powerful anti-pyretics, but have no local action, and are, therefore, valuable medicines in cases of fever. They are quite similar in action; kairoline is, however, less energetic and slower in action than kairine. Kairine has been tried in a series of acute and chronic febrile diseases, and in all, its antithermic action was found to be constant.

The hydrochloride is the salt employed; it is a clear crystalline greyish-yellow powder, very soluble in water, and has a bitter somewhat aromatic taste. After administering the powder, water should be drunk freely. Its use is not accompanied by any unpleasant effects, such as headache, ringing in the ears, sickness, &c. With regard to its antithermic properties, doses of 1 to 1·5 gram in healthy adults have no physiological action and no effect on the temperature; whilst in cases of adult patients or debilitated subjects, a dose of 1 gram every two hours must not be exceeded, otherwise cyanosis is apt to ensue. The most suitable dose in adult fever cases is 0·3 to 0·5 gram every hour or 1½ hour. The interval between 1 gram doses should not exceed 2½ hours, and that between 0 5 gram doses not more than 1½ to 2 hours, for the effect of 1 gram only last three hours, whilst that of 0·5 gram is of 2¼ hours' duration; to produce a less pronounced effect reduce the doses, but do not increase the interval. When the influence of the drug ceases, the temperature rises again with a feeling of chilliness amounting sometimes to actual rigor. Less than 0·3 gram given at once has no practical effect on the temperature, a dose of 0·3 to 1 gram lowers the temperature by ½ to 2°, another dose given before the effect of the former one passes away, causes a further reduction, and if 0·5 gram be given hourly, it invariably follows that, without any injurious effect, the temperature falls to the normal point or below it after the fourth (sometimes after the third, or even the second) dose. The temperature cannot be brought below 37—36·5°, and the low temperature is maintained only as long as the administration of the drug is continued every 2½ hours at least, otherwise shivering occurs, and the temperature rises to the point corresponding to the acuteness of the disease; this drawback is overcome, so as not to disturb the night's rest, by judicious dosing during the day, and by giving a full dose of 2 grams of *kairoline* the last thing at night. The action of kairine begins 25 minutes after the dose of 0·5 to 1 gram is taken by the mouth; the fall in temperature is more rapid the larger the dose, and is always accompanied by profuse sweating, which lasts only as long as the temperature continues to fall. During the use of these drugs, the urine becomes green, but contains no sugar or albumin. Pneumonia patients especially have enjoyed great comfort from the use of this drug; in fact, such cases can be kept quite free of fever. It is suggested to use kairine as a remedy in malarial affections, by giving 1 gram hourly, three hours before the expected attacks. D. A. L.

Chemistry of Vegetable Physiology and Agriculture.

Influence of Light on the Development of Bacteria. By J. JAMIESON (*Bied. Centr.*, 1883, 857).—Bacteria were destroyed by direct sunlight, but not by diffused light. The experiments showed that at a moderate or low temperature the direct sunlight had no destructive action. Dry bacteria were killed in three or four days when exposed to sunlight and air. From this it is evident that the action of light on bacteria is not yet accurately ascertained.

E. W. P.

Occurrence of the Butyric Ferment. By W. Zopf (*Bied. Centr.*, 1883, 858).—The saccharine matter of plants, cucumbers, cabbages, &c., is first converted by the lactic ferment, which is probably only a variety of *Clostridium butyricum*, into lactic acid, then the true butyric ferment begins its work. Upon this process depends the ripening of cheese and formation of sauer kraut. E. W. P.

Yeast. (*Dingl. polyt. J.*, **249**, 227, 231.)—According to Delbrück alcohol and sulphuric acid have peculiar influence on both yeast and bacteria. They are both poisonous for bacteria, and both prevent the growth of yeast without however destroying its fermentative power. A very large amount of sulphuric acid may be present, for an hour at least, without destroying this power, but no increase of the cells takes place. Similarly in the mash, the presence of 5 to 7 per cent. of alcohol prevents growth in the yeast, but the fermentative power remains. Heinzelmann has found that 0·1 gram of salicylic acid to the litre of yeast increases its fermentative power, 0·12 gram begins to diminish this power, and with 0·375 gram the yeast is killed. 200 grams malt mashed to 1 litre, and treated with 0·1 gram salicylic acid, gave a better sugaring and stronger fermentation than without the acid, so that it appears advisable to add the acid to the yeast preparation, and then to prepare the mash in the usual manner.

Lintner, investigating the formation of diastase under various conditions, could only obtain accordant results with the same barley after careful drying at 50°. Moist and bad barley so treated give very uniform results. J. T.

Formation and Accumulation of Saccharose in the Beet. By A. Girard (*Compt. rend.*, **97**, 1305—1308).—The author confirms Peligot's statement that the root never contains any sugar but saccharose, and finds that saccharose exists together with glucose not only in the petioles and ribs, but also in the blade of the leaves. The root and its beard, and the petioles, have the same composition in the night as in the day, but the proportion of saccharose in the blades varies, and is frequently twice as great in the evening as it is the next morning. The quantity of glucose in the blades is sensibly the same at night as in the morning, and increases only with the development of the plant. The proportion of saccharose, however, depends on the amount of light that the plant has recently received, and at the close of a bright day may approach 1 per cent., but at the close of a dull day it is considerably less. In all cases, however, about half and sometimes even a higher proportion of the saccharose formed during the day disappears from the blades during the night. The composition of the petioles connected with the midribs undergoes no sensible diurnal variation. It would seem, therefore, that the saccharose is first formed directly in the blades under the influence of light, and is afterwards transported through the petioles to the roots, where it is gradually stored up. Since the leaves increase in bulk, but retain the same percentage of inorganic matter, it seems probable that a double osmotic movement takes place in the plant by which the inorganic substances absorbed from the soil are transported to the leaves, whilst the saccharose formed in the leaves is transported to the root. C. H. B.

Ratio of Flesh to Stone in Stone Fruit. By G. WILHELM (*Bied. Centr.*, 1883, 851).—

		Reine Claude. Per cent.	Damask plum. Per cent.

E. W. P.

Chemical Changes in Decayed Wood. By A. WAGNER (*Dingl. polyt. J.*, **249**, 342—346).—Timbers undergoing three different kinds of decay were examined:—(*a*) red rot; (*b*) white rot; and (*c*) that produced by *Merulius destruens.* The composition of the rotten timbers in all three cases did not deviate much from that of sound timber, although the physical change was so great.

	a.	*b.*	*c.*
Water	9·9	11·71	17·12
Ash	3·35	1·77	2·41

Dried at 100° they gave respectively—

C	50·04	50·89	51·16
H	6·48	6·37	4·70
O and N	39·77	40·74	41·24
Ash	3·71	2·00	2·90
SO_3 in ash	6·41	3·35	1·54

The high sulphuric anhydride in *a* is ascribed to the material with which the timber was in contact.

Boiling water extracts only small quantities from *a* and *b*, producing light yellow solutions, whilst from *c* considerable quantities of organic matter are taken up producing a strong brownish-red solution. Boiling potash-solution is still more striking in its action; *c* is almost completely dissolved with a dark brown colour, whilst *a*, and particularly *b*, are only slightly attacked, with much lighter and more reddish colour. J. T.

Elementary Composition of Certain Kinds of Wood, with a Calorimetric Investigation into their Combustibility. By E. GOTTLIEB (*J. pr. Chem.* [2], **28**, 385—421).—The results of the author's analysis of woods from various Danish trees agree on the whole with those of Chevandier and Brix. The following are the average results obtained from samples taken both from near the roots and near the tops of the trees, and dried at 115°:—

Wood.	Carbon.	Hydrogen.	Oxygen and nitrogen.	Ash.
Oak	50·16	6·02	43·45	0 37
Ash	49·18	6·27	43·98	0·57
Hornbeam	48·99	6·20	44·31	0·50
Beech	49·06	6·11	44·17 0·09	0·57
Birch	48·88	6·06	44·67 0·10	0·29
Fir	50·36	5·92	43·39 0·05	0·28
Pine	50·31	6·20	43·08 0·04	0·37

The quantity of carbon and hydrogen, however, was found to vary slightly according as the sample was taken near the root or the top in the cases of oak, ash, and hornbeam, but not in the case of beech. A specimen from a beech tree grown on a chalky soil contained less carbon These results show the quantity of carbon in all the dried samples to be greater than that in cellulose. The small quantities of tannin, resin, fatty or nitrogenous bodies cannot account for this, nor can the author throw any light on the quantity of the substances which raises the total quantity of carbon in wood above that contained in pure cellulose and similar substances. The quantity of nitrogen was never above 0·1 per cent., which is not in accordance with the results (over or about 1 per cent.) of Chevandier. The author describes minutely the form of calorimeter which he constructed and used for obtaining the following results; 1 gram of the substance (dried at 115°) being used:—

	Heat-units.
Oak (180 years old)	4620
Hornbeam	4728
Beech (60 years old)	4766
„ (100 years old)	4770
„ (130 years old)	4785
Fir (40 years old)	5035
Ash	4711
Birch	4771
Pine	5085

According to Dulong, the heat of combustion of a substance may be calculated by adding that of the single parts, abstracting however that of as much hydrogen as is capable of forming water with the oxygen contained in the substance. J. Thomsen, moreover, has shown (*Pogg. Ann.*, **148**, 392, and this Journal, 1873, 126) that on burning the hydrocarbons, ethylene and acetylene, the estimated heats of combustion are near the calculated quantities. Calculating, however, by Dulong's formula, the heat of combustion of beech wood and pine wood respectively, the numbers 4139 and 4240 are obtained, whilst experiment gave 4785 and 5085. Calculating, on the other hand, that the carbon combines completely with the oxygen of the wood to form carbonic acid, and the hydrogen with the oxygen supplied, the numbers 4663 and 4778 are obtained. From this, the author considers that in no case can the heat of combustion be calculated from the results of elementary analysis, the quantity found being always greater. He finds the heat of combustion of pure cellulose (purified and dried cotton-wool) to be 4155, whilst Berthelot found 4142, and v. Rechenberg 4452, and that of charcoal, prepared from pure cotton-wool (containing 96·7 to 96·9 per cent. C, and 1·3 to 1·5 per cent. H), 8033, whilst Favre and Silbermann found 8088. A. B.

Note on Paraguay Tea. By T. PECKOLT (*Pharm. J. Trans.* [3], **14**, 121—124).—This tea is made from *Ilex paraguayensis*, indigenous in the South American region which lies between 18° and 30° S. latitude; it has been planted, and seems to succeed well, in the Cape of Good Hope, Spain, and Portugal. It is stated on experimental evidence, that six different species of the *Ilex* are used in the preparation of this tea. The plant *I. paraguayensis* in the wild state grows to the size of an apple tree, but when cultivated it remains a mere bush. The trees are cultivated from seed, and used when four years old. It is calculated that 1600 trees can be grown on 220 square meters, yielding an average of 35 kilos. per tree. The leaves are collected at different times in different localities, and have most aroma when the fruit is nearly ripe. In some cases the leaves are dried in ovens, in others they are roasted. In the Spanish Republic three different sorts of maté are sold. 1. Caá-cuy or Caá-ciup, the new leaves and scarcely developed shoots, is of a delicate texture and yellow colour, and has an agreeable and pleasant flavour. 2. Caá-mirim, the leaves separated from the twigs and stalks, the mid-rib is also removed from the leaves. 3. Caá-guacu, or Caá-unu, or Jerva de Palos, large old leaves with twigs and fragments of wood, has a strong bitter taste. In Rio Janeiro two sorts are known in commerce—maté leaf and maté powder. Maté has been frequently analysed, and the results have been published from time to time. The author has analysed the fresh leaves, &c., of the *Ilex paraguayensis* from the Orgu Mountains in Neufreiburg, with the following results:—

In the air-dried leaves.	Per 1000.
Stearoptene	0·021
Volatile oil, extracted by ether	0·099
Fat and wax	19·800
Green colouring matter	10·900
Chlorophyll and soft resin	20·966
Brown acid resin	48·500
Caffeine	6·398
Bitter extractive matter	2·033
Sugar	39·266
Extractive matter and organic acids	8·815
Maté-tannic acid, pure	27·472

In the air-dried leaves.	Per 1000.
Maté-viridic, crystallised	0·024
Albumin, organised, inorganic salts, dextrin, &c.	47·660
Moisture	166·660
Cellulose	601·356

He has also analysed leaves and maté from Parana, and the quantities of the several constituents in 1000 parts are given in the subjoined table.

	In air-dried leaves, from which maté is prepared.	In commercial maté.
Volatile oil, extracted by ether	0·179	0 026
Caffeine	16·750	5·550
Chlorophyll and soft resin	51·200	16·755
Brown acid resin	84·500	25·500
Matétannic acid, pure	44·975	16·755
Matéviridic acid, crystalline	0·025	0·024
Extractive matter	65·130	16·610
Albumin, salts, dextrin, &c.	36·102	18·159
Cellular matter and moisture	6·643	908·379

Various authors have identified the individual constituents of this substance thus: Trommsdorff found tannin; Stenhouse, caffeine; Rochleder recognised the identity of matétannic acid, and caffetannic acid, Hoffmann showed that it was also identical with tannin from tea. Arata distinguishes between the maté- and caffe-tannic acids in this way; the former requires 73·66 vols. of alcohol for solution, and by dry distillation yields *catechol* and *resorcinol*, whilst the latter requires 52·84 vols. of alcohol, and gives *catechol only* by dry distillation. Soubeiran and Delondre state that maté contains the same essential constituents as coffee-leaf and in greater amount than coffee beans; the author confirms this statement by numerous experiments. The aromatic principle has not been isolated, but by dry distillation a volatile oil is obtained of phenolic character and soluble in alcohol. D. A. L.

Constituents of Lactarius piperatus and Elaphomyces granulatus. By T. Bissinger (*Arch. Pharm.* [3], 21, 321—345).—The author has examined the chief constituents of these fungi. The fat extracted from *Lactarius piperatus* by ether yielded (1) a non-volatile acid melting at 69—70°, having the formula $C_{15}H_{30}O_2$. This acid had previously been isolated from the fat of another fungus, *Agaricus integer*, by Thörner (Abstr., 1880, 44); (2) a volatile acid, which was proved to be butyric acid; (3) glycerol; (4) a substance crystallising from alcohol in rhombic tables melting at 36—37°, which is probably an alcohol of the formula $C_{14}H_{30}O$. The non-volatile acid appears to exist in the fat in the free state; the butyric acid is combined as a glyceride. An analysis of the ash of *Lactarius piperatus* gave the following results expressed as percentage numbers:—

KCl	2·41	Fe_2O_3	3·55
K_2SO_4	10·40	$Mn_3(PO_4)_2$	0·38
K_2CO_3	44·76	$Ca_3(PO_4)_2$	0·47
Na_3PO_4	12 03	$CaCO_3$	0·62
K_3PO_4	18·37	$MgCO_3$	2·66
$Fe_2(PO_4)_2$	1·57	SiO_2	3·68

Mannitol was obtained from *Elaphomyces granulatus*; it has previously been found in *Agaricus integer* by Thörner (Abstr., 1880, 44).

W. R. D.

Vine Diseases and their Remedies. By H. Müller and others (*Bied. Centr.*, 1883, 630—637).—In the autumn of 1882, the vines of the Rhine provinces of Prussia were attacked by *Peronospora viticola*, and the disease spread rapidly into Hesse, Baden, and Alsace, it was thought, from the course so taken that Germany proper would not suffer as much as southern lands. An idea prevails that because the disease appears on the leaves only, it is not injurious to the grapes; but the author combats this idea, as the office of the leaves is to form sugar indispensable to the existence of the plant. The organism lives in the interior of the vine-leaf and the buds; on the underside of the leaf it sends out its reproductive organs, delicate filaments with spores at the end of each; one of these if placed on a healthy vine leaf and moistened with a drop of rain or dew suffices to infect it, and it is quickly covered with the white spots denoting the disease; moist weather is therefore most favourable to its propagation. The spores carried to earth by the falling leaves survive in sufficient numbers to propagate the species next season. The author recommends all the leaves to be burned outside the vineyard after the vintage, and the vines washed with a solution of 1 part sulphate of iron in 2 parts water.

Gœthe states that during a journey in France he noticed, on the same vines, *Peronospora* and *Torula dissiliens*, causing spots running from light brown to black, and causing the immediate fall of the leaf. Millordet and others describe several other vine diseases, American mildew grape-rust, which he ascribes to the *Phoma uvicola*, which does not itself kill the grapes, but attaches itself to those previously killed by the peronospora.

Amongst the various remedies, besides that before named, is a solution of sodium bicarbonate. F. v. Tchümen describes a fungus which attacks the roots of the vine, *Roesleria hypogœa*, completely destroying the whole stock. This disease has committed great ravages in the department Haute Marne. Moisture is a most favourable condition for the spread of this organism; the only remedy proposed is to pull up the vines by the roots, burn them, and cultivate other crops until the *Roesleria* disappears.

Another disease, *folletage de la vigne*, is distinguished by sudden falling off of leaves and buds, but the vines themselves do not always die.

J. F.

Phylloxera and Insecticide. By Girardin and others (*Bied. Centr.*, 1883, 624—625).—Amongst the many remedies proposed for the extirpation of these ruinous insects, Gerandin says the best results have followed the use of carbon bisulphide and the planting and grafting of American vine stocks. Martin says the stocks should be young and strong. Schule, on the other hand, has not found the planting of American vines to withstand the disease. The use of naphthalene as an insecticide is recommended by Fischer; the trials made with this substance have been numerous, but, apart from its suitability, its comparatively high price is an objection to its use.

J. F.

Continuous Cultivation of Wheat and Barley at Woburn. By A. VOELCKER (*Bied. Centr.*, 1883, 595—597).—This is a review of the operations at Woburn for the year 1882, as published in the *Journal of the Royal Agricultural Society*. The seed was of the same class as that of the preceding year, Browick wheat. The yield of grain was decidedly smaller than in 1881, but the straw was more abundant, owing to the damp weather. Sodium nitrate, both alone and in combination with other mineral salts, has operated less favourably than in the past year, due probably to the damp also. Mineral manures used alone have produced but a small increase, confirming the results of previous years. Two plots manured the year before with sodium nitrate showed that there was no effective ammonia left in the soil, as they did not this year produce more than others which were unmanured for six years. Yearly applications of mineral manures alone on two other plots failed to give any increased production, whereas on the addition of ammonium sulphate or sodium nitrate the crop was at once trebled. Certain plots strongly manured last year with stable manure prove that there was very little nutritive matter left after the crop had been taken off, and that the ammonia was exhausted in the one season as in the case of the sodium nitrate.

J. F.

Culture of Cereals. By MÄRCKER and others (*Bied. Centr.*, 1883, 620—624).—Märcker contributes some notes on the culture of barley. He finds that hoeing more than pays for the additional labour, that a highly nitrogenous manure requires a thinner sowing, and that the distance between the drills largely influences the result. When the field is heavily manured, it is better to have them far apart, but when lightly manured it is better they should be closer together. The experiments are incomplete.

The remainder of the paper contains details of various culture experiments, but they are only of local interest. J. F.

Digestibility of Certain Leguminose Straws. By WEISKE and others (*Bied. Centr.*, 1883, 824—826).—The digestive coefficients of horse-, garden-, and Soja-bean straws as obtained from experiments with sheep, are as follows:—

	Dry matter.	Organic matter.	Albumin.	Fat.	Fibre.	Extractive.	Ash.
Horse-bean ..	51·77	52·17	47·21	57·21	41·20	64·38	46·49
Garden-bean..	60·83	61·74	53·58	52·58	50·81	72·27	49·30
Soja-bean	49·63	52·11	39·41	58·65	42·30	62·80	24·97

E. W. P.

Sunflower-seed Cake as Fodder for Milch Cows. By M. SCHRODT and v. PETER (*Bied. Centr.*, 1883, 609—612).—The use of this cake has been strongly recommended and highly praised by observers in Sweden and Denmark as a cheap and valuable fodder. The authors' experiments, however, lead them to different conclusions; the sunflower-seed as compared with palm-nut cake is more costly and produces less milk. The cattle, however, like it and eat it greedily.

J. F.

Cultivation and Yield of Potatoes. By O. CIMBAL and others (*Bied. Centr.*, 1883, 828—839).—Cimbal, out of 38 sorts of potatoes, finds Aurora to produce the heaviest yield of starch per acre, and Snowflake the lowest. Nitykowski, near Bremen, finds Imperator the best and Snowflake the worst out of 37 varieties. Sattig considers Gleason's Seed to be the heaviest cropper on heavy land and also on light land, whilst Daberscbe is most liable to disease. Yellow Rose, according to Kenneman, is the best. J. Timm finds Chicago Early to do best on sandy loam, and Late Rose on marshy soils. Gierth found Early Rose to be most affected by wet, and Anderssen the best cropper, and also to have the highest percentage of starch. Emmel notes that the best yield is produced when whole large seed is employed, and when the eyes are downwards. A. Leydhecker states that sets containing only the eyes from the end produce better crops than those sets which include only the side eyes. E. W. P.

Potato Culture. By GURADZE-KOTTULIN and others (*Bied. Centr.*, 1883, 625—630).—The author gives an account of experiments in culture on a large scale. The field was of 31 morgen of marly clay on limestone, and had been manured the preceding autumn with 150 centners per morgen of stable manure. In the middle of April 16 well-chosen sorts of potatoes were sown, the ground kept carefully cleared of weeds, and the crop harvested in October, with the results given in Table I (p. 484).

A similar set of experiments were made by Sattig and Holdefleiss with 23 varieties, the soil being a mild loam. The crops yielded the number of centners per morgen given in Table II (p. 484).

Champions and Early Rose were all sound; the others were more or less attacked by disease.

Jacobs at Siernki made some few experiments in a field planted with rye the previous year, in good state, and which was manured again with 140 cntr. cow manure, 1 cntr. Chili saltpetre, 1 cntr.

Paulsen's Aurora....	156·4	Kopsel's Early White Rose.	141·3
Seed or Gleason	150·0	Early Goodrich	139·5

All of them withstood the disease well, but the Gleason and White Rose were the healthiest.

Vibrans reports experiments with various kinds on two descriptions of soil. The first field (see Table III, p. 485) was a good black strong loam, on which barley after beets had been grown the previous year. In December, 150 cntr. of stable manure per morgen was put in, in April ploughed for seed, and top dressed with 1 cntr. superphosphate and ½ cntr. saltpetre, harrowed and sown. The second field was high, dry, sandy with humus. The summer was hot and dry, favourable for the first, but unfavourable for the second.

The reports from various districts are all very favourable to the

Champion, both for hardiness and resistance to disease, as well as being a large yielder.

A variety of suggestions are made to prevent the disease, such as trenching them up very high, planting them before winter 20—24 cm. deep, and in the next spring another row between the first at the depth of 8—12 cm. The deeply-planted were not frozen, and at harvest none of them were diseased, and but few of the spring sown.

Another plan is to wash the seed potatoes, dust them with flour sulphur and common chloride of lime till they acquire quite a thickish coating, then strew ashes on them. J. F.

Researches on Sugar-beet. By H. HELLRIEGEL and others (*Bied. Centr.*, 1883, 842).—By "pitting" beet, an increase to the amount of 5 per cent. of its weight is obtained, due to absorbed moisture. The extraction process shows a smaller percentage of sugar than the polarisation method in the ratio of 95 : 100. The juice has a higher

sp. gr. than the root. Of two methods of obtaining the sugar from the juice, the digestion is better as regards yield than the extraction. In drawing samples, only good ones of medium size should be taken.
E. W. P.

Heat Radiation from the Earth. By J. TYNDALL (*Bied. Centr.*, 1883, 577—512).—A summary of experiments made by Tyndall, which originally appeared in *Nature*, the points chiefly dwelt on by the reviewer being the effect of invisible aqueous vapour in the atmosphere, the presence of which prevents the radiation of heat from the earth.
J. F.

Micro-organisms in Soils. By R. KOCH and P. MIGUEL (*Bied. Centr.*, 1883, 581—582).—From examinations of a large number of samples, Koch found that the superficial layers of soil were very rich in germs of bacteria, particularly in bacilli. Micrococci were only found in places which had not been cleansed from decaying matter; the latter perished on heating the samples, but the bacilli did not, being mostly in the condition of spores, and it appears probable that they are introduced by means of manures and household offal.

The quantity of micro-organisms diminishes very rapidly with increase of depth, so that at the distance of 1 metre from the surface the earth is very free from them. Miguel attempts to estimate the number present in 1 gram of soil taken from a depth of 0·20 metre from the surface, and found in three samples from—

Montsouris	700,000 organisms.
Gennevilliers, manured with liquid sewage .	870,000 „
Do. not so treated..............	900,000 „

The office of those minute organisms appears to be of great importance in the transformation of substances to forms suitable for plant-food.
J. F.

Sterile Soil from California. By A. VOELCKER (*Bied. Centr.*, 1883, 642).—The composition of this soil shows no deficiency in plant foods. The author thinks its sterility is due to its strongly alkaline reaction. To cold water it yields a half per cent. of mineral matter; sodium and potassium carbonates, sodium chloride, and nitrate. The author thinks nothing would make it fit for tillage but irrigating frequently to wash out the alkalis.
J. F.

Theory of Manuring. By P. WAGNER and others (*Bied. Centr.*, 1883, 798—818).—In a set of experiments already described, the results were untrustworthy, because of the small quantities of phosphate employed. In the present series, a larger quantity has been used, so that the differences of yield are more marked. Buckwheat, peas, oats, and vetches were the plants, and they were manured with precipitated calcium phosphate, and 21 per cent. citrate soluble phosphate (858 kilos. per hectare). Of these plants, vetches produced the highest increase above the blank plots, buckwheat least, and the albuminoïds and phosphates of the peas and buckwheat were sensibly raised. In 1882 experiments were made to estimate the value of calcium and potassium phosphates in comparison with the soluble phosphoric acid of superphosphates. Peas were grown in zinc boxes 25 cm. broad and 50 cm. deep, containing sandy soil; precipitated calcium phosphate was added at the rate of 150, 300, and 450 kilos. per hectare; and as gypsum is present in a "super," some plots were set apart for this substance. Nitrogen as sodium nitrate (50 kilos. N per hectare, 200 kilos. potash as potassium chloride, and 300 kilos. superphosphate) were the other manures. As the plants grew, the phosphates showed their influence by the darker green, broader leaves and stronger stem; at the same time the lower leaves became yellow and spotted prematurely. On weighing the yield, it was found that nitrogen had had no great effect by itself, producing only an increase of 1·5 per cent., and in conjunction with phosphate and potash, 5·3 per cent. Phosphates and potash were the most productive, but the increased ratio of phosphate to potash produced a corresponding fall in the ratio of straw to grain. The presence of the gypsum is considered to have been decidedly lowering to the yield, as one plot indicates; and the superphosphates, whether soluble in water or in "citrate," seemed to be equally valuable. The addition of phosphates was accompanied by a decreased yield and by an earlier yellowing of the leaves, with an increased percentage of phosphate in the plant itself. The addition of phosphates to nitrogen and potash raised the yield, but no increase in assimilated phosphoric acid; consequently, the author considers that the modern theory of the solvent action of nitrates on the phosphates in the soil must be modified. As stated above, the phosphates in the whole crop were increased, but further investigation showed that the increase was in the straw, whilst the percentage in the seed fell. The effect of the various manures on the albuminoïds was only noticeable in those plants manured with superphosphate and nitrogen, when it was found that the albuminoïds increased in the straw, but fell in the seed. A second series of experiments was also instituted in 1882, when the manures were 20 kilos. N per hectare, half as sodium nitrate, half as ammonium nitrate, 178·6 kilos. potash as chloride, and 40, 55, 70, 85, 100, 115, 130 kilos. phosphoric acid as fine superphosphate, precipitated phosphate, washed mineral "super," and potassium phosphate, also as much gypsum as corresponded to that in the washed super. The experiment is to be found in a previous communication. The results obtained are fully described, given in tabular form. It was found that so long as an increase of phosphate produces an increase of yield, the two increments bear a constant ratio to one another; but that after a certain point no further advantage is gained by increasing the quantity of manure. In the cases in question, the limit was 115 kilos. per hectare. When the various phosphates are compared with one another as regards their value, putting fine-grained super = 100, we find coarse-grained = 155, precipitated phosphate = 104, washed superphosphate = 80, and potassium phosphate = 103. If we allow that the gypsum present in the supers has a lowering effect in all cases, equal to that produced by gypsum alone, we may then calculate the effect of phosphates free from gypsum. This has been done, with the remarkable result that all the various phosphates produced practically the same effects in the crops. Increase of phosphates in the ash of the plants was independent of the form in which the phosphate was applied, and the quantity in the ash increased with that applied. In like manner, the albuminoids were not affected by the form of combination, or by the quantity so long as there was an increase in the yield. To test the after-action of various phosphates, the soil, after removal of the peas, was planted with vetches and barley, and then it was found that, as before, the increase of yield was in direct proportion to the increase in manure, and that 115 kilos. phosphoric acid per hectare was the limit beyond which it was not advisable to pass: also as regards the manurial value of the different sorts, the results were identical with those of the previous season. The action of several other manures on plants has been described by the authors, as will be seen by reference to a previous number, where it is stated that potash has an injurious effect on the quality of potatoes; but the experiments of 1881 show that potassium chloride, after a strong manuring of phosphates, has no detrimental influence. E. W. P.

Value of Various Nitrogenous Manures. By M. MÄRCKER (*Bied. Centr.*, 1883, 584—590).—These experiments were made to verify those previously made by Seyffert, and were carried out by Albert. Chili saltpetre: The plants to which this manure was applied flourished during their entire growth. Ammonium sulphate had not so good an effect, the plants being far inferior to those of the first experiment. Horn-meal gave very satisfactory results at first, but a sort of second growth springing from the roots shortly before ripening weakened the plants. Blood-meal was slow in operation for three-fourths of the time, but then the plants made great progress; leather-meal gave very poor results; the fermented meal something better than the raw, but both unsatisfactory. Bone-meal, both raw and fermented, were very satisfactory, the latter causing a larger yield of straw; fermented blood-meal acted similarly to unfermented, but with greater energy. A plot which received no nitrogenous manure, but to which were added all mineral salts necessary for the growth of plants, made a very poor appearance, and the results in both straw and grain were unsatisfactory. The results show the sodium nitrate and horn-meal as the first, and the leather as the lowest in the scale of the manures tried.

The influence of these manures on the composition of the oats grown with them was very marked, the percentage of proteïn matter in that with leather, ammonium sulphate, and sodium nitrate being lowest, and with blood-meal and horn-meal yielding the highest. The time of harvesting also was influenced by the nature of the manures, those in which the nitrogen existed in an easily assimilable condition being first ready for cutting, but where it was present in an organic state as albumin, fibrin, &c., the harvest was some eight days later and the ripening irregular; the nitrogen in bones being in the form of gluten, was easily available.

Experiments were also made in order to test the reputed poisonous influence of cyanides on vegetation, but ammonium cyanide was found not to be actually poisonous, and in certain cases its effects on oats were beneficial. The author thinks that farmers need not be too much afraid of purchasing superphosphates with a small percentage of cyanides. J. F.

Examination of Aves Guano. By M. MÄRCKER (*Bied. Centr.*, 1883, 582—584).—This deposit of guano, recently introduced to commerce, is found in the Aves Island, situate in the Carribean Sea off the coasts of Venezuela. The quantity is considerable, and according to the analyses of Märcker and others, it is one of those guano phosphates rich in phosphoric acid, but poor in nitrogen, the estimation of the former in different samples being 33·83; 25·18; 23·33; 33·12 per cent.; nitrogen, 0·21 to 0·28 per cent. It is described as being in good condition, a 5 kilo. sample which was examined containing powder 77·6 per cent.; grains 1—2 mm. 15·8; pieces over 2 mm., 6·6 per cent. J. F.

Guano from Aves Island. By E. GÜNTZ (*Dingl. polyt. J.*, **249**, 187).—This island, off the coast of Venezuela, contains an enormous deposit of guano, which, when suitably prepared, has the following composition:—

Water	6·83	per cent.
Organic matter	7·03	,,
Iron oxide	0·22	,,
Alumina	0·36	,,
Lime	42·62	,,
Magnesia	2·03	,,
Potash	0·14	,,
Soda	1·44	,,
Ammonium oxide	0·22	,,
Phosphoric anhydride	33·12	,,
Sulphuric anhydride	1·19	,,
Carbonic ,,	3 84	,,
Nitric ,,	traces	
Chlorine	1·07	,,
Silica	0·18	,,
Fluorine	0·00	,,
Sand	0·17	,,
	100·46	

The total nitrogen in this prepared guano is 0·284 per cent. J. T.

Preparation of Poudrette. By WEIGELT and C. ENGLER (*Bied. Centr.*, 1883, 819—821).—The contents of the cesspools are first disinfected by manganous chloride, and the liquid portion heated with lime, and boiled by steam, the resulting ammonia being collected in sulphuric acid. The liquid thus freed from ammonia then passes through a series of cisterns containing peat, which retains much of the potash and nitrogen in forms other than ammonia. The sediment in the original liquor is dried, pressed, ground, and sold as poudrette, and contains 3—10 per cent. P_2O_5, 0·3—10 per cent. K_2O, 1—5 per cent. N.

Engler compares this process with those of Podewits and Lernur, and considers that the one described above (Buhl and Keller) is the most economical. E. W. P.

Some of the Changes which the Nitrogenous Matter in the Soil Experiences. By R. WARINGTON (*Bied. Centr.*, 1883, 794—796).—The supply of nitrogen to the soil is kept up by the residue of the plant growing therein, the added nitrogenous manures applied, and that which is contained in the rain which falls, viz., 3—4 kilos. per hectare yearly, also a small quantity which is absorbed by the soil directly from the air as ammonia. The fertility of the soil is in a direct ratio to its richness in nitrogen, and that this law is correct is shown by the results obtained by the experiments on wheat and barley at Rothamsted; in both cases, the percentage of nitrogen and carbon is highest on those plots which received 7 tons farmyard manure per hectare, and which consequently produced the heaviest crops. Those plots which received ammonia salts were not rich in nitrogen, as much of it passed away into the drains as nitrates. Grasses and clover are the best retainers of nitrogen, whereas roots are the worst. The author likewise describes the nitrification process, and adduces figures from his analyses of the drainage waters in support of the theory. E. W. P.

Inferior Manures. By STUTZER and others (*Bied. Centr.*, 1883, 590—592).—The authors notice certain manures sold principally in the vicinity of Cologne, which are of inferior composition, one in particular, called a siliceous poudrette, contained soluble phosphoric acid, none; total phosphoric acid, 0·2; nitrogen, 0·3; sand and clay, 82·8; silicic acid, 11·1; the selling price being 6 marks per centner, and the valuation 33 pfennige or ⅓ mark. J. F.

Continuous Cultivation without Stable Manure, employing Artificial Manures. By D'AVÈNE (*Bied. Centr.*, 1883, 643).—This cultivation has been continued at Montoir (Loire and Cher) for 14 years with great success. The land in harvest is manured with 500 kilos. superphosphate, and in spring with 500 kilos. of special St. Gobain manure, or other equal to it. The accounts show a balance to profit. J. F.

Manuring of Tobacco. By J. NESSLER (*Bied. Centr.*, 1883, 642). —Tobacco requires much potash in manure used in its cultivation, from one hectare yielding 33 centners it withdraws 75 to 100 kilos. potash; the potash cannot be applied in the form of chloride, as that yields a badly burning tobacco, so do other chlorides. Sulphates and nitrates, on the contrary, give a quick burning leaf; the best results have followed the application of 150 to 200 kilos. per hectare in suitable form. Stable manure should be cautiously used; phosphates are not of much use, but nitrogen should be used freely. Wool-dust would be a very good manure if its nitrogen was of quicker assimilation; if used in a compost it should do well. Tobacco requires moisture and a loose humous soil: stable manure containing chlorides should be used early, and probably would do better if applied to the crop grown immediately previous to the tobacco. J. F.

Sodium Nitrate and Ammonium Sulphate as Manures for Beets. By P. P. Dehérain (*Bied. Centr.*, 1883, 593—594).—It may not be important, on some soils, whether nitrogen be applied in either of those forms, but the author has found a great difference in the results of their application on his experimental field at Grignon, a light soil containing lime, the ammonium salt having a very injurious effect on the roots if the soil did not possess sufficient organic constituents, some plots which were strongly manured with ammonium sulphate having had to be resown. He also found that the use of too strong a dose of the nitrate had not the effect of increasing the yield in proportion. In one experiment, in 1877, 400 kilos. per hectare produced 36,900 kilos. of roots, testing 17·4 per cent. of sugar; whilst 1,220 kilos. per hectare yielded but 29,800 kilos. of 12·7 per cent. sugar.

These results differ so much from a similar series of experiments made by Märcker, that the editor suggests there may be some conditions attached to the experiments which have escaped notice. J. F.

Stassfurt Salts as Absorbents in Stables. By M. Märcker (*Bied. Centr.*, 1883, 598—599).—The use of potash salts in stables for the purpose of absorbing and fixing ammoniacal exhalations is strongly recommended, but the author advises care in their selection, as those which contain much chlorides are less suitable, being very deliquescent and unpleasant to manage. Of the four cheaper salts: carnallite, kainite, polyhallite, and krugite, the first contains 24·3 per cent. of potassium chloride and 31·0 of magnesium chloride; it is therefore least suitable of all. Kainite containing 17 per cent. magnesium chloride can be used, but the author recommends krugite containing 20 per cent. potassium sulphate, and nearly 34 per cent. calcium sulphate, as the most useful for the purpose. J. F.

Analytical Chemistry.

On Desiccators. By E. Fleischer (*Anal. Zeitschr.*, **23**, 33—35).—It is generally assumed that the air contained in a desiccator, after exposure for a few hours to the desiccating substance, is perfectly devoid of moisture. The author has made some experiments with a Lambrecht's hygrometer, and finds that whilst sulphuric acid after 35 minutes left but 30 per cent. of the original amount of moisture, after 1 hour 18 per cent., and after 105 minutes none at all, calcium chloride after 2 hours left 31 per cent., after 4 hours 25 per cent., and after 6 hours 21 per cent. of moisture. The author therefore condemns the use of calcium chloride as a drying substance for desiccators.

O. H.

Detection of Chlorine, Bromine, and Iodine. By F. Jones (*Chem. News*, **48**, 296).—With regard to Vortmann's process for the separation of chlorine, bromine, and iodine (Abstr., 1883, 119, 1167), the author has introduced a simple plan of utilising the same principle.

A small quantity of the substance to be tested is put in a test-tube along with some manganese dioxide and a little water. One drop only of dilute sulphuric acid (1 in 10 of water) is added; a brown tinge indicates iodine; boil until violet vapours cease to appear, and repeat the treatment with one drop of acid, and boiling until no more iodine vapour appears. Now add 2 c.c. of the dilute sulphuric acid and boil; bromine, if present, will be evolved. Repeat treatment with 1 c.c. of acid and boiling until all the bromine is expelled. Allow residue to cool completely, then mix with an equal volume of concentrated sulphuric acid and warm; if chlorine is present, it will be evolved.

D. A. L.

Estimation of Sulphur in Pyrites. By G. Lunge and C. Bodewig (*Chem. News*, **48**, 285).—Lunge has decided, from the results of experiment, that the nitric acid used in the aqua regia employed for dissolving pyrites should not exceed sp. gr. 1·420. Bodewig's process for "opening up" pyrites is as follows:—About 0·5 gram of substance is put into a small stoppered flask with 30 c.c. of water; 4 c.c. of bromine are then added, the stopper put in, and the flask shaken for five minutes. When the oxidation is complete, that is, when all the bromine is dissolved and all the pulverulent sulphur has disappeared, the liquid is washed into a shallow vessel, the greater part of the bromine allowed to evaporate, and the solution neutralised with ammonia, but not so as to form a permanent precipitate. It is then poured into excess of hot ammonia in a platinum capsule, and after digesting for 15 minutes over a flame, is filtered. The sulphuric acid is determined in the filtrate in the usual manner. Iron cannot be determined in the same sample, as some of the metal is always volatilised with the bromine.

D. A. L.

Estimation of Thiosulphuric Acid. By G. Brügelmann (*Anal. Zeitschr.*, **23**, 24—25).—The proposed method consists in the oxidation of the thiosulphate by an excess of permanganate, and the estimation of the sulphate formed.

O. H.

Note.—The proposal is neither novel, nor has it any advantage over the ordinary volumetric methods.—O. H.

Volumetric Determination of Ammonia. By H. Beckurts (*Dingl. polyt. J.*, **249**, 426).—The author states that phenolphthaleïn cannot be used as indicator for the titration of ammonia; he, however, advocates the use of phenacetolin.

D. B.

Purification of Ammonium Fluoride. By P. T. Austen and F. A. Wilber (*Chem. News*, **48**, 274).—One of the most convenient methods of determining silica in ores is to expel it as fluoride by means of ammonium fluoride and sulphuric acid or hydrofluoric acid alone; but neither pure hydrofluoric acid nor ammonium fluoride can be purchased. The authors have therefore introduced the following method for their purification. The ammonium fluoride or hydrofluoric acid is treated in a platinum dish with excess of strong ammonia; it is then filtered direct into the crucible containing the ore, through a folded filter previously washed with hydrofluoric acid, and supported in a ring of platinum wire. The liquid is acidified with sulphuric acid, evaporated to dryness, and ignited as usual. D. A. L.

Estimation of Ammonia in Vegetable Extracts. By E. SCHULZE (*Anal. Zeitschr.*, 23, 13—16).—It has been pointed out that Schlösing's method is not applicable in presence of asparagine, as this is decomposed with formation of ammonia. The author shows, however, that even after two days' contact with caustic lime only about 1 per cent. of the asparagine is decomposed, whilst ammonia salts yield during that time the entire amount of the ammonia contained in them, and that therefore even in fluids comparatively rich in asparagine the error is very small, and may safely be neglected. O. H.

Volumetric Determination of Combined Nitrous Acid. By L. P. KINNICUTT and J. U. NEF (*Chem. News*, 48, 274).—Finding the old method for the determination of nitrous acid in commercial samples of potassium and sodium nitrites unsatisfactory, the authors, after numerous experiments, devised the following modification of it. One part of the sample of nitrite is dissolved in at least 300 parts of water, and decinormal potassium permanganate is dropped in until a decided and permanent red colour is obtained; two or three drops of dilute sulphuric acid are then added, and immediately afterwards an excess of the permanganate solution. The liquid is made strongly acid with sulphuric acid, heated to boiling, and the excess of permanganate titrated with decinormal oxalic acid. Concordant results have been obtained by this method. The volumetric method for the determination of sulphites has been studied, but the results are not satisfactory either by the method described above or by iron alum and permanganate. D. A. L.

Ammonium Ferrous Sulphate as a Reagent for Nitric Acid. By P. T. AUSTEN and J. C. CHAMBERLAIN (*Amer. Chem. J.*, 5, 209).—As solutions of this salt are quite fit for use after standing for three months in a closed bottle, or for three weeks in a loosely-covered beaker, the authors recommend it for use in place of ferrous sulphate. Addition of about 2 per cent. of sulphuric acid improves its keeping powers. It is quite as delicate a test as ferrous sulphate. A. J. G.

Estimation of Phosphoric Acid as Magnesium Pyrophosphate, and the Influence of Reagents employed in separating the Acid from Bases. By D. LINDO (*Chem. News*, 48, 217—221; 230—231; and 239—243).—Pure microcosmic salt is employed in this investigation. After crushing and pressing between filter-papers, it can be preserved in well-ground stoppered bottles for some time without change, although in time it loses weight.

In order to vary the tests, the pure salt was employed in different conditions, and test-solutions of various strengths were used thus:—Magnesia mixture containing per c.c.—(1) 0·0156 gram $MgCl_2$, 0·0825 NH_4Cl, 0·0194 NH_3; (2) 0·0312 $MgCl_2$, 0·1650 NH_4Cl, 0·0127 NH_3; (3) same as (1) without NH_3. Dilute ammonia containing—(1) 6·34, (2) 2·52, (3) 1·20, (4) 11·54 NH_3 per cent.

Gooch's method of filtration is employed, the perforated crucible being provided with a plain one to act as a jacket. 500 c.c. of solution only were made at a time, and contained 7·5318 grams of microcosmic salt. For test experiments, 25 c.c. of this solution diluted with 75 c.c. water was precipitated with 12 c.c. of magnesia mixture (1), 10 c.c. of ammonia (1) added when the precipitate had settled, and the precipitate was washed with 200 (c.c.) of ammonia (3). Modified test experiments had the 10 c.c. of ammonia (1) added before instead of after precipitation; this is not to be recommended. Over 490 experiments have been made, and the author's conclusions, with some average results, are given below.

Experiments with *solid salt method* yielded accurate results. *Moderate heat* (60°) does not affect the accuracy of the results. Large *excess of magnesia mixture added gradually* never does harm, except in cases mentioned below, and is even necessary in presence of ammonium chloride, oxalate, and citrate, but even moderate excess *added all at once* causes high results, thus:—P_2O_5 per cent. found = 100·15 with 33 magnesia mixture (1) added gradually, 100·37 with 15 c.c. magnesia mixture (1) added all at once, and 100·10 in tests. The best *method of adding the magnesia mixture* is from a burette, a drop per second, with constant stirring. When *concentrated solutions* are precipitated, low results are obtained with magnesia mixture (1): this is owing to the ammonia present, as accurate results are obtained with mixture (3).

12 c.c. Mg. mix. (1).	Test.	12 c.c. Mg. mix. (3).	Test.	
99·86	100·12	100·02	99·98	P_2O_5 per cent.

With *neutral magnesia mixture* (3), the precipitation is not complete until the ammonia is added, which should be dilute (No. 3 solution), and should be run in by drops, stirring constantly. The precipitate is highly crystalline and easily washed; the results are accurate. *Precipitation in presence of excess of free ammonia* gives rise to low results; thus, when a solution was precipitated containing 85 c.c. of ammonia (4), 99·63 per cent was obtained, the tests averaging 100·04. This is probably due to the fact that the precipitate being bulky, amorphous, and difficult to wash, the washing solution dissolves more of it than in the case of crystalline precipitates. The precipitate is crystalline in presence of ammonium citrate, oxalate, or chloride (in large quantities), even when there is much free ammonia.

With regard to the *solubility of the precipitate in dilute ammonia*, no measureable difference has been detected between the solubility of the highly crystalline precipitates and that of the more bulky precipitates obtained in the ordinary test experiments. By a series of experiments it was found that precipitates washed with 200 c.c. ammonia (2) gave an average 100·04, whilst others washed with 600 c.c. gave 99·62. The difference, 0·42 per cent., represents the solvent action of 400 c.c. of ammonia (2), which would amount to 0·0063 gram of $Mg_2P_2O_7$ per 3 litres of this solution. By direct quantitative experiments 3 litres of ammonia (2) washings gave an average of 0·0068 $Mg_2P_2O_7$. From similar observations with solution (3), the numbers 0·0086 gram calculated, 0·009 gram found, were obtained. Therefore, in washing with ammonia (2) 0·0002, and with ammonia (3) 0·0003 must be added to the weight of the precipitate for every 100 c.c. employed. *Precipitation in the presence of ammonium chloride, oxalate*, and *citrate* is generally productive of low results, and that this is not wholly due to the solvent action of these salts on the precipitate is evident from the fact that the quantity of magnesia mixture required to counteract the solvent action of a given quantity of oxalate or citrate will not, if used in excess, precipitate all the phosphoric acid in presence of a similar quantity of oxalate or citrate, the volumes of the solutions being the same in both cases. It is probable, therefore, these reagents exert an action which impedes the formation of ammonium-magnesium phosphate, as will be observed by comparing some of the results in the tables (p. 496), which illustrates the effect exerted by these salts on the results obtained. When citric acid is employed, it is necessary to ignite the precipitate strongly to get rid of the carbon; this causes a somewhat greater loss in weight than when ignited in the usual way.

There is no evidence to support the idea that excess of magnesia mixture throws down magnesium oxalate or citrate, and therefore gives high results.

The *solvent action of these ammonium salts* on the precipitate is seen in the next table, along with the effect of using excess of magnesia mixture, which retards or even stops this solvent action.

Ammonium sulphate gives rise to slightly high results; so that if reprecipitation is necessary accurate results are required in presence of this salt. Phosphoric acid can be separated by the oxalic method quite as accurately as by the molybdic method, even in the presence of aluminium and iron, provided the simple but necessary

precautions indicated above are taken. Use only moderate excess of ammonium oxalate for precipitating the lime; use citric acid freely in presence of metallic oxides; precipitate with an excess of weak magnesia mixture added in the manner recommended, and when the precipitate is settled a large quantity of stronger magnesia mixture should be dropped in, &c.

In mixing citric acid solutions of ferric chloride with ammonia, the ammonia should always be added, as is generally done, after the citric acid and iron, for by doing the reverse the author obtained a precipitate deeply stained with ferric oxide in the subsequent precipitation of ammonium magnesium phosphate. D. A. L.

Separation of Strontium from Calcium. By M. D. SIDERSKY (*Chem. News*, **48**, 296).—The method is based on the fact that when a mixture of ammonium oxalate and sulphate is added to a solution containing strontium and calcium, all the strontium is precipitated as sulphate, whilst the calcium is found as oxalate, or its precipitation may be prevented altogether by acidifying the solution with hydrochloric acid. It is applied in the following manner:—Iron, alumina, &c., having been removed, filtered off, &c., the solution is acidified with hydrochloric acid, and precipitated by a solution containing per litre 200 grams of ammonium sulphate and 30 grams of oxalate. The strontium sulphate is filtered off, and the calcium is precipitated as oxalate by supersaturating the filtrate with ammonia. Satisfactory results have been obtained. D. A. L.

Qualitative and Quantitative Separation of Bismuth from Copper. By J. LÖWE (*Chem. News*, **45**, 296).—In a previous communication, it was shown that bismuth and copper were precipitated from their solutions by potash and soda in the presence of glycerol, but that they were redissolved by excess of the precipitant. In this alkaline solution both are reduced by glucose at a boiling heat, the copper to red oxide, the bismuth to finely-divided metal, but in the cold or at a gentle heat the copper only is reduced after several hours, whilst the bismuth in solution remains unchanged, and even after several days only small quantities of the metal are deposited. This difference of behaviour is applied in the following manner for analytical purposes.

A moderately concentrated and slightly acid solution of the nitrates of the metals in question is mixed with a measured volume of soda until a precipitate forms and the liquid is alkaline; twice this volume of soda is now added, and pure glycerol stirred in until the precipitate is redissolved and the liquid clear. This solution is now mixed with a solution of glucose (1 in 6 or 8 of water) in quantity sufficient to make the sugar equal to three or four times the joint weight of the metals. The beaker is now covered over and left in a cool dark place for eight to ten hours, when the liquid will have lost its blue colour, and all the copper will be deposited as red oxide, from which the supernatant liquid is separated. The copper oxide is washed first with water containing glycerol and soda, collected on a weighed filter, well washed with water, dried at 100", and weighed. The alkaline liquid from the copper oxide is boiled in a porcelain capsule, stirring gently, for a short time, and when cool the metallic bismuth is filtered on a weighed filter, having been previously washed with water containing soda; it is then washed, dried, &c., in the same way as the copper. The operations with the finely-divided bismuth should be conducted as quickly as possible. D. A. L.

Analysis of Stannate of Soda. By P. T. Austen (*Amer. Chem. J.*, 5, 210—211).—The amount of stannic acid in this salt is usually determined by adding sulphuric acid to the hot solution until it becomes faintly acid; the results so obtained are good, but the gelatinous precipitate is very troublesome to wash. By adding strong nitric acid in excess and boiling, the author finds that the tin is completely precipitated as metastannic acid, and is much more readily washed and filtered than that precipitated in the usual manner. A. J. G.

Brucine a Test for Tin. By E. R. Dryer (*Chem. News*, **48**, 257).—Dissolve 0·1 gram of crystallised brucine in 1 c.c. pure nitric acid, add 50 c.c. water, heat to boiling, and cool. This solution gives a purple coloration with solutions containing stannous chloride. Neither zinc chloride, nor nascent hydrogen, nor organic matter, interferes with the reaction, but ammonium sulphide and sodium hyposulphite act like stannous chloride. To test for tin, dissolve the mixed sulphides of antimony and tin, obtained in the ordinary analytical separation, in hydrochloric acid, evaporate, dilute with water, and place a strip of platinum and a strip of zinc in the solution and in contact for several hours; metallic antimony is deposited on the platinum, whilst stannous chloride remains in solution, and can be tested for with a few drops of the brucine reagent. A distinct colour has been obtained with a drop containing only 0·0000025 gram of stannous chloride, whilst a drop containing 0·00002 gram gave a barely perceptible cloudiness with mercuric chloride. The reagent must not be too dilute, or the colour will be pale and indistinct; neither must it be used in excess, for then dirty green is produced instead of purple. The author finds this test for tin more delicate, more striking, and more convenient than the mercuric chloride test. D. A. L.

Separation of Cobalt from Nickel. By J. Clark (*Chem. News*, **48**, 262—263).—The author has modified Dirvell's process (Abstr., 1880, 287), the following being the chief points:—Instead of microcosmic salt, ammonium phosphate is found most suitable for precipitating the cobalt; sodium phosphate may be used, but large excess is necessary, whilst only a small amount of ammonium phosphate over that required for precipitating the cobalt, need be employed. Also it is not necessary to use ammonium carbonate or acetate, for ammonium chloride or sulphate, or nitrate, will do as well as the latter, and better than the carbonate. The following is the process:—In ores, the cobalt and nickel are precipitated as sulphides in an acetic acid solution, great care being taken to eliminate manganese, which would interfere with the correct estimation of the cobalt. The mixed sulphides are ignited, weighed, and dissolved in nitro-hydrochloric acid. The solution containing the two metals is mixed with ammonium phosphate (about five times the weight of the combined cobalt and nickel) and with about 5 parts of the hydrochloric acid for every part of the ammonium salt, the mixture is boiled, the vessel removed from the flame, and while still hot ammonia is added in small quantities at a time until the precipitate, at first formed, is redissolved. The solution is then stirred vigorously, when the fine purple crystalline ammonium cobalt-phosphate separates out; 10 drops of ammonia are added, and the beaker placed on a water-bath for a few minutes. As soon as the precipitate settles, it is filtered, &c., and weighed as cobalt pyrophosphate. The filtrate is a clear blue, and probably contains a small quantity of cobalt, it is therefore heated at 100°, until the nickel begins to come down. If there is cobalt the precipitate will be reddish, if not it will be green. The precipitate is dissolved in hydrochloric acid, and the cobalt determined in the manner described. The nickel is precipitated as sulphide, and weighed as oxide. Very good results have been obtained, and the process is approved of by several chemists. The metals may be present as nitrates, chlorides, or sulphates, and nitric or sulphuric acid may be used instead of hydrochloric. D. A. L.

Volumetric Determination of Manganese. By G. C. STONE (*Chem. News*, **48**, 273).—This paper is a reply to Macintosh's criticisms (this vol., 220) on the existence of a precipitate of the composition $10MnO_2,MnO$. The author points out that his process referred to the analysis of spiegeleisen, and that Macintosh ignores the probable influence of the hydrocarbons derived from the carbon in the spiegel. The author's method of analysis is: 0·5 gram of spiegel is dissolved by boiling in 40 c.c. nitric acid (1·42 sp. gr.), excess of potassium chlorate gradually added, the whole cooled, filtered through asbestos, and the precipitate washed. The precipitate and asbestos are added to excess of standard oxalic acid (8 to 8·5 grams per litre), sulphuric acid is poured in, the whole heated until dissolved, and the excess of oxalic acid titrated by permanganate (3 grams per litre). The results were in favour of the formula $10MnO_2,MnO$, as against MnO_2. Similar experiments show that the author's modification (see above) of Williams's method is better than the original. The author has not found any appreciable difference in the results, whether he works with his method of adding the chlorate or that recommended by Macintosh (*loc. cit.*). Neither does he recognise the importance of the cooling for some time after the precipitation with chlorate. Finally, he considers that his present experiments confirm his original conclusions with regard to the spiegeleisen precipitate.

D. A. L.

Titration of Organic Matter in Potable Waters, by Means of Permanganate. By A. R. LEEDS (*Anal. Zeitschr.*, **23**, 17—21).—A few experiments are quoted, showing that on boiling standard permanganate in alkaline solution (Schulze-Trommsdorf's method) the permanganate undergoes an appreciable amount of decomposition, thus yielding indications of organic matter, which are beyond the amounts present, whilst no such decomposition takes place on boiling an acid solution (Kubel-Tieman's method). The latter mode of procedure is therefore recommended. O. H.

Investigation of Petroleum. By F. BEILSTEIN (*Dingl. polyt. J.*, **250**, 169).—Although the forms of apparatus invented by Abel, Engler, and others, for the purpose of ascertaining the flashing point of petroleum, give concordant results in trained hands, it is necessary in constructing them to adhere strictly to the same form of apparatus, as a slight deviation influences the results to a considerable extent. The results obtained with the apparatus introduced by Liebermann and Stoddard vary with the size of the apparatus and the mode of applying the igniting flame.

The author recommends the following form of apparatus. It consists of a glass cylinder 35 mm. in diameter and 175 mm. long, marked at a distance of 70 and 140 mm. from the bottom with a divisional line. The cylinder is filled to the bottom line with oil. Air is admitted through a small brass tube, which dips into the oil and is bent round the cylinder, its end being provided with a rose-jet. The bulb of the thermometer is immersed into the middle of the oil column. At intervals of every degree of temperature air is forced through the liquid at a rate sufficient to raise the foam to the top line, a light being applied at the same time to test the flashing point. The results are said to be 5° higher than those obtained with Engler's apparatus.

The author states that the flashing point of petroleum determines only its degree of inflammability, and not the burning properties of the oil. This can be tested only by subjecting the oil to fractional distillation. American petroleum should not yield more than 5 per cent. of distillate under 150°, and not more than 15 per cent. of heavy oil boiling above 270°. Caucasian petroleum contains the hydrogen addition-products, C_nH_{2n}, of the aromatic hydrocarbons: hence it has a higher density and greater illuminating power than American petroleum. D. B.

Estimation of Sulphur in Organic Compounds. By E. H. KEISER (*Amer. Chem. J.*, **5**, 207—208).—The author obtains very accurate results by the following modification of Liebig's method for the estimation of sulphur in non-volatile compounds:—10 grams of potash is fused in a silver crucible, allowed to cool, the weighed substance (0·1—0·3 gram) added, the crucible heated until the contents have become thoroughly mixed; 1 gram of potassium nitrate is then added, and the heating continued until the mass has become clear. When cold the fused mass is dissolved in water, neutralised with hydrochloric acid, and diluted to $\frac{3}{4}$—1 litre, when all silver taken up from the crucible during the fusion is precipitated. This is filtered off, and the sulphuric acid in the filtrate determined in the usual way, by precipitation with barium chloride. The barium sulphate does not need reprecipitation. A. J. G.

Potassium Ferrocyamide Production. By K. ZULKOWSKY (*Dingl. polyt. J.*, **249**, 168—178).—The author gives a rapid and adequate method for the examination of the fused product in making ferrocyanide. As is well known, the ferrocyanide is first produced on the addition of water to the fused mass; in the solution obtained, other cyanides are present in small quantity along with sulphides, potassium carbonate, &c. In a manufactory, the author found a method in use for estimating ferrocyanide which has not before been published; it is founded on the known reaction between potassium ferrocyanide and a soluble zinc salt. The author has investigated the process and devised a satisfactory method of working it. A standard zinc sulphate solution is acidified with dilute sulphuric acid, and the filtered ferrocyanide is run in from a burette until a slight excess has been added; this is ascertained by carefully placing a drop of the mixed solutions on filter-paper, and then placing near a drop of dilute ferric chloride solution, care being taken that no portion of the zinc precipitate is touched with the chloride solution. Adding the zinc solution to the potassium ferrocyanide is not satisfactory. Too much sulphuric acid diminishes somewhat the amount of ferrocyanide required for a given amount of zinc solution. When the acidified zinc solution is heated to boiling variations in the amount of sulphuric acid no longer have any influence, the zinc precipitate is pulverulent, so that more care is required in applying the ferric chloride. The following equation represents the process:—

$$10ZnSO_4 + 7K_4FCy_6 = 10K_2SO_4 + (5Zn_2FeCy_6 + 2K_4FeCy_6).$$

Thiocyanates.—Although a portion of the thiocyanate in the solution is probably formed during the lixiviation, the amount found is usually returned as being present in the fused product. To estimate this, a measured volume of the solution is treated with a large excess of aqueous sulphurous acid, and allowed to stand about a day. Sulphur and a brown mass, produced by the decomposition of hydrocyanic acid, separate out. The acid liquid is neutralised with zinc oxide, and zinc sulphate is added to precipitate the ferrocyanide. The filtate is concentrated, treated with aqueous sulphurous acid and sufficient copper sulphate to produce a distinctly green colour. The white precipitate is heated with sulphur in a current of hydrogen.

J. T.

Wine Examination. (*Dingl. polyt. J.*, **249**, 311—312.)—According to S. Kilicsan, not only young wines but old and well kept wines contain ammonia; in six samples from 0·0057—0·0113 per cent. was found. Formic acid can often be detected in the distillate from unsulphured wines. Since the precipitate produced in a wine distillate by silver nitrate contains carbon, probably from the presence of organic acids, Kilicsan considers Wartha's process for the detection of sulphurous acid in wines to be untrustworthy.

J. Nessler and M. Barth give a method for estimating free tartaric acid in wine as an improvement of the original Berthelot-Fleurieu's process. 50 c.c. of wine are evaporated to thin syrup, this is well shaken with 70 c.c. of 96 per cent. alcohol, and allowed to stand four hours in a cool place, to permit the tartrate to settle out. The precipitate is separated, and its acidity reckoned as tartrate. The filtrate is freed from alcohol, and 0·5 c.c. of acidified 20 per cent. solution of potassium acetate is stirred into the syrupy residue, and the newly formed tartrate is estimated as before. But this method fails in case of wines strongly plastered, although negative values cannot be obtained, as are sometimes got by the older method.

For the estimation of sugar by Fehling's solution, the tannin must first be removed by lead acetate, the excess of lead being removed by sodium carbonate. Ordinary fully fermented wine usually contains under 0·1 per cent. sugar, and may be decolorised by a small quantity of animal charcoal; after rendering it alkaline with a little caustic alkali or carbonate, 5 c.c. is warmed with 2 c.c. Fehling, in a water-bath. If the blue colour completely disappears the wine contains over 0·2 per cent. sugar. If the blue colour persists 5 c.c. more wine may be added, and the warming repeated. In this way an approximation to the amount of sugar may be made.

J. T.

Detection of the Colouring Matter of Campechy Wood in Wine. By Boni (*Bied. Centr.*, 1883, 854).—Decompose with milk of lime, filter, dilute, add sulphuric acid until the liquid begins to appear red, then pour in absolute alcohol and filter. The addition of ammonium molybdate changes the colour into purple-red if the wine has been adulterated. E. W. P.

Detection of Artificial Colouring Matters in Wine. By P. Pastrovitch (*Bied. Centr.*, 1883, 865).—Magenta is not decolorised by manganese peroxide, but the juice of bilberries, elderberries, red and blue woods, cochineal, and orseille are all altered in colour; cochineal is decolorised, but the red in wines are changed to brown-yellow.

E. W. P.

Sugar Analysis. (*Dingl. polyt. J.*, **250**, 133—136.)—According to Vivien, it is difficult to estimate the glucose in sugar when the quantity is less than 0·1 per cent. The following colorimetric method is recommended:—10 grams of sugar are dissolved in 200 c.c. water, treated with 10 mgrms. glucose, and boiled. If after allowing the mixture to settle the supernatant fluid is decolorised, and a red precipitate formed, the sugar contains at least 0·1 per cent. of glucose. If no decolorisation occurs the change on raising the mixture to boiling is compared with ten solutions of glucose similarly treated, containing 1—9 mgrms. glucose. Zulkowsky states that the optical examination of a mixture of cane- and invert-sugar is adapted only to cases in which the quantity of invert-sugar predominates, as the specific rotatory power of this sugar is so small that the unavoidable errors of observation give rise to serious differences. Clerget's formula $R = 100 (D + D^1) : 144 - 0{\cdot}5t$, recommended by Reichardt and Bittmann for the estimation of cane-sugar in molasses, &c., gives inaccurate results when the quantity of invert-sugar is large, as then the temperature must be taken into account both before and after inversion.

The values for the quantity of invert-sugar in 100 c.c. of solution for various temperatures are based on the observations of Tuchschmied, who found that 17·21 grams of invert-sugar obtained from 16·35 grams of sucrose dissolved to 100 c.c., exert an optical action of $-(44{\cdot}16-0{\cdot}506t)^\circ$ Soleil. Zulkowsky has accordingly calculated the quantities of invert-sugar, corresponding with 1° of saccharimeter for the temperatures of 15—22°. The following table illustrates the results obtained:—

Temperature observed.	Grams invert-sugar contained in 100 c.c. solution by the optical action of		
	1° Soleil.	1° Ventzke.	1° Wild.
15°	0·4706	0·7506	2·1676
16	0·4772	0·7612	2·1983
17	0·4839	0·7719	2·2292
17·5	0·4875	0·7776	2·2456
18	0·4910	0·7832	2·2616
19	0·4981	0·7945	2·2944
20	0·5056	0·8064	2·3287
21	0·5133	0·8187	2·3642
22	0·5210	0·8311	2·3992

For the determination of invert-sugar and cane-sugar, Zulkowsky first determines the amount of sucrose by polarisation, then the quantity of invert-sugar. His method is described in detail in the original paper. D. B.

Clerget's Method of Sugar Analysis by Inversion. By A. J. King (*Chem. News*, **48**, 229).—In using this method for determining the amount of cane-sugar in a mixture already containing invert-sugar, attention is called to the importance of taking the reading of the polariscope both before and after the inversion at the same temperature; for the rotatory power of invert-sugar varies with the temperature, a factor which should remain constant if the true value of the cane-sugar is to be found by this method (comp. *ibid.*, **45**, 148). D. A. L.

Estimation of Phenol in Commercial Carbolic Acid. By Kleinert (*Anal. Zeitschr.*, **23**, 1—13).—The author has compared the results of estimating phenol by Koppeschaar's method (titration by means of standard bromine solution) and by fractional distillation. He finds that they in nowise agree, the bromine titration yielding figures which are far higher than the quantity of phenol which can be present. All samples which he examined yielded but a very small proportion of products volatile between 150° and 200°, phenol distilling between those temperatures. Between 200° and 250° the largest fractions are obtained, practically devoid of phenol, and yet giving copious bromine precipitates. Even at temperatures higher than 250° distillates are obtained, which give the bromine reaction, but do not show the well-known phenol indications with ferric chloride, hypochlorite, or fir-wood and hydrochloric acid. Kleinert therefore concludes that Koppeschaar's method is not applicable for the valuation of commercial carbolic acid. O. H.

Estimation of Tartaric Acid in Wine. By R. KAYSER (*Anal. Zeitschr.*, **23**, 28—29).—For this purpose Berthelot's method, consisting in the separation of the acid in the form of acid potassium tartrate and titration of the latter with normal alkali, is usually employed; but in addition to other sources of error which have often been pointed out, this method involves the separation of the calcium present in the form of calcium tartrate, which, of course, is neutral to normal alkali. In a number of determinations of the lime contained in the precipitate, the error involved was found to vary from 0·2—0·6 per cent. of tartaric acid, and in several instances was larger than the total amount of tartaric acid calculated from the acidity only. The error is the greater the older the wine and the smaller the percentage of tartaric acid. The amount of lime has therefore to be determined, and an equivalent quantity of tartaric acid to be added to that found acidimetrically by Berthelot's method. O. H.

Examination of Fats. By E. VALENTA (*Dingl. polyt. J.*, **249**, 270—273).—The author has examined a series of fats by a method proposed by J. Kottstorfer, for the detection of foreign fats in butter. The fat to be examined, if necessary, is filtered whilst warm, and a weighed portion is saponified with standard alcoholic solution of potash. After warming on the water-bath about 15 minutes, the excess of potash is titrated by half normal hydrochloric acid, using phenolphthaleïn as indicator. Pure butter fat requires per gram about 227 mgrms. of potassium hydroxide for saponification, whilst many fats used for adulteration, such as suet, lard, bacon fat, mutton fat, rape oil, olive oil, oleomargarine, poppy oil, and walrus oil, require about 197—198 mgrms. The author has examined both animal and vegetable fats. Some of the results obtained tend to throw doubt on the suitability of the method for butter testing, whilst in other cases the nature of single fats can be ascertained, and adulteration can be detected quantitatively if somewhat considerable. The results obtained are given in tabular form. Palm-kernel oil with 247 mgrms., and cocoa-nut oil with 257—268 mgrms., are much higher than any others of the list, excepting cod-liver oil with 213 mgrms. Cocoa-nut oil contains not inconsiderable quantities of laurine and myristic acids, also small quantities of caprylic acid, &c. These acids contain much less carbon in the molecule than do palmitic, stearic, and oleic acids, hence the high saponifying value of this fat. Apricot-kernel oil, oil of sweet almonds, oil of bitter almonds, arachis oil, cotton-seed oil, olive oil, sesame oil, average 193 mgrms. Pumpkin-seed oil, oil-cake oil, rape oil (Hungarian product), average 188·1 mgrms. Rape oil, mustard-seed oil, and castor-oil average 177·1 mgrms. American bone-fat, goose-fat, pig-fat, average 191—196. J. T.

Iodine in Cod-liver Oil. By E. C. C. STANFORD (*Chem. News*, **48**, 233).—Various authorities have published results at various times in which cod-liver oil is said to contain from 0·487 to 0·0295 per cent. of iodine, and in Garrod's *Materia Medica* it is stated to contain 0·06 per cent. If such were the case, cod-liver oil would be one of the richest sources of iodine, which the author considers improbable. Bird (*Pharm. J. Trans.* [2], 1, 546) published results of six analyses of cod-liver oils, four from Norway averaging 0·001355 per cent. iodine, and two from Newfoundland with 0·000993 per cent. The author has now made some determinations by a process which he has employed daily for many years in estimating small quantities of iodine, and by which $\frac{1}{250000}$ part of iodine is easily detected and measured, and up to $\frac{1}{100000}$ part accurately estimated. 5000 grains of oil are saponified with 1000 grains pure caustic soda, then carbonised in a porcelain crucible, the resulting charcoal is treated with water, and the solution made up to 5000 grains measure. 500 grains of this solution are treated with 100 grains measure of carbon bisulphide, and about three drops of nitrosulphuric acid—sulphuric acid, sp. gr. 1·843, saturated with gaseous nitrous anhydride—dropped in. The testings are performed in large even tubes, and the colour produced compared with graduated standard solutions of potassium iodide, treated in the same manner. The results of the analyses of several samples of cod-liver oil and some other substances are as follows:—

	Per cent. iodine.
Cod-liver oil, pale	0·000410
„ Norway	0·000434
„ Carr and Sons	0·000276
„ English	0·000138
„ Newfoundland	0·000315
Light brown cod-liver oil	0·000360
Cod liver, fresh	0·000817
*Cod-liver oil, dragées	0·056366
Oil vomited by the fulmar, a bird of St. Kilda	0·000095
†Fresh cod-fish, 0·00016 .... dry =	0·000829
†Scotch herring, salted	0·00065
† „ brine	0·00012
Whale oil, cold drawn	0·00001
Bottlenose oil, cold drawn	0·00010
Seal oil, cold drawn	0·00005

To analyse kelp, 100 grains are treated twice with four ounces of hot water, the residue is washed, and the solution made up to 5000 grains; 500 grains of this are treated with carbon bisulphide, &c., as described above. In the actual testing, the author never operates on a solution containing more than one-tenth of a grain of iodine; for if this quantity is exceeded, the solution is diluted before testing. Seaweeds or organic materials are first carbonised previous to being treated as described. Carbonising is preferable to burning to ash, because all the iodine is retained and the salts are easily extracted, whilst burning to ash causes loss of iodine and frequently leaves a fused mass. For testing the free iodine, carbon bisulphide is far preferable to starch, inasmuch as the latter is liable to change, is in many cases untrustworthy, and gives turbid solutions with the colour distributed throughout; whilst the former does not change, is quite trustworthy, the solutions are clear, and the colour is concentrated at the bottom of the tube. The author recovers the iodine from the bisulphide by means of zinc in the presence of water. D. A. L.

---

* Made of cod liver from which the oil is removed; for analysis 1000 grains were saponified with 200 grains of caustic soda.

† In these cases 5000 grains were treated with 500 grains of caustic soda. Other analyses were conducted as described above.

Examination of Beeswax. By Hübl (*Dingl. polyt J.*, **249**, 338—342).—Along with physical examination, F. Becker's saponifying test is of value. This test is given as Köttstorfer's butter test (see Abstr., p. 504). According to Becker, 1 gram beeswax requires 97 to 107 mgrm. potassium hydroxide for complete saponification. By mixing various waxy substances, impure beeswax can be made to give the same number. This difficulty can be overcome by ascertaining not only the total amount of potash required for complete saponification, but also that required to saturate the free acid (cerotic acid) present. Two numbers are thus obtained, which bear the constant relation of 1:3·7, as determined in about 20 samples of yellow wax. About 4 grams wax is treated with 20 c.c. neutral 95 per cent. alcohol, heated to fusion, and titrated with alcoholic potash solution, phenolphthaleïn being used as indicator. When the first number has been obtained, 20 c.c. potash solution are added, and the excess titrated with half normal hydrochloric acid. For the acid in 1 gram wax about 19 to 21 mgrm. KHO are required, and for the saponification 73 to 76 more are required. The proportion varies between 1:3·6 and 1:3·8, and the total potassium hydroxide used is 92 to 97 mgrm. The author designates the numbers thus obtained as acid number, ether number, and saponifying number respectively. Wax substitutes give very different values for these numbers, as the following average results show:—

Substance.	Acid number.	Ether number.	Saponifying number.	Proportion ether : acid.
Japan wax	20	200	220	10
Carnauba wax	4	75	79	19
Tallow	4	176	180	44
Stearic acid	195	0	195	0 : 195
Resin	110	1·6	112	0·015
Neutral substances Paraffin Ceresine	0	0	0	0
Yellow beeswax	20	75	95	3·75

Hence if the saponifying number falls below 92 with a proper proportion, the wax is adulterated with an inert substance (*i.e.*, paraffin). If the proportion be greater than 3·8, an addition of Japan or carnauba wax or tallow is probable. If the acid number be low, Japan wax is excluded, and of the remaining two the ether number will determine which has been used. If the proportion be below 3·6, stearic acid or resin has probably been added. It is also clear that the simultaneous presence of an active and an inactive substance may be detected by the figures obtained. The subject is being further investigated. J. T.

Estimation of Urea. By W. H. Greene (*Compt. rend.*, **97**, 1141—1142).—A tube of 20—25 c.c. capacity, closed at one end and graduated, is sealed on to the upper part of a flask of about 50 c.c. capacity, with a side tubulus. The flask and tube are completely filled with sodium hypobromite solution, and the urine to be examined is slowly introduced into the middle of the flask by means of a graduated pipette with a narrow curved end. When the evolution of gas ceases, a funnel tube is attached by means of the tubulus, hypobromite solution is poured into it until the levels in the funnel tube and the graduated tube coincide, and the volume of the gas is read off. Instead of using the side tube, the apparatus, with the tubulus open, may be immersed in a vessel of water until the level of the water coincides with that of the hypobromite. As a control, a similar experiment may be made with a standard solution of urea.

C. H. B.

Separation and Estimation of Digitalin, Digitaleïn, and Digitin. By R. Palm (*Anal. Zeitschr.*, **23**, 22—23).—The German method of separating digitalin from the other alkaloïds occurring in *Digitalis purpurea* is based on the precipitation of that alkaloïd by means of tannin; the French method on the insolubility of digitalin and digitin in water, digitaleïn being readily soluble.

Both methods are troublesome and demand much time. The author extracts the powdered herb with water, filters the solution through animal charcoal until it is colourless, and precipitates the organic acids with neutral plumbic acetate. A solution of lead acetate and alcoholic ammonia is then added to the filtrate as long as a precipitate is produced. This contains all the alkaloïds and is washed with water, and decomposed with hydrogen sulphide. The solution, separated from the precipitate, contains all the digitaleïn, the precipitate consisting of plumbic sulphide, digitalin, and digitin. The digitalin is extracted from the dried residue by chloroform, and digitin with alcohol. O. H.

Valuation of Indigo. By C. H. Wolff (*Anal. Zeitschr.*, **23**, 29—32).—The author has previously described (*Anal. Zeitschr.*, **17**, 310) a method of estimating the percentage of indigotin in commercial indigo by means of quantitative spectrum analysis, as introduced by Vierordt. He then employed a standard solution made from indigotin, which had been prepared by Trommsdorff. The artificial preparation of indigotin by Baeyer's process has now furnished the means of obtaining the colouring matter in a state of perfect purity, and Wolff has compared this with samples of indigotin prepared by various manufacturers and also with commercial indigos, when the following results were obtained:—

Indigotin, Baeyer	100·00 per cent.
„ Trommsdorff	91·58 „
„ sublimated, Schuchardt	83·41 „
„ „ Wolff	82·45 „
„ Vierordt	81·95 „
„ crys. Schuchardt	79·08 „
Indigo, Java	72 42 „
„ Bengal, best	63 97 „
„ „ medium	60·47 „
„ „ third quality	20 94 „
„ Guatemala	50·70 „
„ Madras	23·10 „
„ Manilla	9·41 „

Technical Chemistry.

Antiseptic Action of Carbonic Anhydride. By H. KOLBE (*J. pr. Chem.* [2], **28**, 61—62).—The author has pointed out that carbonic anhydride is an excellent means for preventing the putrefaction of meat (Abstr., 1883, 395). This was observed by Hermbstädt in 1791.

H. B.

Illuminating Gas and Gas Engines. By F. FISCHER (*Dingl. polyt. J.*, **249**, 178—182).—A sample of Hanover gas, analysed by a method described, was found to contain

Benzene	0·69
Propylene	0·37
Acetylene	2·11
Methane	37·55
Hydrogen	46·27
Carbonic oxide	11·19
Carbonic anhydride	0 81
Oxygen	trace
Nitrogen	1·01
	100 00

When this gas was used to drive a 6 horse-power Otto's gas engine, the waste gases were found to contain 6·0 to 7·7 per cent. of carbonic anhydride, and 9·9 per cent. of oxygen. When the engine was running without load, the waste gases contained 2·4 per cent. carbonic anhydrine, and 17·2 per cent. oxygen. The temperature was about 400° C.

An engine driven by petroleum gas gave waste gases with 9·4 per cent. carbonic anhydride, and 5·1 per cent. oxygen; some little petroleum was carried over unconsumed. The temperature was 253° C. in this case, and when running light, the temperature was 130° C. with 6·0 per cent. carbonic anhydride, and 11·4 per cent. oxygen in the waste gas. Evidently the gas engine works with twice as much air as is necessary, and when running light, with three or four times as much. Hence much poorer gas can be employed by properly adjusting the amount of air supplied, and probably even generator gas may be used.

E. Graban shows that the cost of steam driving per horse-power per hour varies from 3·4 to 8·1 pfennige, whilst the price of gas driving varies from 4·3 to 12·55 pfennige, according as gas varies from 3 to 14 pfennige per cubic metre. J. T.

Retort Furnaces with Gaseous Fuel. By F. Fischer (*Dingl. polyt. J.*, **249**, 346—350).—The author compares the working of three different systems in operation at the Hannover Gas Works. Samples of generator gas were taken from two of the furnaces, the Klönne and the Stettin, and for comparison the composition of gas from the Munich generator is also given on Table I. A sample from the third furnace (Liegel) could not be obtained.

Table I.

	Klonne.				Stettin.		Munich.			
	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.
CO_2....	3·00	13·10	7·06	4·40	5·19	5·10	9·1	12·2	9·3	8·6
CO	29·99	16·39	27·43	30·21	28·19	27·76	19·8	17·4	20·4	20·6
CH_4....	—	1·06	1·22	0·14	—	—	—	—	—	—

In sample 1, the steam supply under the grate was somewhat weak; 2 was taken just after cleaning out the grate; 3, taken with grate somewhat slagged; 4, working well; 5 and 6, working well. In 7, 8, 9, and 10, no account appears to have been taken of methane. An average sample of the coke used, taken on the last day of the experiments, gave C 92·7, H 0·29, ash 4·95, O, N, S and loss 2·06 per cent. The Klonne and Liegel furnaces have a regenerative arrangement to heat the air before combustion, whilst the Stettin furnace is not so provided. The following table (p. 510) shows the composition of the waste gases, and an estimation of the relative efficiency of the furnaces.

The results marked with a (+) are when the furnace is working normally. For each 100 kilos. coal in the retorts the Klónne furnace requires 13 kilos. coke, the Liegel 15 kilos., and the Stettin 19 kilos.; whilst by ordinary grate firing 23 kilos. coke are necessary.

Furnace.	Composition of gases.				Temp. in chimney.	Loss of heat per kilo. coke.	Per cent. of total calorific value.

An Evaporation Experiment. By F. FISCHER (*Dingl. polyt. J.*, **250**, 72—79).—The author gives a description of a comparative experiment made with a view to ascertain the evaporative power of coal and the variations in the composition of the flue gases. The boilers employed were of two constructions. In the one case, a German boiler was used, having a wide corrugated fire-tube inserted laterally; whilst as a comparison an ordinary Lancashire boiler with two smooth fire tubes was used. The heating surface in both cases amounted to 86 square meters, the area of the hearth of the English boiler being 2·8 square meters, and that of the German boiler 1·9 in the trials made July 5 and 6; and 2·4 square meters in those made August 3 and 4. The coal was obtained from the Saelzer and Neuack mine, and gave by analysis:—

C.	H.	N.	S.	O.	H_2O.	Ash.
79·63	4·08	1·22	0·88	4·43	3·00	6·76

corresponding according to Dulong's formula to

$$[8100 \times 79{\cdot}63 + 28{,}800\left(4{\cdot}08 - \frac{4{\cdot}43}{8}\right) + 2500 \times 0{\cdot}88 - 600 \times 3] : 100$$

= 7471 units of heat calculated on water of 20° as combustion product. The results of the experiments are summarised in the subjoined table (p. 511).

The widest differences in the composition of the gases at intervals of 60 minutes were obtained with the English boiler; this the author attributes to the difference in the dimensions of the fire tubes of the two boilers.

D. B.

Contamination of the Atmosphere by Products of Respiration. By J. T. H. HERMANS (*Dingl. polyt. J.*, **249**, 419—423).—It is a well known fact that men who live in crowded spaces are more readily subject to disturbances of health than other persons, and that supplies of fresh air improve the health and activity of such inhabitants. The author has made it his object to determine the causes of atmospheric contamination induced by the influence of respiration, and the work of the human skin.

An Evaporation Experiment.

Regnault and Reiset have shown that the breathing of animals in air containing 10 per cent. of oxygen is increased in rapidity; whilst air containing 4 to 5 per cent. of oxygen is incapable of sustaining life. According to Müller, breathing is retarded in air with 5 to 7·5 per cent. of oxygen; whilst air with 15 per cent. of oxygen does not affect the respiratory process. If the quantity of oxygen in the atmosphere be reduced to 4—7 per cent., and the exposure to such air continued for any length of time, a diminution in the oxidative processes in the human body takes place, which may be neutralised by an increase in the respiratory functions. The quantity of carbonic anhydride necessary to act on the animal organism is very considerable. Thus, Friedländer and Herter found that on breathing air diluted with 20 per cent. of carbonic anhydride, animals exhibited no toxic effects, but merely showed signs of their respiratory organs having been excited, and the work of the heart increased. The atmosphere of the natural hot baths of Oeynhausen, although containing several per cent. of carbonic anhydride, can be inhaled for 30 to 60 minutes without difficulty. Since, therefore, the changes in the normal constituents of the atmosphere are quantitatively insufficient to explain the ill-effects of the air in rooms, it has been thought that besides carbonic anhydride, other substances contained in small quantities in air are exhaled by the human body, which, being gradually re-inhaled, produce poisonous effects. The author has undertaken a series of investigations in this direction, as the conclusions at present arrived at have not been corroborated. He found that a small amount of organic matter is added to the air during respiration, as well as watery vapour. He, however, ascertained that under normal conditions man does not exhale volatile combustible products, at least not in appreciable quantity, and that when found in expired air their presence is due to the evolution of gases formed by defective digestion in the abdomen, especially in consequence of the introduction of improper food.

In conclusion, it is argued that the task of removing the expired gases from the surroundings of men by means of ventilation is of less importance than the question of limiting or preventing their formation. In order to breathe pure air, it is most essential to improve the diet as much as possible, and keep both body and dress free from dirt.

D. B.

Bromine as a Disinfectant. By A. Frank (*Dingl. polyt. J.*, **249**, 167).—The bromine is soaked up by infusorial earth, and is conveniently placed in a Brüner's pan of glass or porcelain, instead of lead, having a very deep depression in the cover.

The water sealing the joint of the lid becomes charged with bromine from the interior, whence the bromine gradually diffuses into the room. To accelerate the rate of diffusion, warm water may be poured into the depression in the centre of the cover.

Frank recommends petroleum to reduce the action of bromine on organic substances with which it may come into contact, or to quickly remove its odour.

J. T.

The Salt Work of Giraud in France. By G. LUNGE (*Dingl. polyt. J.*, **249**, 517—523).—The salterns of Giraud belong to the great firm of Pechiney and Co., who own also the works of Salindres, where the manufacture of soda, chloride of lime, potassium chlorate, sodium chlorate, and aluminium is carried on. The company has the right of possession over an area of 20,000 hectares of water, which comprises the greater part of the lakes of Carmague, but only a small portion of these is at present worked, the actual evaporating surface embracing only 1,500 hectares. The junction with the sea consists in a narrow creek known as "Grau de la dent," leading to a branch of the Rhone, which is cut off from the land. At a distance of 3 kilos. from the inlet, a large steam pump is stationed, which raises the partly concentrated sea water to a height of 0·7 meter, and delivers it into a large primitive lagoon having an area of 250 hectares called "Étang de la Galère." The water then flows into the actual evaporating spaces (surfaces évaporantes, partènements, chauffoirs) arranged in groups round a reservoir of considerable size, called the "Cuvette," which occupies the lowest position in the series. The sea water which at the commencement has a density of 3·6° B. gradually increases in concentration, and at 16° B. deposits considerable quantities of calcium sulphate. By carefully regulating the supply of sea water it is possible to obtain a brine in the "cuvette," having a concentration of 25° B., so that 1 cubic meter of sea water is condensed to 102 litres. This process is usually commenced in the month of May, and is ended in about 120 days. From the "cuvette" the liquor passes through a channel, from whence it is pumped into raised salt beds (tables salentes), which are 140 meters in length and width, and 30 cm. in depth. The separation begins as soon as the brine reaches a density of 25·6° B., a layer of salt 1 mm. thick being obtained every day corresponding with the evaporation of a column of water 6 to 7 mm. in height. At the end of the evaporating process 1 hectare of salt bed yields a layer of salt 30 to 55 mm. in thickness, equivalent to 800 tons of salt.

At Giraud, three varieties of salt are produced, the first being obtained from a brine having a density of 25·6 to 27° B.; the second from the mother-liquors of the first, when they have reached a concentration of from 27° to 28·5° B.; and the third from the mother-liquors of the second after they have been concentrated to 31° B. The following analyses illustrate the composition of these varieties. I. Table salt; II. Salt for works; III. Salt for salting, &c.:—

	$CaSO_4$.	$MgSO_4$.	KCl.	$MgCl_2$.	NaCl.	H_2O.	Insoluble.
I.	1·115	0·221	—	0·100	97·100	1·400	0·050
II.	0·621	0·506	trace	0·377	94·212	4·201	0·080
III.	0·440	0·612	0·122	1·300	91·217	5·758	0·050

The final liquors when allowed to evaporate to a strength of 32·5° to 35° B. deposit the so-called "sels mixtes," a mixture of sodium chloride and magnesium sulphate. The residual mother-liquors are transferred to large cisterns, and deposit in the winter at a temperature of + 12° crystallised Epsom salt. The temperature should not be less than 12°, otherwise carnallite crystallises out with the magnesium sulphate. The liquor remaining after the separation of the magnesium sulphate has a density of 33° B., and is worked up in the factory. 1 cubic meter of sea water yields only 16 liters of this final mother-liquor.

In conclusion, the author refers to some improvements made by Pechiney in dehydrating the vast quantities of hydrated sodium sulphate obtained by submitting the mixed solutions of sodium chloride and magnesium sulphate (sels mixtes) to artificial refrigeration by means of Carré's machine, when double decomposition takes place, crystallised sodium sulphate and solution of magnesium chloride being produced, which are then separated from each other by means of hydro-extractors. Pechiney adds 45 per cent. of "sels mixtes" to the hydrated sodium sulphate, and heats to 80°, when anhydrous sodium sulphate is obtained, which is then separated by machining. The whole process is performed in a short time, and its cost is very small. The filtrate is used for the production of more hydrated sulphate. With the view to separate potassium chloride in the form of carnallite from the mother-liquors which have deposited magnesium sulphate during the winter season, the solutions must be mixed together whilst hot, and in as concentrated a form as possible.

D. B.

Commercial Sodium Nitrite. By P. MacEwan (*Pharm. J. Trans.* [3], 14, 121).—The author has examined several samples of this salt, and finds that they contain widely different proportions of nitrite. He points out that by fusing the sodium nitrate with lead or copper, instead of carbon, a much purer product can be obtained. He also suggests that old stock of sodium nitrite (a sample analysed contained only 0·028 per cent. $NaNO_2$) should be looked over, and that the fused nitrite of soda of the 1864 Pharmacopœia—a sample analysed contained only 9·6 per cent. $NaNO_2$—should not be dispensed.

D. A. L.

Improvements in Metallurgy. (*Dingl. polyt. J.*, 250, 79—88, and 123—133.)—Referring to the reduction of agglomerated mixtures of ores and flux in zinc ovens, Binon suggests that the mixings should be introduced into the oven in a strongly compressed state. Hitherto it has been supposed that by adding the mixings in a finely divided state the carbonic oxide would penetrate more readily and deeply into the mass, and thus facilitate the reduction process. This Binon disproves. In a pressed form it is possible to fill the distillation tubes with 50 per cent. more charge, a saving of 10—15 per cent. being simultaneously effected in the amount of reducing agent required.

Egleston states that the presence of tellurium in copper is injurious. Samples of black copper from Colorado ores evolved fumes of tellurous anhydride when refined. The following is the composition of the matter of two samples of the black copper and of the refined copper:—

	Matte.	Black copper.		Refined copper.
Cu	55·02	97·120	98 090	99·705
Au	0·06	—	—	—
Ag	0·40	0·132	0·128	0·135
Pb	17·87	0·777	0·757	—
Zn and Ni ..	2·22	0·070	0·100	0·024
Fe	4·18	0·130	0·080	0·031
S..........	20·02	0·236	—	traces
Te	0·12	0·093	0·097	0·083
As	—	0·006	—	0·091
Slag, &c. ..	—	1·270	0·192	—
	99 89	99 834	99·444	100·069

The refined copper had all the appearance of being good copper, but on rolling it into plates 30 mm. in thickness, very fine cracks showed themselves, which penetrated the plate on each side. At a thickness of 8 mm. it began to fall to pieces. When cold the metal was tough and malleable.

In copper smelting, the treatment of the coarse metal in the Bessemer converter has been practised since 1866. Manhes has recently worked up the coarse metal at Eguilles and Vedènes in this manner. In the commencement a converter with a charge of 200 kilos. was used. The bottom of the converter communicated with a blast chamber and a number of vertical tuyeres. It was, however, found more expedient to employ horizontal tuyeres, and to introduce the air into the metal bath some distance above the bottom of the converter, as the vertical tuyeres soon became blocked, owing to the fact that at the end of the operation the heat did not suffice to keep the metal bath and the ferruginous slag in a fluid condition. The apparatus worked satisfactorily, and the copper produced did not contain more than 1·5 per cent. of foreign ingredients. In the case of poorer ores the process was divided into two operations, in the first the coarse metal was blown until it contained 60 per cent. of copper, the slag was then removed and the operation completed in a second converter. Manhes has refined coarse metal of various degrees of purity, also ores containing arsenic, antimony, lead, zinc, &c. The foreign constituents are volatilised or scorified, and it is recommended to add ferromanganese to the impure copper, in order to render the slag more fluid. The process is of importance where fuel is expensive and cheap water power at disposal.

Johnsson proposes to fuse sulphuretted copper ores in a Pilz-Mansfeld furnace provided with 6 or 8 tuyeres. The resulting product, containing about 35 per cent. copper and 26 per cent. sulphur, is then worked up into black copper in a Siemens furnace.

The treatment of the Riotinto cupriferous ores is described in detail in the *Allgemeine Metall. Zeit.*, 1883, 1. The exported ores contain 3—3·5 per cent. of copper, and are used in England and Germany for the manufacture of sulphuric acid. The burnt residues are worked up for copper and silver in the usual manner. After referring to the roasting of the ores rich in copper, as conducted at Riotinto, the extraction of copper and its precipitation by iron is discussed. It is stated that owing to the fact that 1 ton of refined copper requires 2 tons of pig-iron, this process is being gradually abandoned, and the precipitation of the copper effected by means of hydrogen sulphide. The final liquors, which should be free from hydrogen sulphide, can be used for lixiviating purposes, as they contain free acid.

The roasting of the ores has been abandoned at two experimental stations of the Riotinto works. In its place the Dötsch process is used, which resembles the method introduced by Kopp and Chalandre. According to Cumenge and Wimmer, this method of extracting copper is applicable to pyrites containing on an average 2·68 per cent. of copper. The metal is present as CuS and Cu_2S. On treatment with ferric chloride the ores are decomposed according to the equations—

$$CuS + Fe_2Cl_6 = 2FeCl_2 + CuCl_2 + S \text{ and } Cu_2S + Fe_2Cl_6 = 2FeCl_2 + Cu_2Cl_2 + S.$$

The practical utility of these reactions consists in the circumstance that the ferric chloride in solution attacks the cupriferous pyrites or the copper sulphides, whilst the iron pyrites remains unaltered. Instead of ferric chloride, a solution of ferric sulphate and salt may be used, which suffers decomposition into sodium sulphate and ferric chloride. This solution is allowed to percolate slowly through the ores piled up in heaps. 1 cubic meter of the filtered liquor contains 5—6 kilos. copper, mainly in the form of cuprous chloride, hence the consumption of iron for precipitation is considerably reduced. The residual solution of ferrous chloride is converted into the ferric salt, and used for a further operation. The conversion is effected by means of chlorine obtained by heating a mixture of rock-salt and ferrous or ferric sulphate in a reverberatory furnace provided with three doors, the combustion-products being supplied with a current of air introduced into the furnace through the fire bridge.

It is stated that on roasting ores containing lead, silver, copper, or nickel, and antimony or arsenic with sodium chloride, according to the process for roasting antimonial ores introduced by Lyte, fumes of the chlorides of silver and lead are given off, besides antimony and other volatile chlorides. To prevent this loss, the roasted or non-roasted metallic sulphides are subjected to the action of hydrochloric acid at 250—400° in reverberatory or muffle furnaces. The less volatile chlorides of silver and lead remain in the residue, whilst the chloride of antimony is volatilised, its vapour being condensed in hydrochloric acid. The chlorides of silver and lead are extracted by means of a hot solution of salt; on cooling, lead chloride separates in a crystalline form. The separation of the silver and the remainder of the lead from the decanted solution is effected by means of zinc.

Helmhacker (*Bergund. Hüttenm. Zeit.*, 1883, 191) enters into a long discussion on the processes for recovering and refining antimony. According to Föhr, the Boëtius furnace is now largely used in Upper Silesian zinc works, and is preferred to the Siemens furnace.

D. B.

Metallic Alloys. (*Dingl. polyt. J.*, **250**, 31—36.)—For the preparation of alloys of chromium with iron, and of tungsten with iron, Guétat and Chavanne recommend to mix the soluble salts of the two metals in the required proportions, and precipitate them by double decomposition as chromate or tungstate of iron. The precipitates are then dried, roasted, mixed with carbon, and heated to whiteness in well-luted graphite crucibles. For the preparation of cupric phosphide, cupric chloride is decomposed with calcium phosphate, and the resulting cupric phosphate reduced in graphite crucibles.

According to Dick, the hardness and toughness of alloys of copper and tin, and copper and zinc, is increased by the addition of small quantities of iron.

Seyboth proposes to clean metals and metallic alloys by means of an aqueous solution of potassium or sodium carbonate and calcium phosphate, mixed with pulverised charcoal to a stiff paste, which is then added to the fused metal or metallic alloy. For cylinders used in calico printing, Hauvell recommends an alloy of the following composition:—Cu = 86, Sn = 14, and Zn = 2. Rondel analysed English cylinder metal, and found it to contain Cu = 5·6, Zn = 78·3, and Sn = 15·8. Although these proportions yield a hard fine-grained alloy, it is thought that the dye-stuffs employed in printing would readily attack the same. Analyses of the doctors used in printing gave the following numbers :—

	Cu	Zn.	Sn.
Yellow French doctor according to Salvétat ..	78·75	12·50	8·75
Yellow English doctor according to Berthier ..	80·50	10·50	8·00
Yellow German doctor according to Elsner	85·80	9·80	4·90

From a series of trials it is concluded that besides the red cuprous oxide, alloys containing 25—30 per cent. zinc, and 75—70 per cent. copper, are most suited for printing purposes. The presence of lead is condemned. D. B.

Bessemer Process. (*Dingl. polyt. J.*, **249**, 264—269.)—As an appendix to a former paper, Finkener shows that in the basic process silicon and manganese first diminishes, then the carbon, and lastly, the phosphorus and manganese, if the latter has not already disappeared with the silicon. Experiments show that the carbon is removed as carbonic oxide essentially, with but very little carbonic anhydride, but the relative amount of the two may vary with the temperature and quality of the iron, the carbonic anhydride disappearing only when the iron is rich in carbon. The phosphorus is oxidised to phosphoric anhydride simultaneously with so much iron that a bibasic ferrous phosphate is formed; a compound with less iron cannot separate out from the fluid iron, as the latter decomposes it. So long as silicon is present, carbonic oxide is reduced as fast as produced, silicate and carbide being produced. Ferro-silicon is so powerful a reducing agent that under its action normal ferrous silicate yields part of its iron in the metallic state. The more easily reduced phosphate is decomposed, so that no phosphorus is removed so long as any silicon remains. As the silicon protects phosphorus, so does manganese protect iron. After removal of the silicon, carbonic oxide is evolved containing some little carbonic anhydride; the latter increases slightly in amount as the carbon in the iron diminishes. Manganous or ferrous phosphate is formed, but only to a slight extent, the greater portion being reduced again by the iron carbide present. This reduction can only be ascribed to the mixed carbonic oxide and anhydride, on the supposition that the reducing power of the gaseous mixture increases more rapidly with a rise in temperature than does that of the carbide.

Metallic iron picked out of the slag is found to contain little phosphorus, but if carbonic oxide acted reducingly on the phosphate in the slag this iron might be expected to be richer in phosphorus. If iron carbide is the reducing agent, the phosphide produced combines with iron. When carbon has been removed, the separation of ferrous phosphate proceeds, since this compound can exist along with iron. Iron sulphide is undecomposed after the dephosphorisation; it can exist during the formation of iron oxide. A small amount of sulphur remains almost unchanged; a larger amount of sulphur is reduced, owing to the action of the slag on the iron. After the addition of spiegel, the amount of phosphorus increases, some of the phosphate in the slag being reduced, probably, as mentioned above, by the iron carbide now present again. The author gives details of experiments showing the action of silica, phosphoric acid, ferrous phosphate and pyrophosphate, sulphurous anhydride, and calcium sulphite, on metallic iron, the substances being heated up to whiteness in a porcelain tube.

J. E. Stead gives analyses of gannister from Sheffield used for Bessemer vessel linings, also analysis of basic lining as follows:—

CaO.	MgO.	Al_2O_3.	Fe_2O_3.	SiO_2.	
49·91	30·72	4·50	3·46	11·41	= 100·00

This is mixed with tar and rammed in the vessels, or previously moulded into blocks. The pig-iron now used for the acid process may contain as much as 0·15 per cent. sulphur, whilst formerly 0·05 was the maximum limit; this is due to the richer spiegel now obtainable, so that more manganese can now be added to counteract the effect of the sulphur. The following figures show the changes taking place during an ordinary blow:—

	Beginning of the blow.	After 5 min.	10 min.	15 min.	20 min.	25 min.
C......	3·5	3 6	3·3	3·25	2·0	trace
Si	2·25	1·0	0·5	0·2	0·1	trace
Mn	1·00	0·35	0·2	trace	—	—

During a *hot* blow the carbon burns more quickly, thus:—

C......	3·5	3·6	3·3	2·5	1·0	trace
Si	3·0	1·75	0·25	0·9	0·7	0·5
Mn	0·75	0·25	trace	—	—	—

The flame does not drop so readily during a hot blow, and the blast is continued until brown fumes of burning iron appear. With increasing temperature consequently the affinity of oxygen and carbon increases, a circumstance of importance in the production of compact castings by the addition of silicon, since the silicon ceases to act as soon as the affinity of oxygen to carbon exceeds that of oxygen to silicon. Pig-iron suitable for the basic process has the following composition:—

C.	Mn.	Si.	S.	P.
3·35	0·60	1·30	0·15	1·75
to	to	to	to	to
3·50	1·00	1·00	0·12	2·75

After the addition of 15—17 per cent. of lime, the following changes take place during a blow:—

	Beginning of the blow.	After 5 min.	10 min.	15 min.	18 min.
C......	3·50	3·55	2·35	0·07	trace
Si	1·15	0·50	0·09	trace	—
Mn	0·71	0·56	0·27	0·12	trace
P......	1·57	1·60	1·43	1·22	0·08
S......	0·16	0·14	0·13	0·12	0·10

The highly basic ferruginous slag formed is again decomposed, and the more readily the more intimately it is mixed with the iron. The following formulæ show these various reactions:—

$$2FeO + Si = SiO_2 + Fe_2. \qquad FeO + Mn = MnO + Fe.$$
$$6FeO + 2P = FeP_2O_6 + 5Fe. \qquad FeP_2O_6 + 6C = Fe + P_2 + 6CO.$$
$$FeP_2O_6 + 3Si = 3SiO_2P_2 + Fe.$$

So long, therefore, as silicon and carbon are present, and a thick bath of iron exists over the tuyeres, practically no phosphorus is removed. On the contrary, with a shallow bath of iron and a powerful blast so that the slag is kept well on the surface, phosphorus can be removed before the whole of the carbon has gone, as Thomas and Gilchrist found in their early experiments. With an acid lining, phosphorus is not removed, since calcium and iron phosphates are converted into silicates by silica, with separation of phosphoric acid, which latter then gives phosphorus and ferrous oxide under the action of iron. Analyses of the slags produced are given by the author, and also of the resulting steel. J. T.

Modern Processes for the Manufacture of Iron and Steel and the Properties and Methods of Testing these Materials. By F. KUPELWIESER (*Dingl. polyt. J.*, **250**, 37—46).—The author states that the manufacture of iron and steel embraces processes belonging to the category of indirect processes, as the iron ores are smelted in order to obtain pig-iron therefrom, which is then subjected to oxidation processes. These have for their object the separation as far as possible of foreign substances which accompany the iron, and the conversion of the metal into soft iron or steel, eliminating at the same time more or less carbon. The efficiency of the separation of the impurities depends on the oxidation process employed; as to whether the end product of the oxidation process is obtained as spongy blooms or in a perfectly fluid condition depends on the final temperature. By conducting the refining in hearth and reverberatory furnaces, loose spongy iron masses are obtained, from which it is difficult to remove all the slag. In order to obtain a fluid product, the puddled iron is subjected to a final operation of reheating to a welding temperature. The great drawback to this process is its cost, and the difficulty of obtaining a homogeneous product. It has therefore been gradually abandoned.

Chief among the modern refining processes ranks the Bessemer process, which has been brought to further perfection by the improvements introduced by Thomas and Gilchrist. The Siemens-Martin process differs from the final operation of remelting the metal in crucibles by the iron being heated on the open hearth of a regenerative furnace, otherwise it bears great resemblance to the old process of reheating.

Referring to the properties of iron and steel, it is mentioned that they are influenced by the quantity and quality of the foreign substances present, also by the homogeneity of the material and the mechanical treatment to which the metal is subjected. The conditions most suited for the production of the best kinds of iron are the entire absence of foreign constituents except carbon, and the presence of the latter in quantities sufficient merely to impart to the metal its requisite degree of hardness, firmness, elasticity, &c. It is difficult but not impossible to obtain such a product on a large scale.

The author discusses the changes in the properties of iron caused by the presence of foreign ingredients, such as carbon, silicon, manganese, sulphur, and phosphorus; he also refers to the question as to the production of sound castings free from porous and blistered places. The paper, which is of considerable length, examines minutely the probable causes and effects of the differences in the mechanical treatment, temperature used, and uniformity of the raw material employed; and concludes with some remarks in connection with the testing of rails. D. B.

Notes on the Dephosphorisation of Iron. By G. HILGENSTOCK (*Dingl. polyt. J.*, **250**, 330).—The slag obtained in the basic process worked at Hörde frequently exhibits a crystalline appearance. Selected specimens of crystals gave by analysis 61·1 per cent. lime and 38·14 per cent. phosphoric acid, corresponding with the formula $Ca_4P_2O_9$.

According to Carnot and Richard, basic slag from Joeuf contained blue translucent crystals of the following composition:—

P_2O_5.	SiO_2.	Al_2O_3.	CaO.	MgO.	FeO.	MnO.
29·65	12·42	2·76	53·20	traces	1·80	traces

D. B.

Action of Organic Acids on Nickel-plated Iron Vessels. By K. BIRNBAUM (*Dingl. polyt. J.*, **249**, 515—517).—Culinary vessels made of nickel-plated iron have recently been brought into commerce, and from their pleasing appearance will probably be rapidly introduced into kitchens. It is not unlikely that these vessels will be used without due regard to the various operations in connection with the preparation of food, as in recommending them reference is made to a statement by Schulz that 2 litres of milk, when kept in a nickel pan for eight days, dissolved only 0·022 gram of metal, and that a dog received during 21 days a total of 10·5 grams of nickelous acetate without exhibiting any marked symptoms. The author has made a series of experiments, and found that by working with a much smaller quantity of liquid than that employed by Schulz, considerably more than 0·022 gram of metal was dissolved, so that the thin coating of nickel would soon disappear. Referring to the physiological experiments on the toxic action of nickel and its salts, it is doubtful whether human beings will not be affected in a different manner; moreover, it is not shown whether the nickel compounds pass rapidly through the system or remain in the same, in the latter case, the period of observation of three weeks was scarcely sufficient to determine to what extent nickel is poisonous. Until this has been definitely decided, nickel-plated vessels should be used with great caution, and their use wholly abandoned for the preparation of hot foods.

D. B.

Polished Brass. By MEIDINGER (*Dingl. polyt. J.*, **250**, 330).—About 10 years ago large slabs, plates, signs with ornaments, heads, &c., pressed out of thin sheets of brass in slight relief, were brought into the market from Antwerp, representing imitations of ancient brasses. They were called *cuivre repoussé*, and were used for decorating walls. About the same time small artistic objects, such as candlesticks, inkstands, ashtrays, &c., cast in brass, were introduced into commerce as coming from Paris under the name of *cuivre poli*. Their manufacture was subsequently taken up in Berlin, where the best articles were prepared. In order to obtain a fine polished surface, the castings were turned in a lathe, into which wire brushes, emery discs, and polishing cloths are fixed. D. B.

Contribution to a Knowledge of Mineral Fuel. By BOUSSINGAULT (*Dingl. polyt. J.*, **250**, 331).—The author has examined bitumen from the hot springs of Ho-Tsing in the province of Szu-Tchaun, China. It is fluid at the ordinary temperature, but deposits naphthalene (?) on cooling. Composition:—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
Fluid	86·82	13·16	—	0·02
Solid	82·85	13·09	4·06	—

Asphalte from Egypt (I) and mineral pitch (Jew's pitch) from the Dead Sea (II), gave by analysis:—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
I	85·29	8·24	6·22	0·25
II	77·84	8·93	11·53	1·70

Fossil resin resembling amber, from the alluvions of New Granada, found in one piece weighing 12 kilos. at the gold washing works of Giron, near Bucaramanga (I), and fossil resin from the deltas of Antioquia (II), gave :—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
I	82·70	10·80	6·50	—
II	71·89	6·51	21·57	0·03

Coal from Canoas, on the plateau of Bogota, Cordilleras (I), and coal from the province of Antioquia (II), had the following composition :—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
I	80·96	5·13	12·50	1·41
II	87·05	5·00	6·56	1·39

Coal resembling wood-charcoal, hence called "Fusain," from the mines of Blanzi (I) and Montrambert, Loire (II), gave by analysis—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
I	87·81	3·88	7·67	0·64
II	93·05	3·35	3·43	0·17

Anthracite from Chili (I) and Muso, New Granda (II), gave—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
I	92·25	2·27	4·94	0·54
II	94·83	1·27	3·16	0·74

Graphite from Karsoh contained—

Carbon.	Hydrogen.	Oxygen.	Nitrogen.
97·87	0·37	1·70	0·06

On treatment with dry chlorine gas at a red-heat, pure carbon was obtained. D. B.

Geological and Chemical Investigation of Bentheim Asphalte with reference to Analogous Occurrences in Italy. By Strippelmann and Engler (*Dingl. polyt. J.*, **250**, 216—227, 265—271, and 316—321).—In the first part of the paper, Strippelmann speaks of the occurrence of asphalte at Bentheim, and of similar asphaltic deposits at Paterno, Castro, Colla San Magna, and other places. He then enters into a minute discussion on the formation of these bitumens. His conclusions confirm the views held by Mendelejeff as to the formation of bitumen by inorganic means. Bitumen is frequently met with at places where, from a geological point of view, its occurrence can be explained only by duly recognising the theory as to the direct influence of volcanic forces on the formation of fissures, and by assuming that the bitumen accumulated within the fissures is formed in the same manner as that contained in lavatic geodes, and separated from prehistorical tufaceous deposits, but by inorganic means.

In regard to the practical utility of the Bentheim asphalte, it is stated that it is of high value for the purpose of gas-making and for the preparation of burning oil, paraffin, lubricating oil, and coke. According to Engler the asphalte has a sp. gr. of 1·092. It is insoluble in alcohol, ether, carbon bisulphide, oil of turpentine, and similar solvents, and melts when heated strongly. It contains—

	I.	II.
Carbon	89·46	89·33
Hydrogen...........	9·55	9·88
Residue (ash)	1·09	1·14

The following products are obtained on fractional distillation :—

1. Distilled in glass retorts without steam—

	I.	II.
Tar................	36·8	38
Coke	48·9	48
Loss (gas and water)	14·3	14

The tar has a sp. gr. of 0·834, and forms a thick semi-liquid mass of dark colour, boiling at 80° and yielding the following fractions when subjected to distillation :—

At 150°. 10 3 per cent. oil. Sp. gr. 0·743.
150—310°. 43·3 per cent. burning oil. Sp. gr. 0·806.
Residue, 46·4 per cent.

2. Distilled in glass retorts by the aid of steam :—

	I.	II.
Tar................	41·4	41·8
Coke	43·5	45·0
Loss (gas and water)	15·6	13·2

The tar has a sp. gr. of 0·853, and yields by fractional distillation :—

At 150°. 7·1 per cent. of oil. Sp. gr. 0·743.
150—310°. 34·4 per cent. of burning oil. Sp. gr. 0·805.
Residue, 58·4 per cent.

3. Distilled in stills or retorts on a large scale :—

(a.) *Cast-iron Stills.*

	I.	II.
Tar................	33·0	34·5
Coke	47·0	45·0
Loss (water and gas)	20·0	20·5

Sp. gr. of the tar = 0·0838.

(b.) *Cast-iron Horizontal Retorts.*

Tar	28·66
Coke	46·09
Loss (gas and water)	25·25

Sp. gr. of the tar = 0·830.

The tar obtained by the distillation of the asphalte on a large scale was free from phenol and creosotic compounds. On treatment with 4 per cent. sulphuric acid (containing 95 per cent. H_2SO_4) at 60°, 94 per cent. of refined tar was obtained, this when rectified over 0·4 per cent. caustic soda in cast-iron stills yielded the following products:—

Light Oils 25·5 *per cent.*

Oil	2·0	2·4	2·4	2·4	2·4	2·4	11·5
Sp. gr.....	0·776	0·785	0·786	0·789	0·791	0·795	0·805

Medium Oils 21·8 *per cent.*

Oil	10·8	11·0
Sp. gr.......	0·822	0·834

Oil..	44·8	2·4	3·2	2·3
	Paraffin mass	Paraffin grease	Coke	Loss of gases

making 100 in all.

The paraffin was separated from the oil by cooling, filtering, and pressing. Obtained:—

9·91 per cent. crude paraffin, melting point 51°
90·09 per cent. oil, sp. gr. 0·864.

Hence, by subjecting Bentheim asphalte to distillation on a large scale, the following products are obtained:—

Burning oils	12·72
Gas and lubricating oils	9·78
Paraffin	1·50
Paraffin grease	0·65
Coke from retorts..............	46·09
Coke from tar	0·86
Pitch	1·52
Loss (gas and water)...........	26 88
	100 00

A series of carbonising trials, made with Bentheim asphalte, showed that the yield of gas obtained largely exceeded that of other kinds of gas-coal.

Engler has investigated Italian petroleum from Terra di Lavoro. The crude oil forms a dark brownish-black thick fluid, having an unpleasant smell. It has a sp. gr. of 0·970 at 21°, and gives by analysis:—

	I.	II.	III.	IV.
Carbon......	83·72	83·52	—	—
Hydrogen ..	10·71	10·88	—	—
Sulphur	—	—	1·08	1·30

Besides hydrocarbons, oxygenated resinous substances are present in large quantities, also sulphur compounds. Paraffin could not be detected, although by subjecting the crude oil to fractional distillation the higher boiling portions deposited small quantities of paraffin on cooling. It is doubtful, however, whether it has not been formed by distillation. Cumene, which has been detected in most kinds of petroleum (Pennsylvania, Galicia, Baku, Alsace), was found also in this variety. Phenols or creosote are absent. Owing to the high boiling point and high specific gravity, this oil cannot be used for burning purposes; it is, however, specially adapted for the manufacture of lubricating oils. The subjoined table gives the results of experiments on the quantity and properties of the gas obtainable from Italian petroleum :—

Investigator.	Sp. gr. of the petroleum.	Quantity of petroleum used in the trial.	Duration of the distillation in hours.	Gas for 1 kilo. of petroleum.	Petroleum required for the production of 24 cubic meters of gas = 100 candles per hour.
		kilos.		cub meters.	kilos.
P. Jacques, Turin....	0·975	10 50	2·00	0·439	9·11
	0·975	16·80	2·00	0·487	8·21
L. Ferrario, Rome....	0·975	11·00	1·55	0·431	9·27
	0·975	14·90	2·00	0·426	9·39
F. Scheuer, Lugano..	0·975	17·70	1·33	0·325	12·31
	0·925	15·90	1·32	0·384	10·40
Sulzer Bros., Winterthur	0·975	16 80	1·59	0·454	8·81
	0·925	13·20	2·00	0·560	7·13
Anonymous Society for water and gas installation, Vienna	0·975	30 00	2·00	0·456	8·77
	0·925	30·70	1·42	0·457	8·74
H. Hirzel, Leipzig....	0·975	14·70	1·39	0·421	9·50
	0·925	16·00	1·30	0·264	15·13

The oils of 0·925 sp. gr. are rectified, the remainder crude petroleum.

In conclusion, it is stated that although the boiling points of the various fractions obtained by the distillation of Italian petroleum and Bentheim asphalte correspond with one another, there is a marked difference in their respective specific gravities. For example, the fraction boiling below 290° has a sp. gr. of 0·882 in the case of the Italian oil, whilst the density of the corresponding fraction from the oils obtained from Bentheim asphalte, is below 0·880. Engler is of opinion that such wide differences in the density of the same boiling fractions of various mineral oils, have not been observed hitherto; this circumstance proves how variable the internal constitution of these hydrocarbons must be, although they may belong to the ethane or ethylene series. D. B.

New Bye-product from Coal Distillation. By G. E. Davis (*Chem. News*, 48, 229).—With regard to the distillation of coal, &c.

(comp. this vol., 224), attention is drawn in the present paper to the use of gas for heating and cooking purposes, and as it is generally acknowledged that for such purposes a luminous and smoky flame is not desirable, therefore, before being applied to this use, the gas may with advantage be deprived of illuminants. Now, in the author's opinion, all the published analyses, &c., of coal-gas, are misleading, valueless, and inaccurate, inasmuch as he finds, from experiments, that the chief illuminants of coal-gas are not ethylene, diethyl, &c., but the vapours of easily condensable hydrocarbons, beginning to boil at 18°, and containing many hydrocarbons, including naphthalene. These illuminants are easily absorbed by olive, rape, or even hydrocarbon oils; and the absorption can be made so complete that the gas after treatment burns with a flame of exceedingly feeble luminosity. Five gallons of condensed hydrocarbons of great technical value can be obtained from the gas yielded by one ton of coal; the author proposes to call them "crude benzol." The quality of the "crude benzol" depends greatly on the temperature, both within and outside the retorts, and therefore if their recovery is contemplated, heating operations must be conducted with greater care than is necessary in ordinary gas making. The presence of paraffins in the "crude benzol" is proved by the short yield of aniline obtained from them.

D. A. L.

Artichokes a Source of Spirit. (*Bied. Centr.*, 1883, 856.)—The spirit made from artichokes is somewhat cheaper than that from potatoes, and when potato disease is prevalent it is advantageous to employ this plant. E. W. P.

Evaporation of Alcohol from Wooden Vats. By A. SCHROBE (*Bied. Centr.*, 1883, 854).—During the first year the loss was 0·73 per cent. monthly, during the second year 0·42 per cent. monthly, in the third 0·42, in the fourth 0·31, in the fifth 0·31, and in the sixth, seventh, and eighth years 0·21 per cent. monthly. E. W. P.

Presence of Arsenic in Wines Free from Artificial Colouring-matter. By A. BARTHÉLEMY (*Compt. rend.*, **97**, 752).—Some wine sold in the department of Midi was found to contain a relatively considerable quantity of arsenic. This wine had been kept in old barrels, whilst the same wine stored in new barrels was free from arsenic. The arsenic was derived from sulphuric acid with which the old barrels had been repeatedly washed, and which, as sold in the neighbourhood of Toulouse, contains a large proportion of arsenic.

C. H. B.

Steeping of Barley. By F. ULLIK (*Bied. Centr.*, 1883, 639—641).—The author continues the experiments already noted (Abstr., 1882, 645 and 761), on this occasion to ascertain the effect of different quantities of water and frequent changes; the water had nearly the same composition as that previously used. He found that when the same quantity was used frequent changing had no appreciable influence, but that the employment of larger quantities extracts more matter from the barley, and more lime enters the grain. The potash dissolved is not greatly different, but soda, lime, magnesia, and phosphoric acid increase, as do organic matters, carbohydrates and nitrogen particularly. The use of water containing a small percentage of sodium chloride withdraws lime, and causes soda to enter into the grain. Further experiments convince the author that the condition of the barley itself has more effect on the substances withdrawn during steeping than the quantity or quality of the water, and that greater quantities of extract are to be had from old than from fresh barley. As the nitrogenous substances possess particular interest, the author made a steep of 600 grams barley, and found a total of 0·133 gram nitrogen, of which 0·112 gram remained in the residue from the phosphotungstic filtration. No peptones were traceable, and the bulk of nitrogenous matter was derived from amides. The author has begun experiments which show that steeping causes changes to occur which are intimately connected with the life and growth of the grain.

J. F.

Employment of Maize in Brewing. By J. F. Gent (*Bied. Centr.*, 1883, 853).—According to this patent, the corn is coarsely crushed between rollers and freed from husk and embryo, and then softened by steam, and finally pressed and dried between hot rollers. To brew from this, 65 parts are added to 35 parts of barley malt.

E. W. P.

Pasteurising Beer. By M. Schwarz (*Bied. Centr.*, 1883, 560).—According to Behrend, yeast cells are not killed by warming; the author, on the contrary, finds that at 55° all the cells are killed. Yeast killed at 55° placed in a food solution with addition of fresh malt-extract, did not show a single living cell after 40 hours at a temperature of 6—7°. Every single bottle of beer should be heated uniformly for a considerable time to the necessary temperature, say 2—3° over 55°. Badly pasteurised beer remains clear when kept cool, but the warmth of a room turns it turbid from formation of yeast, bacteria, fungi, albuminate, and some hop resin. The turbidity of well-pasteurised beer the author finds to be due to a separation of gluten; by heating such beer to 50° it will again become clear, and remain so for a long time.

J. T.

Behaviour of Tannin in Hops towards the Albuminoïds in Malt. By Moritz and Lee (*Bied. Centr.*, 1883, 854).—The tannin in hops precipitates as much again of the albuminoïds in malt as simple boiling does; but there is a sufficiency of these compounds in the malt to feed the hops after all the tannin has been precipitated.

E. W. P.

Separation of Sugar from Molasses or Syrup by Strontia or Lime at Low Temperatures. By C. Scheibler and others (*Bied. Centr.*, 1883, 637—639).—The author has taken out another patent relating to the strontia process, which is thus described. On boiling a mixture of sugar and strontia solution, the sparingly soluble distrontium saccharate is precipitated; this does not occur in the cold, but either pure strontium hydroxide or monostrontium saccharate crystallises, $C_{12}H_{22}O_{11}SrO + 5H_2O$, and the latter is sure to happen provided a certain quantity of the compound obtained from a previous operation is stirred into the mixture of molasses and strontia. The proportion yielding the best results is obtained by adding so much $Sr(HO)_2 + 8H_2O$ to the molasses as the latter contains sugar, the strontium hydroxide being previously dissolved in three times its weight of boiling water. The mixture remains clear while just under the temperature of boiling water, but on cooling, the monosaccharate separates in warty masses, which are dried by filter-presses or other means. The saccharate so obtained contains two-thirds or three-fourths of the whole sugar, and the remainder can be recovered as di-saccharate. The monosaccharate yields strontium carbonate and sugar when treated with carbonic anhydride. Another way of obtaining sugar from molasses in the cold is described by Walters, by the addition of sharply burnt lime, which first forms a soluble saccharate, but after a time becomes an insoluble compound—tetra-calcium saccharate. Much of the success of this process depends on the manner of burning the lime employed. Lippman says that if powdered calcium hydroxide be added to a solution already saturated with lime, at a moderate temperature, the sugar is precipitated in the cold as a tribasic lime salt with an excess of uncombined lime.

J. F.

Manufacture of Maize-starch as a New Branch of Agricultural Industry. By L. v. WAGNER (*Dingl. polyt. J.*, **250**, 173—182).—This paper discusses in detail the manufacture of maize-starch, and the recovery of the bye-products (proteïds) for feeding purposes. The process recently introduced by Gillitzer has the advantage that in the preparation of starch from maize the proteïds are recovered in an unaltered condition, the yield of starch and of proteïds recovered being almost theoretical. The starch is of the best quality. 100 parts of maize produce 52—60 parts starch, 8—15 parts proteïds (maize fibrin and gluten), and 12—18 parts husks, &c. The author shows that the cultivation of maize in conjunction with the manufacture of maize-starch is more remunerative than the cultivation of potatoes. The recovery of the bye-products pays for working costs, so that the difference in the price at which the maize is bought and that at which the resulting maize-starch is sold is profit.

D. B.

Researches by Witz on the Oxidation of Cellulose. By H. SCHMID (*Dingl. polyt. J.*, **250**, 271—280).—The methods for animalising vegetable tissues with a view to render them better able to receive colours in dyeing are based on the following reactions:—(1) nitration, (2) merceration, the result of the action of alkalis, and (3) hydration of the cellulose, caused by the action of acids.

Witz has introduced a new process, in which any substance capable of producing oxidation may be employed. By the action of oxidising agents in acid or neutral solutions, textile fabrics are so altered as to enable them to more readily receive dye-stuffs. The author discusses the investigations of Witz more minutely. He considers that Witz's reaction depends on the conversion of cellulose—a carbohydrate constituted like an alcohol—into a compound having acid properties, so that its power to attract basic dye-stuffs is analogous to the affinity which characterises benzoic acid, tannin, and other aromatic acids.

Its action would in point of fact consist in the precipitation of insoluble compounds of the complex amines of the rosaniline-group and similar colouring matters. The resulting lakes do not, however, adhere to the fibre as firmly as the corresponding tannin colours. As oxidising agents, Witz has employed the hypochlorites, also hypochlorous acid disengaged from the hypochlorites, chromates, hydrogen peroxide, ozone, and atmospheric oxygen. The goods may, moreover, be simply exposed to light. D. B.

Analysis of Malt-extract. By J. F. C. Junge (*Pharm. J. Trans.* [3], **14**, 104—108).—An extract of malt that is soluble in water, has a pleasant taste, and remains unfermented for a long time, is usually considered to be good, but as many worthless preparations have these characteristics their value cannot be ascertained from these alone. In the author's opinion, it should in addition be light in colour, contain but little free acid, and only a limited quantity of water; all the soluble constituents of the malt should be present, diastase being the most important, and the albuminoïds should be in an easily digestible form. The presence of a large proportion of phosphates or other ash constituents is no criterion of a good extract. The author's analytical examinations are based on these considerations. The *solid matter and water* are best determined by means of a maltometer, or by taking the sp. gr. at 17·5° of a solution of the extract in an equal weight of water, and referring to a table given in the paper. A good extract should not contain less than 50 per cent. of extracted matter, as in dilute extracts, some beers, for example, diastase cannot exist, and the preparations are often treated with salicylic acid in order to delay the decomposition of the dextrin; this may be detected by agitating the extract with ether, evaporating the ethereal extract, and testing for the salicylic acid with ferric chloride. For the *determination of free acid*, the author employs a solution of soda containing 5 grams of sodium hydroxide to a litre of water, and very sensitive litmus-papers for the indicator. 10 grams of a good extract ought not to require more than 6 or 7 c.c. of the soda solution; if it requires more than 10 c.c., that is more than 0·5 mm. of soda for 100 c.c. of extract, it will not retain its diastatic power for long. The *determination of diastase* is conducted in the following manner. Several clear and uniform 2-oz. vials are charged with 2 ozs. of distilled water and 2 drops of iodine solution containing 2 grams of iodine and 4 grams of potassium iodide dissolved in 250 c.c. of water. 10 grams of starch are stirred with 30 grams of water, then poured into 150 grams of boiling water, and stirred and boiled for some time; a good thermometer is now introduced, and the starch mucilage is cooled to and kept at 100° F. on a water-bath. 10 grams of malt-extract dissolved in 10 c.c. of water are stirred into the mucilage, the time being noted, and after one minute, or when the mucilage has become thin, two drops are transferred to one of the vials, which is shaken and placed near a window. This operation is repeated until no coloration, or scarcely any, is produced in the vials; the time occupied indicates the amount of diastase present. Various colorations produced with the iodine solution show the progress of the changes. 1. A greenish-blue coloration, and after standing the appearance of a blue precipitate indicates *undecomposed starch.* 2. A dark blue solution without a precipitate, *soluble starch.* 3. A purple solution shows that the *quantity of soluble starch equals that of the dextrin and sugar.* 4. A red colour points to the predominance of *dextrin or sugar*, according to depth, the redness increasing with the former. 5. No colour, or scarcely any colour, indicates completion of the change. This plan of procedure is adopted in the experiments with diastase described below. A good malt-extract will convert its own weight of starch at 62° F. within 40 minutes, at 100° F. within 10 minutes, and at 150° F. within 3 minutes, or it will convert five times its weight of starch in 40 minutes at 100° F., or eight times that amount in 90 minutes. Moreover, an extract of this strength will digest the following boiled amylaceous articles:—Potatoes, 4 parts in 3 minutes, 16 parts in 15 minutes; rice, 4 parts in 10 minutes; bread, 4 parts in 9 minutes, 16 parts in 45 minutes; sago, 4 parts in 12 minutes, 8 parts in 30 minutes. The *albuminoids* are determined by shaking in a tall graduated cylinder 80 parts of a cold saturated solution of picric acid with 20 parts of malt-extract until the extract is dissolved; the precipitate is allowed to settle, and after 24 hours its height is read off. Each division represents 1 per cent. by weight of nitrogenous matter dried at 212° F. The quantity ought to be on an average from 3 to 3·25 per cent. These determinations are sufficient to pronounce an extract good or worthless. The *dextrin, sugar,* and *glycerol* can be determined in the following manner:—2 to 5 grams of extract are mixed with 20 grams of dry clean sand, and then dried and weighed, the loss is *water.* The dried mixture is transferred to a percolating tube supported on a small wire stand; the whole is dried and weighed, then percolated with ether, and the residue is dried and weighed; the loss is the *resin.* Percolation of this residue with a mixture of 2 volumes of absolute alcohol and 3 volumes of ether removes the *glycerol,* whilst the *sugar* is removed by subsequent exhaustion with strong alcohol. Treatment with hot water dissolves away the *dextrin* from the albumin; and finally the latter may be destroyed by igniting the sand, which on cooling ought to weigh the same as it did at the beginning of the operation.

The author has made several experiments to study the action of acids, alkalis, and alcohol on diastase. The quantities employed in each experiment were 5 fluid ounces of starch-paste containing 100 grams of starch with 100 minims of saliva, or 100 minims of malt-extract dissolved in 100 minims of water. The malt-solution was prepared fresh every day from the same sample of malt-extract, and was tested to secure a uniformity of diastatic power; it had an acid reaction. The saliva was collected from a number of persons, adults and children, and was tested from time to time; it was always neutral. The starch-paste was heated to and kept at or about 100° F. on a water-bath, the reagent was added and mixed well in, and finally the malt-solution or saliva. The tests were made with the iodine solution as described above, and the observations recorded in the following manner:—

100 minims of	Per cent. reagent.	Colour 1. After minutes.	Colour 2. After minutes.	Colour 3. After minutes.	Colour 4. After minutes.	Nearly colourless. After minutes.	Remarks.
Extract of malt	—	—	—	1	2	7	Relative diastatic power of malt-extract and saliva.
Saliva	—	—	—	4	6	14	
Extract of malt and HCl	$\frac{1}{40}$	—	—	1	—	2	Diastatic power of both much increased.
Saliva with HCl	$\frac{1}{40}$	—	1	5	8	10	
Extract of malt with HCl	$\frac{1}{30}$	—	—	—	—	—	Diastatic power completely arrested.
Saliva with HCl	$\frac{1}{30}$	—	—	—	—	—	
Extract of malt + acetic acid	$\frac{1}{5}$	—	—	—	1	2	Power more than doubled.
Saliva and acetic acid	$\frac{1}{5}$	—	—	1	4	6	
Extract of malt and acetic	$\frac{2}{5}$	—	1	2	3	6	Good result with malt. Action of saliva arrested in 2 hours.
Saliva and acetic acid	$\frac{2}{5}$	60	120	—	—	—	
and so on.							

With a further increasing quantity of acetic acid, the power of malt-extract gradually decreases, until it is arrested when 1½ per cent. acid is exceeded. With lactic acid, $\frac{1}{20}$ per cent., the action of both malt-extract and saliva is much increased, especially in the case of saliva; with $\frac{1}{10}$ per cent., the malt increased, the saliva retarded; $\frac{1}{5}$ per cent. is favourable to malt, but fatal to saliva; and ½ per cent. lactic acid stops nearly all diastatic action of the malt-extract. $\frac{1}{10}$ per cent. of a mixture of 1 part hydrochloric acid, 2 parts lactic acid, and 8 parts acetic acid proves very favourable to the action of both malt and saliva, whilst $\frac{1}{5}$ per cent. of this mixture is favourable to the malt only. Leaving out the lactic acid in the mixture caused a diminution of diastatic action of both. $\frac{1}{20}$ per cent. of caustic soda totally destroys the action of saliva, whilst the malt is rendered inactive by $\frac{1}{10}$ per cent. Alkaline carbonates act less energetically.

Alcohol has only a slight influence on diastatic action, and its action is more marked with saliva or neutral malt-extract. The effect of wines and spirits on diastatic power seems to depend on the proportion the amount of acid present bears to the quantity of starch and malt-extract or saliva; so that when the proportion of acid is large and the quantity of starch and diastase small, the action is very sluggish or stops altogether. This is more evident in the case of saliva than with malt-extract. For example—

	Alcohol p.c.	Acid p.c.	Starch p.c.	Extract p.c.	Saliva p.c.	Colourless in minutes.
Extract of malt with wine	1·5	0·125	3·46	1·73	—	5
” ” ” ”	2·56	0·214	2·9	1·45	—	5
” ” ” ”	5·5	0·460	1·5	1·5	—	Colour 2. After 60 mins.
Saliva ” ” ”	1·5	0·125	3·46	—	3·46	45

Contribution to a Knowledge of Rye Grain. By E. EGGER (*Dingl. polyt. J.*, **249**, 425).—By subjecting the fruit of rye, which is generally of a greyish-brown colour, to close examination, the author detected shades varying from yellow to dark brown, whilst the grain in some instances exhibited a bluish-green coloration. Under the microscope, some of the gluten cells showed a dark blue colour. Dilute hydrochloric and sulphuric acids change the blue to red, and dilute solutions of alkalis give a yellow colour, which acids do not reconvert into red. By pulverising and sifting the grain, and treating the residual bran with alcohol acidified with hydrochloric acid, a pink extract is obtained. D. B.

Formation of Alcohol in the Fermentation of Bread. By V. MARCANO (*Compt. rend.*, **97**, 1070—1071).—A leaven, known in France as *levain de chef*, made by mixing potatoes, yams, &c., cooked by steam, with water and flour, yielded on distillation an amount of alcohol equivalent to 54·7 c.c. of absolute alcohol per kilogram of leaven. The solid residue consisted of cellulose with very little starch, and the liquid was saturated with dextrin.

A similar result is obtained on distilling bread paste just before it is put in the oven. These facts show that in the tropics the formation of alcohol at the expense of starch is a constant and regular phenomenon in the fermentation of bread. C. H. B.

Alteration of Flour. By BALLAND (*Compt. rend.*, **97**, 651—652).—Wheat contains a ferment which appears to exist in the neighbourhood of the embryo. This ferment has the properties of organised ferments, is insoluble, and withstands a temperature of 100° when dry, but is destroyed by boiling water. It is active only in presence of heat and moisture, a temperature of 25° being most favourable to its development. When the wheat is carefully ground, the greater part of the ferment is left in the bran, its proportion in the flour being smaller the more carefully the latter is dressed. If the grinding is too rapid or violent, a larger quantity of the ferment passes into the flour, hence the liability to alteration of flour which is said to be *échauffée*. This can be avoided by grinding with rollers.

The acidity of old flour is not the cause of the disappearance of gluten, but is the result of it. The gluten appears to exist as such in wheat in the same manner as starch, and is not a product of the action of water on a glutenogen. In stored flour, the gluten retains all its properties, but the action of the ferment is retarded by the absence of water. On adding water and warming, its activity is restored. The addition of oatmeal to army flour, although advantageous on account of its nutritive properties and cheapness, renders the flour much more liable to alteration. This might however be prevented by keeping the flour and oatmeal separate, and only mixing them when required for use. C. H. B.

Acceleration of the Oxidation of Drying Oils. By A. LIVACHE (*Compt. rend.*, **97**, 1311—1314).—When a drying oil, previously treated with litharge or finely divided metallic lead (Abstr., 1883,

p. 757), is agitated with a solution of zinc sulphate, all the lead is precipitated from the oil, but the latter now holds zinc in solution. By using manganese sulphate, copper sulphate, &c., in this way, every trace of lead is removed from the oil, but the lead is replaced by manganese, copper, &c. If an oil charged with lead will dry in 24 hours when spread out in a thin layer on glass, it will dry completely in five or six hours if charged with manganese, in 30 to 36 hours with copper, zinc, or cobalt, and in more than 48 hours with nickel, iron, chromium, &c.

It is more convenient to use the solid finely powdered salt in place of a solution, since the latter forms an emulsion with the oil. In fact, treatment with metallic lead and a solid sulphate may take place simultaneously, but in this case the oil will contain some lead in addition to the other metal.

Although solidification of a drying oil charged with manganese takes place in five or six hours when spread out in thin layers, the solidification of thick layers requires a long time, even though the protecting pellicle which forms on the surface is continually removed. Oxidation is more rapid at a higher temperature, but with thick layers a long time is required for complete solidification, even under these conditions.

A temperature of 50—60° accelerates the oxidation of drying oil, partly because the oil becomes more fluid, and partly because the oxygen is more active at a higher temperature.

When a manganiferous oil is dissolved in an equal volume of benzene, and agitated with air in a closed vessel, rapid absorption of oxygen takes place, especially at a temperature of 40—50°. If the air is continually renewed, so as to furnish the oxygen required for the maximum oxidation of the oil, the liquid becomes thick, and on distilling and separating the solvent a liquid is obtained which solidifies on cooling to a very dry and perfectly elastic solid. It is evident that by limiting the oxidation a series of products of varying viscosity can be obtained intermediate between the original oil and the solid formed by maximum oxidation. The last product is characterised by its remarkable elasticity, and its absolute insolubility in water, alcohol, and ether. It is almost instantly saponified by potash in the cold, and on subsequent separation of the fatty acids it is found that the solid fatty acids have undergone no alteration, whilst the liquid fatty acid has almost completely disappeared, and has been converted into viscous products, characterised by their solubility in water and by the various salts which they form.

C. H. B.

American Milk. By E. H. Jenkins (*Bied. Centr.*, 1883, 528—530).—The author gives the following milk analyses:—

	Jersey cows.			Guernsey cows.			Average of six cows.
	From six cows, Jersey.	From five cows, Ayrshire.	From six cows, native.	1.	2.	3.	
Water.......	85·28	87·15	86·43	85·02	82·85	84·82	85·20
Solid residue .	14·72	12·85	13·57	14·98	17·15	15·18	14·80
Casein.......	3 67	3·20	3·34	4·22	4 51	4·00	4·08
Fat	5·21	4·33	4·49	5·00	6·62	5·06	5·23
Sugar	4·93	4·60	4·82	4·47	4·57	4·69	4·50
Ash.........	0·91	0·72	0·92	1·29	1·45	1·43	1·17
Daily yield...	21 lb. 3 oz.	21 lb. 4 oz	22 lb. 9 oz	—	—	—	—
Density......	—	—	—	1·0326	1·034	1·0353	—

The author has made over 200 analyses of milk collected from various herds; the average amount of solid residue was 12·40 per cent., with a minimum of 9·8 and a maximum of 14·4; and the average amount of fat was 4 02 per cent. with a minimum of 2·6 and a maximum of 5·6. Only one sample contained less than 10 per cent. of solid residue; five samples between 10 and 10·5 per cent.; six samples between 10·5 and 11 per cent.; 19 between 11 and 11·5; 27 between 11·5 and 12; and 150 samples over 12 per cent. The author is not quite certain that all the samples were unadulterated, and thinks the one with 9 8 total solids must have been. The author holds that milk with a sp. gr. less than 1·029 must be adulterated.

J. T.

Utilisation of Skim-milk. By B. FOLKERS (*Bied. Centr.*, 1883, 566).—Practical experiments extending over several years have been made by the author near Jever. Fattening calves did not pay, but for pigs the results were economically satisfactory. J. T.

Butter-making. By W. FLEISCHMANN and BLUNCK-SCHILKOWITZ (*Bied. Centr.*, 1883, 554—557).—Milk requiring to be transported before being skimmed for butter-making, gives a better yield of butter when gently agitated from time to time during cooling, before being placed in transport vessels.

Fleischmann finds that butter made without churn in a kneading machine from very thick cream, has the composition 83—86 per cent. fat, 10—16 per cent. water, 0·2 to 0·8 per cent. protein. The thick cream was produced in a Petersen's machine, and such cream can well be made into butter by kneading. The minimum amount of proteïn, 0·224 per cent., was found in a sample of butter made from cream that had been passed a second time through the machine along with water.

J. T.

Preserved Butter. By W. FLEISCHMANN (*Bied. Centr.*, 1883, 557—559).—Such butter should have 4—5 per cent. salt; more does not help to preserve it, spoils the taste, and adds unnecessarily to the weight. Analyses of 16 samples gave 8·34—13·71 per cent. water, 82·91—87·11 butter fat; 0·44—0·79 proteïn; 0·36—0·87 soluble nitrogen-free matter: 1·08—6·13 ash and common salt. The author remarks that the state of the proteïn and nitrogen-free organic matter is of more importance than the amount; for if the proteïn be already in a state of decomposition owing to defective preparation, the butter will not keep, even if little be present. The author finds that sour cream makes as good preserved butter as sweet cream, although this has been denied. J. T.

Insoluble Fatty Acid in Goat's Butter. By C. Jehn (*Arch. Pharm.* [3], **21**, 262).—A fatty acid insoluble in water was isolated from goat's butter in the following way:—5 grams of the pure butter fat were saponified with 2 grams of potassium hydroxide and 50 c.c. of alcohol, the solution was evaporated to a syrup, diluted with 100 c.c. of water, and decomposed with hydrochloric acid. The fatty acid was washed with boiling water and dried. The butter fat contained about 87 per cent. of this acid. Goat's butter and cow's butter are thus shown to yield the same quantity of insoluble fatty acids.

W. R. D.

Blumenthal's Prepared Rennet. By Schmöger (*Bied. Centr.*, 1883, 852).—This preparation is sold in the solid or liquid form; the solid contains 0·87 per cent. of water, 96·01 ash (principally NaCl, and 3·12 per cent. of organic matter, of which 1·06 is albuminoïd). At 35°, this solid, when dissolved, curdles about 80,000 parts of milk, whilst the liquid preparation curdles 8,600 at 35°, and contains 1·83 per cent. organic matter and 13·48 per cent. of ash.

E. W. P.

"Rennet" Ferment from the Seeds of Withania Coagulans. By A. S. Lea (*Chem. News*, **48**, 261—262).—It was noticed that both the fruit and aqueous extract of the seed capsules of *Withania coagulans* coagulated milk. This discovery is of great importance, as the introduction of the cheese-making industry into India depends on finding a vegetable substitute for the ordinary animal rennet, since the natives will not purchase cheese made with the latter. The author has experimented on this vegetable "rennet." The seeds were separated from extraneous matter, the cases, stalks, soil, &c., by crushing and sifting. Then equal weights of the seeds were extracted for 24 hours with equal volumes of water, 5 per cent. sodium chloride solution, 2 per cent. hydrochloric acid, and 3 per cent. sodium carbonate solution, respectively. Equal volumes of each of these extracts in an acid, alkaline, or neutral condition, were added to equal volumes of milk, and heated to 38°. The milk coagulated rapidly with sodium chloride and carbonate extracts, but much more slowly with the other two. Subsequent experiments show that the 5 per cent. salt solution extract is the most active. The ferment is also soluble in glycerol, and closely resembles animal rennet. The ferment is destroyed by boiling, by filtering the solution through animal charcoal, or by treating it with finely powdered kaolin. Alcohol precipitates the ferment from its solutions, but the precipitate, when redissolved, still retains its coagulating properties. A very small quantity of ferment suffices to coagulate milk, large quantities simply hasten the change. If neutral or alkaline ferment solutions are added to neutral milk, a normal clot is formed, with neutral or faintly alkaline reaction, thus showing that the coagulation is not due to the formation of acid by the ferment. The curd is not a mere precipitate, but a true clot, resembling in appearance and properties that formed by animal rennet. All the extracts of the seeds are deep brown in colour, which, however, is unimportant, as the colouring matter remains chiefly in the whey, the curd being white. Extracts may be made up to contain 15 per cent. salt, and these may be treated with 4 per cent of alcohol without apparently impairing the coagulating activity to any appreciable extent, in fact such a preparation corresponds very closely in activity with the commercial solution of animal rennet; it is therefore probable that extracts of this vegetable "rennet" will be prepared for keeping, but how long these will remain active time alone can show. The ferment has been tried in cheese-making, and, from the results, it would seem that the seeds of Withania can be used successfully as a substitute for animal rennet.

D. A. L.

Cheese from Skim-milk and Foreign Fat. By X. A. WILLARD and others (*Bied. Centr.*, 1883, 552).—The well-skimmed milk, according to Willard, is intimately mixed at 54° with $1\frac{1}{2}$ per cent. lard at the same temperature in a mixing machine; the so-called *lard-cream* is thus formed, which is then made into cheese with rennet. Such cheese is largely produced near Little Falls, U S.A.

Griffiths gives analyses of such American cheese purchased in London, as follows:—

	I.	II.	III.	IV.
Water	23·49	28·20	26·55	31·81
Caseïn	36·21	37·01	35·58	36·10
Fat	34·92	30·18	33·85	28·68
Ash	5·24	4·51	3·90	3·40
	99·86	99·90	99·88	99·99

A little arsenic was found in the rind of I and IV, possibly added to keep off insects! Starch was not found.

It is said that olive-oil, and even cotton-seed oil, is largely used instead of lard in several American establishments. J. T.

New Coal-tar Dyes. (*Dingl. polyt. J.*, **249**, 350—355, and 383—389.)—The firm, late Meister, Lucius, and Brüning (Ger. pat., 22,545, 2nd Sept., 1882) obtain a yellow dye, consisting of dinitronaphtholmonosulphonic acid by the simultaneous action of nitrates and nitrites in acid solution on naphthylaminetrisulphonic acid. It is advantageous to prepare the α-naphthylaminetrisulphonic acid by first converting the naphthylamine into the monosulphonic form, and then further sulphonating by treatment with fuming sulphuric acid and neutralising with milk of lime, by which the calcium salt is obtained. Naphthylamine, treated with fuming sulphuric only, gives small quantities of the trisulphonic compound.

The firm, late Brönner of Frankfort-on-the-Main (Ger. pat., 22,547, July 5, 1882), convert the β-naphtholmonosulphonic acid into two new β-naphthylaminesulphonic acids for the preparation of dyes. The monosulphonic acid is produced by Schäffer's method (*Annalen*, **152**, 296). The ammonia salt of this acid is treated under pressure at 180° with calcium hydroxide, or calcined soda and water: the resulting mass is dissolved in hot water and acidified, when the β-naphthylaminemonosulphonic acid separates out. The ammonium salt may be replaced by the corresponding sodium salt, which gives good results when heated with soda and ammonium chloride. An easily soluble β-acid remains in the mother-liquor which is obtained by neutralising with soda, evaporating to dryness, and boiling with alcohol; the acid separates out from the acidified alcoholic solution on cooling. The β-naphthylaminemonosulphonic acid thus obtained dissolves less easily in alcohol than the easily soluble sulphonic acid obtained from β-naphthylamine and fuming sulphuric acid. The diazo-compounds of the first give, with α-naphtholmonosulphonic acid, a beautiful reddish-blue dye; the corresponding compounds of the second acid give a blood-red dye, strongly tending to brown. By combining the diazo-compounds of both acids with phenol, hydroxyphenols, and naphthols, their ethers and sulphonic acids, a new series of beautiful dyes are obtained.

W. Harmsen (Ger. pat., 22,707, Sept. 9, 1882) describes a new method for the preparation of yellow, orange, and red dyes, by mixing diazotised bases with aromatic hydroxy-acids and a β-hydroxynaphtholsulphonic acid. The hydroxy-acids, when mixed with equal molecular weights of diazotised bases, yield dyes whose colours deepen from yellow to red with increase in the carbon present. The carboxyl-group of the hydroxy-acids remains unchanged in the new compounds, so that they still act as acids, decomposing carbonates and even forming salts. The new dyes, which by constitution are hydroxyazocarboxylic acids, dissolve in alcohol, giving bright colours, whilst their alkali salts are soluble in water, and give fast colours on wool as well as on silk. To prepare the dyes, equal molecular weights of diazotised bases and of the sodium salt of an aromatic hydroxy-acid are mixed and rendered alkaline with soda, and the filtered solution is treated with common salt to precipitate the dye in a flocculent form. As the sodium salt of the dye derived from naphthylamine is only slightly soluble in water, it is converted into the sulphonic compound by treating the dry free acid with sulphuric acid, sp. gr. 1·8 at 160°, and the deep blue solution is poured into water, whereon the sulphonic acid separates out. This is dissolved in soda-lye, and treated with common salt, when the sodium salt separates out. This compound is more soluble than the salt directly prepared from the hydroxy-acid, and also possesses stronger dyeing power. The other dyes can be similarly treated by using fuming sulphuric acid instead of the ordinary acid.

Brown Dyes from Chrysoïdine and Diazo-compounds.—The Aniline Manufacturing Company of Berlin (Ger. pat., No. 22,714, November 8, 1882) remark that when diazotised sulphanilic acid or other diazotised amido-acids are used instead of diazobenzene chloride for the preparation of chrysoïdine from metaphenylenediamine, chrysoïdinsulphonic acids, chrysoïdincarboxylic acid, &c., are obtained whose alkali salts are soluble in water. The chrysoïdine and the derived acids just mentioned now take a second molecule of a diazotised base or amido-acid, and yield dyes of the type of phenylenediaminediazobenzene, $(C_6H_5.N_2)_2.C_6H_2(NH_2)_2$, by which the yellow to yellowish-red colour of the chrysoïdine becomes brownish. Usually the dyes prepared from the basic chrysoïdines and diazo-compounds are insoluble in water, but soluble in alcohol. To render these dyes soluble, they are converted into sulphonic acids, and salts of these acids are employed; or the chrysoidine may be acted on with the salt of a diazo-compound or a diazotised amido-acid, or the chrysoidine itself can be treated with a diazoted amido-acid.

E. Nölting and E. v. Salis (Ger. pat., No. 22,268, August 31st, 1882) describe new yellow, orange, and brown dyes obtained from the sulphonic acids of nitrated secondary and tertiary aromatic amines which contain two aromatic and one fatty radical. They are obtained by sulphonating the corresponding nitramine, or by the action of aromatic halogen nitro-compounds on aromatic amido-sulphonic acids. Halogen-compounds in which the nitro-groups hold the ortho- or para-position with reference to the halogen, but the meta-position with reference to each other, act readily on amines; whilst under the action of hydrochloric acid, a secondary or tertiary nitramine is formed. The nitramines so obtained are dyes which as yet have not found practical application owing to their slight solubility and other unfavourable qualities; they, however, yield useful dyes if converted into sulphonic acids.

The aromatic halogen nitro-compounds further act on the sulphonic and carboxyl-derivatives of the amines and yield soluble dyes.

The following dyes appear to be of importance technically:—Trinitrodiphenylaminesulphonic acid, which, as well as its salts, form yellow crystals, soluble in water, especially if hot, and dyes silk and wool yellow directly in an acid bath. Tetranitronaphthylphenylsulphonic acid, which is very similar to the foregoing in its properties, but gives a yellowish-brown dye. Lastly the compounds obtained by acting with picryl chloride, chlorodinitrobenzene, and chlorotetranitronaphthalene on amidazomonosulphonic acid, amidazodisulphonic acid, and phenylamidazobenzenesulphonic acid. Orange and brown dyes are thus obtained, which in acid bath dye wool and silk directly.

Safranine Dyes.—R. Nietzki has investigated this series of dyes (Abstr., 1883, 731). Witt proposes a method of preparation (*Jour. Chem. Ind.*, 1882, 255) by oxidising a mixture of 1 mol. paraphenylenediamine with 2 mols. aniline, by which the first member of this series of dyes is obtained.

Phenosafranine, first obtained by Witt, is prepared by the oxidation of 2 mols. aniline with 1 mol. paraphenylenediamine or of equal molecular weights of aniline and paradiamidodiphenylamine. This dye is not very different in tint from its homologues the safranines of commerce, but is characterised by the great facility with which its salts crystallise out. The chloride forms cantharides-green needles, slightly soluble in cold water, easily soluble in hot, and having the composition $C_{18}H_{16}N_4,HCl$. The sulphate forms long steel-blue needles. *Diethylsafranine* is obtained by oxidising in the presence of 2 mols. aniline, diethylparaphenylenediamine prepared from nitrosodiethylaniline. This dye has a magenta-red colour, its chloride crystallises in beautiful glittering green needles. The platinochloride forms green needles also, which, dried at 100°, have the composition $2C_{18}H_{14}N_4Et_2,H_2PtCl_6$. If a mixture of 1 mol. paraphenylendiamine with 1 mol. diethylaniline and 1 mol. aniline be similarly oxidised, a compound is obtained isomeric with and very similar to the above. Although both these compounds give green sulphates, they do not afford green diazo-compounds. *Tetrethylsafranine* is obtained by oxidising a mixture of equal molecular weights of diethylparaphenylenediamine, diethylaniline, and aniline; this dye has a much more violet tint than the foregoing. It forms a very soluble chloride, and a less easily soluble double chloride with zinc, which crystallises beautifully. The dye is not sufficiently permanent when exposed to light. Bindschedler describes the preparation of *dimethylphenylene-green*, $2C_{16}H_{19}N_3,HCl,ZnCl_2$, also *tetramethylphenylene-safranine;* its nitrate, $C_{22}H_{22}N_4,HNO_3 + H_2O$, is brownish-violet, and easily crystallisable; also *dimethylphenylene-safranine*, a magenta-red dye, $C_{20}H_{18}N_4$, and analogous compounds.

All the safranines are decolorised by reducing agents. Pure phenylene-safranine, $C_{18}H_{14}N_4$, reduced with ferrous ammonium sulphate in an atmosphere of hydrogen, was found to take up 4 atoms of hydrogen in passing to the leucophenylene-safranine. The safranines may be represented by the general formula $C_nH_{2n-22}N_4$.

J. T.

Fixation of Aniline Dye-stuffs by means of Metallic Sulphides. (*Dingl. polyt. J.*, **250**, 183.)—Balanche was the first who utilised certain metallic sulphides as mordants for aniline dyes. The sulphides of zinc and tin, when deposited on cotton, attract magenta, aniline-violet, Bismark-brown, &c., on dyeing. Lüssy has recently experimented with antimony sulphide, and finds that in the dye-bath it absorbs methylene-blue, malachite-green, rosaniline-red, and similar colouring matters. The sulphide process is suitable only for dyeing purposes: the goods are treated with a metallic salt, and then with a soluble sulphide or with a soluble sulpho-salt, and the sulphide is precipitated by an acid. The dyeing is the third operation. In order to apply the sulphide process to steam colours, Schmid recommends the thiosulphate method. Metallic salts, the sulphides of which can be precipitated by means of sodium thiosulphate, are mixed with the latter and the dye-stuff. The mixture is thickened and printed on the fabric. On steaming, the insoluble sulphide is deposited with the dye. Thus it is possible to fix methylene-blue, malachite-green, dimethylaniline-violet, &c., in one operation on the fibre by the aid of the sulphides of cadmium, copper, lead, &c. The resulting colours resist soaping extremely well. D. B.

Extracting by Diffusion. By A. ZWERGEL (*Dingl. polyt. J.*, **249**, 307—310).—The author strongly recommends Kohlrausch's method of extracting by employing a battery of diffusers, having employed it for the extraction of log-wood dye. The advantages over the old method are said to be (*a*) the liquid to be evaporated is reduced by one-half; (*b*) the raw material is more thoroughly exhausted; (*c*) the quality of the extract is essentially improved; (*d*) the work is simplified and its cost reduced. J. T.

Preparation of Aluminium Acetate. By J. ATHENSTADT (*Dingl. polyt. J.*, **250**, 91).—The author separates two-thirds basic aluminium acetate, $Al_2(\overline{Ac}O)_4(OH)_2$, in an amorphous soluble form from concentrated solutions by adding a sufficient amount of sodium sulphate at 30—35°, and stirring the mixture. When freshly prepared, the acetate is perfectly soluble in water and suitable for dyeing. By treatment with lime, a dry mass is obtained which yields a solution of aluminium acetate with separation of gypsum when treated with dilute sulphuric acid. D. B.

Aluminium Thiocyanate Free from Iron. By G. STEIN (*Dingl. polyt. J.*, **250**, 36).—Stork and Strobel having introduced aluminium thiocyanate as a substitute for the acetate for alizarin steam colours, it is important in purchasing this article to ascertain whether iron is present or not. Commercial samples of aluminium thiocyanate are invariably contaminated with a greater or less proportion of iron which is contained in the materials used for its preparation. The dissolved iron is mostly present in the form of ferric thiocyanate, which ether dissolves with a red colour. It is possible to extract all the iron from aluminium thiocyanate by means of this solvent; as, however, ether is miscible with the thiocyanate, it is necessary to expel it from the extract as rapidly as possible, otherwise sulphur will be separated.

Aluminium thiocyanate is said to produce fuller and redder steam colours when free from iron. Thiocyanates containing iron exhibit streaky colours having a bluer tint. D. B.

Explosives. By BERTHELOT (*Compt. rend.*, **97**, 771—772).—A summary of the contents of the author's new work, "Sur la force des matières explosives, d'après la Thermochimie." C. H. B.

Liquid Extract of Senega. By H. J. ROSE (*Pharm. J. Trans.* [3], **14**, 169).—This extract has a great tendency to gelatinise and form a precipitate. The author has remedied the evil by using a mixture of alcohol (7 parts), spirit of nitrous ether (2 parts), and water (7 parts), as a menstruum for extraction, and proceeding as directed in the United States Pharmacopœia. D. A. L.

General and Physical Chemistry.

A New Copper Oxide Cell. By F. DE LALANDE and G. CHAPERON (*Bull. Soc. Chim.* [2], **40**, 173—176).—A very useful cell, especially for chemical laboratories, can be made by placing a sheet-iron box containing oxide of copper at the bottom of a glass jar. A plate formed by a spiral of thick zinc wire is suspended from the lid of the jar at some distance above the iron box, and the jar is filled with a 30 or 40 per cent. solution of potash. The positive pole is formed by a copper wire coated with caoutchouc passing through the lid of the jar and attached to the iron box. Other forms of this battery may be constructed by taking advantage of the fact that a paste of copper oxide and magnesium oxychloride hardens to a porous solid mass.

W. C. W.

Electrolysis. By SCHUCHT (*Zeitschr. Anal. Chem.*, **22**, 485—495).—The author has investigated the separation of a number of metals from their solutions electrolytically. Luckow (Abstr., 1880, 282) has shown that lead is separated from solution, preferably a nitric acid one, as peroxide, or this mixed with hydrated peroxide. It is only from strongly acid solutions that the whole of the lead separates as peroxide; from feebly acid and concentrated solutions the peroxide is mixed with a large proportion of metallic lead. The separated peroxide was found to contain more water when precipitated from a feeble acid solution than from a strongly acid one, the presence of much free alkali also increases the proportion of water. Solutions of thallium resemble those of lead, the metal being separated either entirely as sesquioxide, or mixed with a small proportion of metal, according to the quantity of free acid present. The thallium is separated from alkaline solutions partly as sesquioxide and partly in the metallic state. Silver is precipitated, in the absence of nitrates or free nitric acid, as metal only, whilst, in the presence of the above, a small proportion of silver peroxide, Ag_2O_2, is formed. Solutions of bismuth are decomposed by the current into metal and bismuthic acid, the latter appearing only gradually at the positive pole, whilst the peroxides of the former metals are formed from the commencement of the current. In the electrolysis of ammoniacal solutions of nickel and cobalt, the sesquioxide appears at the positive pole, but its separation is prevented by excess of ammonia; the largest proportion of sesquioxide obtained by the author amounted to 3—3·5 per cent. of the amount of precipitated metal. Manganese is the only metal which is separated exclusively as peroxide from its solutions. The presence of organic acids, ferrous salts, and salts of chromium or ammonium, prevent the formation of the peroxide and the red coloration due to permanganic acid. Selenium and tellurium are readily precipitated by the current, both from acid and alkaline solutions. P. F. F.

Electrolysis of Sodium Chloride. By L. NAUDIN and A. BIDET (*Bull. Soc. Chim.*, **40**, 2—14).—With a view of recovering the chlorine from bleaching liquors the authors have made a study of the electrolysis of sodium chloride with two Daniell's elements coupled for intensity. Four separate factors are to be considered:—1st, the hypochlorous acid; 2nd, the gaseous chlorine dissolved; 3rd, the gaseous chlorine disengaged, constituting the active chlorine; and 4th, the inactive chlorine remaining in combination with the sodium. It was observed that the chlorine disengaged was a function of the time of electrolysis. From the experiments, an empirical equation, $\frac{y^2}{x} = k = 333$, is deduced, in which y is the chlorine disengaged, and x the number of days, *i.e.*, the curve is parabolic. The curves representing the formation of the hypochlorous acid and the dissolved chlorine are in opposite directions, as the former is produced at the expense of the latter. If the ions liberated at the two poles be separated from one another, no hypochlorous acid is formed; after a few days the dissolved chlorine remains constant, while the disengaged chlorine steadily increases; at the end of eighteen days, however, the active chlorine was only about 6 in 273 parts of total chlorine.

V. H. V.

Electrolysis of Chlorates. By LIDOFF and TICHOMIROFF (*Bull. Soc. Chim.*, **39**, 508).—The decomposition of the chlorates by the electric current is never complete when carbon poles are used; these diminish in weight, being attacked by the liberated ozone or oxygen, and converted into mellogen as described by Bartoli and Papasogli.

V. H. V.

Decomposition of Carbon-compounds by the Silent Discharge. By MAQUENNE (*Bull. Soc. Chim.*, **40**, 60—65).—In this paper a study is given of the decomposition of a few organic substances under various pressures by the silent discharge, and the gases obtained as to their composition are compared with those formed in the decomposition of the same substances at a dull or bright red heat.

All the substances investigated, except benzene, were rapidly decomposed into carbonic oxide and anhydride, hydrogen, and hydrocarbons: the results are appended below.

Methyl Alcohol.

	Decomposition by the silent discharge.		Decomposition by heat.	
Pressure of gas.	3—4 mm.	100 mm.	Dull red heat.	Bright rod heat.
CO	24·3	19·6	23·0	31·7
CO_2	—	—	1·5	0·5
C_2H_4 and C_2H_2	4·3	0·9	9·4	3·8
CH_4	5·1	36·7	34·4	18·3
H_2..........	20·4	42·8	31·7	54·7

There were also produced non-volatile resinous products, which escaped analysis, and were dissolved in the excess of the alcohol.

Ethyl Alcohol.

	Decomposition by the silent discharge.		Decomposition by heat.	
Pressure of gas.	2 mm.	100 mm.	Dull red heat.	Bright red heat.
CO_2	2·2	0·5	0·5	0·5
CO	11·0	14·7	22·1	26·4
C_2H_4 and C_2H_2	14·0	1·1	23·5	13·7
C_2H_6	30·1	21·6	13·8	13·6
H_2	42·6	62·1	40·1	45·8

Acetic Acid.

Decomposition by the silent discharge.		
Pressure of gas.	2 mm.	100 mm.
CO_2	20·7	9·6
CO	33·9	44·2
C_2H_4 and C_2H_2	2·4	0·3
CH_4	38·5	11·5
H_2	4·5	34·4

The first products of the reaction are probably carbonic anhydride and methane, which subsequently act on one another to form carbonic oxide and hydrogen.

Acetone.

	Decomposition by the silent discharge.		Decomposition by heat.	
Pressure of gas.	50 mm.	100 mm.	Dull red heat.	Bright red heat.
CO_2	1·1	0·6	1·2	0·6
CO	40·0	42·1	39·5	36·0
C_2H_4	3·5	2·9	7·0	3·3
C_2H_6	29·7	30·0	22·4	21·8
H_2	25·7	24·4	22·9	38·3

Methyl formate was selected in order to compare the results of its decomposition with those of its isomeride acetic acid.

	Decomposition by heat.	
Decomposition by the silent discharge.	Red heat.	Bright red heat.
CO_2	3·2	2·3
CO	61·8	56·0
C_2H_4	1·3	0·5
CH_4	5·8	5·5
H_2	28·7	35·7

From these results it is evident that the decomposition effected by the silent discharge and by heat are strictly comparable.

V. H. V.

Boulier's Pyrometer. By C. LAUTH (*Bull. Soc. Chim.*, **40**, 108—110).—Hitherto all attempts to construct a pyrometer for estimating very high temperatures, such as those attained in the porcelain manufacture, have been unsuccessful; for this purpose Boulier has constructed a pyrometer consisting of a thin copper cylinder several centimeters in length; one end is closed, the other terminates in two tubes, one of which is connected with a reservoir of water, the other is joined to a thermometer. In order to make an observation, the thin copper tube is introduced in the furnace whose temperature is to be ascertained, and a current of water allowed to circulate from the reservoir. The water in the cylinder is heated by contact with the hot air or flame, and the rise of temperature marked by the thermometer at the exit. In order to ensure the regular circulation of the water, an electric balance is introduced into the copper vessel, which, at the least interruption, stops the water flow. At present this apparatus has only been used for relative and not for absolute differences of temperature. V. H. V.

Thermochemical Study of Hydrofluoric Acid. By GUNTZ (*Bull. Soc. Chim.*, 40, 54—57).—In this memoir, are given the determinations of the heats of solution in water of gaseous and liquid hydrofluoric acid of various degrees of concentration.

The heat of solution of the gaseous acid was found for one equivalent—

$$\text{HF (gas)} + H_2O \text{ (liq.)} = \text{HF (dissolved)} = +11{\cdot}8$$

$$\text{but HF (liq.)} + H_2O \text{ (liq.)} = \text{HF (dissolved)} = 4{\cdot}56$$

The heat of volatilisation of hydrofluoric acid is the difference between these values $= 11{\cdot}8 - 4{\cdot}56 = 7{\cdot}22$.

In order to determine the heat of dilution of hydrofluoric acid. a certain quantity of solution containing a known quantity of the anhydrous acid was added to 400 equivalents of water. The results are appended below—

	Heat disengaged.
HF anhydrous added to 400 H_2O	4·56
HF + 5H_2O	2·05
HF + 1·67 H_2O	0·72
HF + 2·25	0·45
HF + 6·5	0·1

These results can be represented by the empirical equations, Q = heat of dilution—

$$\text{For } n = 5 \text{ to } n = 2 \ldots\ldots\ldots \quad Q = \frac{1{\cdot}3}{0{\cdot}13 + n} \text{ (I).}$$

$$\text{,, } n = 2 \text{ to } n = 10 \ldots\ldots \quad Q = \frac{1{\cdot}3}{0{\cdot}13 + n} - 0{\cdot}1 \text{ (II).}$$

Equation (I) is that of a hyperbola asymptotic to the axis of the abscissa and parallel to the axis of the ordinates; equation (II) is also that of a similar hyperbola, the ordinates of which are diminished by 0·1. These results seem to indicate the existence of a definite hydrate, $HF,2H_2O$, and thus confirm the conclusions of Bineau, who obtained a hydrate of this composition on the distillation of the aqueous acid.

It is further noticeable that the dilution of the acid containing more than 2 mols. H_2O does not produce a sensible evolution of heat; in this point, hydrofluoric differs from hydrochloric, hydrobromic, and hydriodic acids. V. H. V.

Heat of Formation of Fluorides. By GUNTZ (*Compt. rend.*, **97**, 1483—1486).—*Ammonium Fluoride.*—NH_3 diss. + HF diss. = NH_4F diss., develops + 15·2 cal. Taking Favre's value for the heat of solution of ammonium fluoride, it follows that NH_3, gas, + HF, gas, = NH_4F, solid, develops + 37·3 cal., and NH_3, gas, + HF, liquid = NH_4F, solid, develops 30·1 cal. These values are somewhat lower than the corresponding values for potassium, as is the case with other acids.

Barium Salt.—BaO diss. + 2HF diss. = BaF_2 diss., develops + 34·8 cal., and BaH_2O_2, solid, + 2HF, gas, = BaF_2, solid, + $2H_2O$, solid, develops + 71·4 cal. This value is affected by the solubility of the fluoride, and is somewhat too low.

Strontium Salt.—SrO diss. + 2HF diss. = SrF_2 diss., develops + 35·8 cal., and SrH_2O_2, solid, + 2HF, gas, = SrF_2, solid, + $2H_2O$, solid, develops + 71·8 cal. This value is affected by the partial solubility of the fluoride, but not to such a great extent as in the case of barium.

Calcium Salt.—CaO, diss. + 2HF, diss. = CaF_2, solid, develops + 37·2 cal., and CaH_2O_2, solid, + 2HF, gas, = CaF_2, solid, + H_2O, solid, develops + 66·6 cal.

A comparison of the heats of formation of the fluorides, chlorides, and sulphates of the alkalis and alkaline earths, shows that in the case of sodium, potassium, and ammonium, the heat of formation of the fluoride is less than that of the chloride; in the case of barium, the difference is much smaller, whilst in the case of strontium and calcium the heat of formation of the fluoride is greater than that of the chloride. The heats of formation of sodium, ammonium, potassium, and barium sulphates, are greater than those of the corresponding fluorides; in the case of strontium, the difference is very small, and in the case of calcium the heat of formation of the fluoride is slightly greater than that of the sulphate. C. H. B.

Heat of Formation of Fluorides. By D. TOMMASI (*Compt. rend.*, **98**, 44—45).—The heats of formation of the alkaline fluorides recently determined by Guntz agree very closely with the values calculated by the author's law of thermochemical constants. This agreement, however, does not obtain in the case of calcium, barium, and strontium fluorides, a result due to the fact that these compounds are insoluble in water, whilst the author's law applies only to soluble substances. C. H. B.

Heat of Formation of Fluorides. By BERTHELOT (*Compt. rend.*, **98**, 61—63).—A criticism of Tommasi's claim to the law of thermochemical constants. C. H. B.

Sodium Fluorides. By Guntz (*Compt. rend.*, **97**, 1558—1560). —The heat of formation of these compounds is deduced from their heats of solution and neutralisation. The heat of solution of NaF is 0·6 cal. at 12°, and that of $NaHF_2$ is −6·2 cal. Combining these data with Thomsen's values for the heats of neutralisation, it follows that—

NaHO solid + HF gas = NaF solid + H_2O solid.................................. develops + 39·9 cal.
NaF solid + HF gas = $NaHF_2$ solid ...... „ + 17·1 cal.

These values are somewhat lower than the corresponding values for potassium, and the heat of formation of sodium fluoride is lower than that of the chloride and sulphate, as in the case of the corresponding potassium compounds. On the other hand, the heat of formation of sodium hydrogen fluoride is greater than that of sodium hydrogen sulphate, although the difference is not so great as with the potassium salts.
C. H. B.

Heat of Formation of Alcoholates. By De Forcrand (*Bull. Soc. Chim.* [2], **40**, 177—183).—Three alcoholates of sodium can be prepared by the action of metallic sodium on alcohol and distilling the product in a vacuum. $C_2H_5.NaO,3EtHO$, is obtained in colourless needles if the reaction takes place at the ordinary temperature, but if the alcohol is heated at 70° the product has the composition $C_2H_5.NaO,2EtHO$; $C_2H_5.NaO$ may be prepared by heating either of the preceding compounds at 200° in a current of hydrogen. These compounds are easily decomposed by moisture and by oxidation. They generally contain one-thirteenth of an equivalent of sodium hydroxide.

The heat of solution in water of each of these compounds is respectively + 13·47, + 10·46, and + 12·34. From these numbers the heat of formation of $C_2H_5.NaO$ may be calculated to be + 17·35, starting from Na_2O or + 0·25 from NaHO, when O = 8.

$$C_2H_5.HO + Na = C_2H_5.NaO + H = +\,32{\cdot}13$$
$$\text{and } 4(C_2H_5.HO) + Na = C_2H_5.NaO,3EtHO + H = +\,40{\cdot}77.$$

The heat of formation of NaHO by the action of Na on H_2O is + 33·3.

The heat of solution of $C_2H_5.NaO$ in a large excess of alcohol is + 12·56.

Barium alcoholate generally contains one-tenth to one-fifth of an equivalent of baryta.

The heat of formation for the compound by the action of an equivalent of alcohol on an equivalent of barium monoxide is + 7·24, and on the hydroxide = − 0·84.

A small quantity of water added to the alcoholic solution of barium ethylate throws down a precipitate of barium hydroxide.
W. C. W.

Heats of Combustion of Ketones and Carbonic Ethers. By W. Louguinine (*Compt. rend.*, **98**, 94—97).

	Per 1 gram.	Per gram-molecule.
Diethyl ketone	8569·0 cal.	736,934 cal.
Dipropyl ketone	9244·5 „	1,053,873 „
Diisopropyl ketone........	9172·4 „	1,045,654 „
Methyl hexyl ketone	9467·1 „	1,211,789 „
Dimethyl carbonate	3774·34 „	339,691 „
Diethyl carbonate	5442·8 „	642,250 „

The difference between the heats of combustion of the isomerides dipropyl ketone and diisopropyl ketone is only 0·8 per cent. of the total value, a difference within the error of experiment. This affords further confirmation of the law that isomerides of the same chemical function develop approximately the same quantities of heat on combustion.

The difference between the heats of combustion of diethyl ketone and dipropyl ketone is 316,939 cal. for $2CH_2$, or 158,470 for CH_2. In the case of dipropyl ketone and methyl hexyl ketone, the difference is 157,916 cal. for CH_2. These values are similar to those obtained in other homologous series.

In the case of the two carbonates, the difference for CH_2 is 151,280 cal. for CH_2, or slightly less than in other homologous series.

On comparing the heats of combustion of dimethyl carbonate and dimethyl ketone, which differ only by O_2, it is found that the introduction of these two atoms of oxygen into the molecule diminishes the heat of combustion by 84,310 cal., or 42,155 cal. for each atom of oxygen. A similar comparison between diethyl carbonate and diethyl ketone gives a difference of 47,342 cal. for each atom of oxygen. The difference between these two values for the influence of oxygen is not much greater than the error of experiment. C. H. B.

Glycollide. By De Forcrand (*Bull. Soc. Chim.* [2], **40**, 57—60).—Various methods have been prepared for the preparation of glycollide: (I) distillation of tartaric acid (Dessaignes); (II) distillation of glycollic acid (Heintz); (III) heating hydrated sodium monochloracetate (Kekulé). But in all these processes water is eliminated simultaneously with the formation of glycollide; as those substances tend slowly to reunite, there is established a final equilibrium between the glycollide formed and the glycollic acid reproduced; the yield is thus materially diminished. Further, the final product is contaminated with substances of composition intermediate between glycollic acid and glycollide. The most practical method of preparing glycollide consists in heating dry sodium monochloracetate.

From the following data, the heat of hydration of glycollide can be calculated:—

Heat of neutralisation of glycollic acid by soda	= + 13·6
Heat of solution of solid glycollic acid................	− 2·76
Heat of transformation of glycollide to sodium glycollate	+ 11·96

Therefore

$$C_2H_2O_2 \text{ (solid)} + H_2O \text{ (liquid)} = C_2H_4O_3 \text{ (solid)} = +\ 1{\cdot}12$$

and

$$C_2H_2O_2 \text{ (solid)} + H_2O \text{ (solid)} = C_2H_4O_3 \text{ (solid)} = -\ 0{\cdot}31$$

Thus the reaction with liquid water is exothermic although the heat evolved is very small; these results are in accordance with the transformation of glycollide into glycollic acid.

Glycollide is thus the thermic analogue of lactide, but stands in marked contrast with such anhydrides as sulphuric; whilst on the other hand, Berthelot's experiments tend to show that the conversion of dissolved carbonic anhydride into carbonic acid would be an endothermic reaction. V. H. V.

Disodium Glycollate. By De Forcrand (*Bull. Soc. Chim.*, **40**, 104—106).—In the course of a study of the heat of formation of different salts of glycollic acid, it was observed that the addition of excess of soda to neutral sodium glycollate caused an appreciable development of heat, which varied with the degree of dilution of the liquid.

In order to isolate the disodium glycollate, the existence of which was suspected from the above phenomenon, a syrupy solution of caustic soda was added to a supersaturated solution of sodium glycollate, and the resultant liquid evaporated in a vacuum; very deliquescent small needles of a salt $C_7H_2O_3Na_2,2H_2O$ separated out. Its heat of formation can be expressed by the equation $2NaHO$ (sol.) + $C_2H_4O_3$ (sol.) = $C_2H_2Na_2O_32H_2O$ (sol.) = + 31·42, or if the anhydrous salts be formed, $2NaHO$ (sol.) + $C_2H_4O_3$ (sol.) = $C_2H_2Na_2O_3$ (sol.) + $2H_2O$ (sol.) = + 24·76. V. H. V.

Crystallisation of Substances at High Pressures. By E. Jannettaz, Neel, and Clermont (*Bull. Soc. Chim.* [2], **40**, 51—54).—Spring has recently succeeded in transforming pulverulent amorphous substances into crystalline masses by means of a pressure of 5000 atmospheres. These experiments have been repeated by Friedel with a different form of machine, but with negative results. This paper deals with some further experiments in this direction, especially as regards the relation of the propagation of heat in substances, and their structure, whether natural or artificial. The following substances were subjected to pressures of 6000—8000 atmospheres:—

Metals. Finely powdered tin, copper, lead, zinc, and iron; antimony and bismuth; Darcel's alloy.

Sulphides of lead and zinc.

Chlorides of sodium, lead, and mercury.

Precipitated magnesia and alumina.

Pulverised silica, chalk.

All these substances were agglutinated into solid masses, but displayed no signs of crystalline, but of schistose form.

The experiments of Sorby, Tyndall, and Daubrée have established that clays take a schistose form when subjected to pressure, and the cleavage plane is perpendicular to the direction of the pressure. One of the authors has also proved that the plane of propagation of heat is identical with that of cleavage. On examining the metallic masses obtained by compression, it was found that they possessed the thermic property characteristic of a schistose structure.

V. H. V.

Crystallisation of Substances under Pressure. By W. SPRING (*Ber.*, **16**, 2833—2835).—A reply to Jannettaz, Neel, and Clermont (preceding Abstract).

Dissociation. By ISAMBERT (*Compt. rend.*, **98**, 97—100).—The author applies Berthelot's general formula of dissociation to cases in which a gas is produced, and introduces a term representing the mechanical work effected. He deduces various relations between the temperatures, specific heats, and maximum tensions, and shows that they are in agreement with his observations on the dissociation of ammonium dihydrosulphide and ammonium carbonate.

C. H. B.

Combustion of Explosive Gaseous Mixtures. By MALLARD and LE CHATELIER (*Bull. Soc. Chim.*, **39**, 572—581).—A continuation of the author's researches.

The irregularity of the velocities of propagation cause determinations of mean velocities between any two given points to be but of a secondary interest; for the mean value varies not only between two successive, but also between the same points in different experiments. By means of a photographic method, the velocities of propagation of explosion of mixtures of carbon bisulphide with oxygen or nitric oxide have been studied. These observations show that there are several distinct phases or periods of propagation.

(I.) *Uniform Movement.*—The flame advances regularly and uniformly.

(II.) *Vibratory Movement.*—The flame advances in oscillations whose amplitude and duration vary very rapidly.

(III.) *Wave of Explosion.*—It is projected suddenly towards the end of the tube.

(IV.) *Extinction.*—In certain cases, the flame is suddenly extinguished, and all combustion ceases.

1st Phase. The velocity of this uniform movement is very constant in different experiments with tubes of the same diameter, but of different lengths; with tubes of different diameters, the velocity diminishes with decrease of diameter. The following may be stated as a general result: on first ignition of an explosive mixture the combustion is propagated with a uniform velocity less than 30 metres per second.

2nd Phase. The further progression of the flame is marked with oscillatory movement. This phase is always noticeable in slow burning mixtures such as carbon bisulphide and nitric oxide; it is not so distinct with more explosive mixtures. The duration of successive vibratory movements varies from 0·025 to 0·0034 second; they stand to one another in a simple arithmetical progression. Their amplitude is greater the longer the period of the vibration; in some cases it was found to be enormous. The brilliancy of the flame varies during the successive phases of the same vibration; in the recoil, it is less than in the advance. The mechanism of this vibratory movement is analogous to that of musical flames.

3rd Phase. The explosive wave has been minutely studied by Berthelot and Vieille; the mixtures of carbon bisulphide with oxygen and nitric oxide displayed this phenomenon, but its mode of production varied in the two cases; with the former, it developed itself very rapidly, succeeding almost immediately the phase of uniform movement; with the latter, it succeeds the period of long vibration.

4th Phase. With mixtures of carbon bisulphide and nitric oxide in tubes of 0·1 in. diameter, the amplitude of the flame oscillations increases very rapidly, then the combustion ceases. This result is analogous to that obtained by Schützenberger in his study of the combustion of limited mixtures of hydrogen and oxygen, when he observed an extinction of combustion at one of the nodes of vibration of the eudiometric tube, *i.e.*, the point of the greatest oscillation of the flame.

In conclusion. a general summary of the various observed phenomena is given, with especial reference to the explosive wave. If the hypothesis of Berthelot and Vieille be correct, then its course of propagation can be explained; for the ignition of the first section of gas tends to increase its volume, and to produce an immediate compression of the sections in front, followed by a recoil. This alternating compression and recoil travels from section to section with the velocity of sound; they tend temporarily to increase or decrease the temperature of each successive section, but the increase is not sufficient to ignite the inflammable mixture, nor the decrease sufficient to extinguish it, if ignited. V. H. V.

Prout's Hypothesis. By M. Gerber (*Bull. Soc. Chim.*, **39**, 562—572).—Prout's hypothesis, supported by a considerable weight of evidence, and by *à priori* probability, is admitted generally in principle, although the value of the fundamental unit is quite unknown. If the elements be divided into four classes, characterised by their dominant atomicity, there is for each class a common factor, integer multiples of which include all the sufficiently known atomic weights. These common factors are in simple relation to one another. The table below contains the four factors—

	O = 15·96.	O = 16.
$d_1 = \frac{10}{13}H$	0·7673	0·7692
$d_2 = 2H$..........	1·995	2·0
$d_3 = \frac{5}{16}(\frac{5}{4}{}^{2})H$	1·5586	1·5625
$d_4 = \frac{5}{4}H$..........	1·247	1·25

In the original memoir, the atomic weights from Clarke's calculations are compared with the values calculated from the integer multiples of these several factors.

In the course of discussion the simplicity of the multiples of these factors is noticed in certain groups of elements such as O, S, Fe, or Li, K, Rb, but a complexity in other groups as Cl, Br, I.

In some cases an element can equally be classed in two of the four divisions, for the terms of the progression nd_4 coincide frequently with those of the progression nd_3, as, for example, $4d_3$—$5d_4$; zinc or mercury can be classed similarly in the second or fourth division.

Further, the stoichometrical determinations will decide whether these relations are merely fortuitous or whether they form a part of a wider generalisation. V. H. V.

Relation between Molecular Weight and Velocity of Evaporation of Liquids. By C. SCHALL (*Ber.*, **16**, 3011—3014).—If equal volumes of benzene and water are distilled consecutively in the same apparatus, and with as nearly as possible equal rates of ebullition, different amounts by weight of the two liquids distil over in a given time. The amount of benzene in a rough experiment was about double the amount of water. In a more exact trial, the liquids were heated in their respective vapours, and the lengths of time required for the evaporation of equal volumes was observed. These observations were reduced by means of the sp. gr. of the liquids at their boiling points to equal weights, and the time of evaporation then calculated. The values obtained for two comparable substances are nearly inversely proportional to their molecular weight. If m and m' are the molecular weights, and t and t' the time of evaporation for each, then $m : m' = t' : t$ and $m = m'\frac{t'}{t}$. Thus he obtained—

Benzene.		Chloroform.	
Boiling point........	79·2°	Boiling point.......	61·5°
Sp. gr...............	0·8136	Sp. gr.............	1·4048

Length of Time of Evaporation of Equal Volumes.

	Benzene.	Chloroform.	Calculated for equal weight of benzene.
I...........	12·7 min.	14·3 min.	8·25 min.
II...........	12·95 „	14·5 „	8·4 „
III...........	12·3 „	14·0 „	8·28 „

By means of the above formula he obtains for the molecular weight of chloroform: I, 119·64; II, 120·25; III, 115·88.

The author also finds that the ratio of the volumes of liquids distilled in equal time is equal to the ratio of their atomic volume at the boiling point. The ratio of benzene to chloroform in experiment I is 1·126 : 1, and taking the atomic volume of benzene at 95·94, that calculated for chloroform in this way is 85·2, whilst Schiff found 84·65. The author has obtained equally good results with benzene and carbon bisulphide, but less satisfactory with other liquids. With some compounds of equal molecular weights, such as amyl alcohol and ethyl acetate, he obtained equal lengths of time of evaporation for equal weights of substances. He intends continuing his work on this subject.

In comparing the latent heat of vaporisation of liquids in relation to their molecular weight, it has been found in seven compounds that the former decreases as the latter increases.

	Latent heat of vaporisation.	Mol. wt.
Water	536·67	18
Alcohol..............	214·3	46
Acetone..	129·72	58
Ethyl acetate	90·7	74
Carbon bisulphide	83·7	76
Chloroform	61·0	119
Carbon tetrachloride ..	46·5	154

Also that certain substances may be grouped, from the fact that the products of the latent heat of vaporisation into the molecular weight gives a number nearly constant for members of a group. Thus water and alcohol form a group; and acetone, chloroform, and carbon tetrachloride, a second. A. B.

Lecture Experiments. By V. MEYER (*Ber.*, 16, 2998—3001).—For the purpose of showing *the action of light on an explosive mixture of chlorine and hydrogen*, the author fills jars 25 cm. high and 35 mm. wide with the mixture, and closes them with paper covers; one is left colourless and others coloured violet and yellow by means of spirit varnish and aniline colours. On igniting a large quantity of magnesium-dust in a Bunsen burner, the gas in the colourless and violet jars instantly explodes, but that in the yellow jar does not, and may be fired with a burning chip. A fourth colourless jar may be kept to show *photochemical induction*, for whilst with sufficient magnesium-dust the explosion takes place instantly, on exposing the mixture to burning magnesium wire, several seconds elapse before the gases combine.

Preparation of Chlorine Monoxide, Cl_2O.—This gas can be prepared by passing a regular stream of dry chlorine over commercial yellow mercuric oxide (previously heated for some time at about 400°) in a horizontal glass tube, ½ m. long, cooled in ice. The chlorine monoxide which is formed is collected by displacement in a vertical narrow cylinder, and can be exploded by throwing in flowers of sulphur or with a light, or if collected in a strong test-tube and closed with an india-rubber stopper by heating the bottom of the tube. The explosion although accompanied with development of light and formation of smoke, is not dangerous.

The author, with the aid of a drawing, describes a form of funnel which he uses for protecting liquids from dust, during evaporation on the water-bath. The rim of the inverted funnel is turned in so as to form a circular trough, in which the condensed vapours are collected. By this means the water-bath and the floor of the draught cupboard are protected from acid and other droppings. A. B.

Inorganic Chemistry.

Ebullition of Liquid Oxygen and Solidification of Nitrogen. By S. WROBLEWSKI (*Compt. rend.*, **97**, 1553—1555).—When oxygen, liquefied by means of the apparatus previously described, is allowed to evaporate rapidly by sudden removal of the pressure, it does not solidify like carbonic anhydride, but a white crystalline residue is deposited on the bottom of the apparatus. This residue disappears as the temperature rises, but whether it is solid oxygen or is due to some impurity in the oxygen (which was made from potassium chlorate and manganese dioxide) has not been determined.

Determinations by a thermoelectric method indicate that the temperature produced by the rapid ebullition of oxygen under these conditions is about —186°. Nitrogen gas cooled at this temperature and then allowed to expand forms a snow-like mass of crystals of considerable size.

Hydrogen compressed under about 150 atmos. at −136° and then allowed to expand suddenly, shows no signs of liquefaction.

C. H. B.

Density of Liquid Oxygen. By MENGES (*Compt. rend.*, **98**. 103—104).—Wroblewski's method of determining the density of liquid oxygen is not satisfactory, because it is assumed that the quantity remaining gaseous is proportional to the total amount of the gas, which is improbable.

If the tube of a Cailletet apparatus is partly immersed in a cold liquid whilst the remainder of the tube is surrounded by a liquid at the ordinary temperature, then—

$$Q = vd + Vx,$$

where v is the volume of the liquid portion, V that of the gaseous portion, d the density of the liquid, and Q the total weight. If another experiment is made with a shorter length of the same tube in the cold liquid, matters being so arranged that the volume of the liquefied gas is the same as in the first experiment, then—

$$Q = v_1d + Vx + V_1d_1,$$

where $V + V_1$ is the total volume of the gaseous part, v_1 the volume of the liquid, and d_1 the density of the gas in that part of the tube near the mercury. The pressure and the temperature of this part of the tube being known, the value of d_1 can be calculated, and the two equations yield the expression—

$$d = \frac{V_1d_1}{v-v_1}.$$

C. H. B.

Duration of the Solidification of Superfused Sulphur. By D. GERNEZ (*Compt. rend.*, **97**, 1477—1480; see also this vol., 389).—In the course of the experiments described in former papers, the author observed the formation of crystals of sulphur, the time of solidification of which, whatever its absolute value, is always intermediate between that of the octohedral and that of the prismatic variety. These crystals are long prisms with a nacreous lustre, and, instead of increasing equally in all three directions, as in the case of the prisms and octohedra, they increase far more rapidly in the direction of the longitudinal axis than in the direction of the transverse axes. In order to produce all three varieties under the same conditions, a graduated U-tube is filled with superfused sulphur and the formation of octohedra is started in one limb. As soon as the surface of the sulphur in this limb has become solid, a glass thread or platinum wire is passed down the other limb to the bend of the tube, and is *gently* tapped against the walls of the tube. The formation of the nacreous prisms begins from the points which have been struck, and proceeds more rapidly than the growth of the octohedra. After a short time, a crystal of prismatic sulphur is dropped into the second limb, and the formation of prisms at once begins and proceeds very rapidly, eventually extending round the bend into the limb in which the octohedra were first formed. If the wire is struck too forcibly against the sides of the tube, the formation of the ordinary prisms ensues. The nacreous prisms are obtained by a *slight* cooling at any point in superfused sulphur; if dropped into a tube of the superfused substance, they give rise exclusively to similar crystals, which devitrify somewhat rapidly when cooled to the ordinary temperature, but which can be broken in the liquid without changing their form.

Observations on the formation of these nacreous crystals similar to those made with the other two varieties, show that their time of solidification is very short when the temperature of superfusion is very low, but gradually increases as this temperature approaches the melting point of the sulphur. The time of solidification depends on the time during which the sulphur was heated above the melting point, and also on the time during which it has remained in a superfused condition. When heated to different initial temperatures, the nacreous crystals behave like the other two varieties; the time of solidification increases very considerably if the sulphur has been heated up to about 170°, but diminishes if the initial temperature has been much higher. These results were obtained with sulphur which had not previously been fused. Experiments with sulphur which had been converted into the nacreous prisms several times, or which had been previously solidified in octohedra or in prisms, confirm the author's conclusions as to the instability of ordinary prismatic sulphur and the influence of time on the modifications which the sulphur is capable of undergoing. C. H. B.

Time of Existence of Thiosulphuric Acid in Aqueous Solution. By H. LANDOLT (*Ber.*, 16, 2958—2967).—The method of observation was to mix solutions of sodium thiosulphate and an acid such as oxalic acid at the same temperature, and by means of a stop watch to note the time which elapsed before the appearance of the sulphur precipitate. The author found that with a solution which remained unaltered for 30 seconds, his error of observation did not exceed 1·5 seconds, and usually was a fraction of a second. He also found that different organic or inorganic acids; an excess of sodium thiosulphate or of acid in the same quantity of water; or the gross quantity of solution used, made no difference in the time of existence. The difference in time depends on the relative quantity of water to thiosulphuric acid formed, and on the temperature of the solutions. As the result of many observations, he finds that the time increases exactly in proportion to the dilution of the solutions at constant temperature, or in other words to the number of parts by weight of water to one part by weight of thiosulphuric acid formed; and that the higher the temperature the more rapid the decomposition. The accelerating influence of heat, however, diminishes as the temperature is raised, and this diminution of the time of existence for a difference in temperature, of say 10°, is more observable the greater the proportion of water by weight to thiosulphuric acid. An equation has been evolved to give the time of existence (E) for any temperature (t) between 10° and 50°, and for any solution in which the parts by weight of water (n) to one part by weight of thiosulphuric acid are between 51 and 279; and the results of 40 tabulated observations are in accordance with it:—

$$E_1 = n(0\cdot6428 - 0\cdot02553t + 0\cdot000272t^2).$$

Neither light nor electricity have any influence on the decomposition, but alcohol increases the time of existence very materially, 50 per cent. of alcohol in place of 50 per cent. of water prolonging in one case the time of existence from 64 seconds to 510 seconds.

Sulphur Salts derived from Phosphorus Trisulphide. By G. Lemoine (*Compt. rend.*, **98**, 45—48).—When an excess of phosphorus trisulphide is allowed to act on a very dilute solution of sodium hydroxide at 0°, and the solution is evaporated in a vacuum, hydrogen sulphide is given off, and acid sodium phosphite is alone obtained. If, however, the sodium hydroxide is in excess, and the filtered liquid is evaporated in a vacuum over sulphuric acid and phosphoric anhydride, in about five months it deposits quadratic prisms of the composition $Na_2S,5H_2O$. After another month, the compound $P_2O_3,2Na_2S,5H_2O$ or $P_2OS_2,2Na_2O,5H_2O$ separates out; its solution gives an orange-yellow precipitate with lead acetate. After four months a third compound, $P_2OS_2,3Na_2O,4H_2O$, separates. Its solution gives a slightly yellowish-white precipitate with lead acetate. Another different preparation gave a salt of the composition $P_2O_3,3Na_2O,3H_2S,3H_2O$. The substance $P_2OS_2,3Na_2O,4H_2O$ is interesting because it represents a sulphur derivative of phosphorous acid in which all three atoms of hydrogen have been replaced by a base.

When an excess of phosphorus trisulphide is gradually added in small portions to ammonium hydrosulphide, cooled at 0°, and the liquid allowed to stand about 15 days, white crystals of ammonium phosphite, $2(NH_4)_2HPO_3 + H_2O$, separate out mixed with small quantities of a sulphur compound. If the mother-liquor is evaporated in a vacuum, hydrogen sulphide is given off in large quantities.

and after about 28 weeks the compound, $P_2OS_3,2(NH_4)_2O,3H_2O$, is deposited. Its solution gives an orange-yellow precipitate with lead acetate. If this salt is dissolved in water, and the solution evaporated in a vacuum, the compound, $P_2O_2S,2(NH_4)_2O,6H_2O$, separates out. It is evident from this fact that these salts lose hydrogen sulphide very easily. This last compound may be regarded as derived from monothiophosphorous acid, P_2O_2S,nH_2O, whilst the others are derived from dithiophosphorous acid P_2OS_2,nH_2O. C. H. B.

Maximum Solubility of Sodium Sulphate. By E. Pauchon (*Compt. rend.*, **97**, 1555—1556).—The heat of solution of a salt in water can be calculated by means of an equation given by Kirchoff, and in this way it can be shown that the heat of solution of sodium sulphate is at first negative, but changes its sign above 33°. It follows therefore that the crystallisation of the salt below 33° ought to develop heat, and heat should be absorbed at higher temperatures; and this supposition agrees with the facts. It is well known that the salt is hydrated if crystallised below 33°, but anhydrous if crystallised at a higher temperature. Berthelot has shown that in the latter case the heat of solution is negative at low temperatures, and the author finds that it is still negative at 50°. C. H. B.

Action of Bromine and Iodide on Silver Chloride, Bromide, and Iodide. By P. Julius (*Zeitschr. Anal. Chem.*, **22**, 523—525).—On passing a current of air saturated with bromine-vapour over silver iodide contained in a porcelain boat and heated to fusion in a piece of combustion tubing, the whole of the iodide is converted into silver bromide in 10 minutes. On substituting silver chloride for the iodide, the whole of the chloride is converted into silver bromide in 1—2 hours' time. If a current of air saturated with iodine-vapour is passed over fused silver chloride or bromide, these are wholly converted into silver iodide, the change requiring 6—10 hours with the former and 3—4 hours with the latter. P. F. F.

Decomposition of the Acid Phosphates of the Alkaline Earths in Presence of Water. By A. Joly (*Compt. rend.*, **97**, 1480—1483).—When a dilute solution of phosphoric acid is mixed with an equivalent quantity of a solution of calcium or barium hydroxide, so that the liquid contains equal equivalents of acid and base, the solution is acid to litmus but neutral to "helianthine." Solutions as dilute as those furnished by lime-water and baryta-water remain neutral when saturation is complete, but if the sides of the vessel are rubbed with a glass rod, or if the liquid is heated to about 80° hydrated dicalcium phosphate is precipitated and phosphoric acid is liberated, the liquid becoming acid to helianthine. In presence of water, the monobasic phosphate first formed is partially decomposed by mechanical disturbance or by elevation of temperature into dibasic phosphate and free phosphoric acid, whilst the remainder of the monobasic phosphate remains in solution. Similar decomposition is produced if a fragment of dibasic phosphate is dropped into the original solution. The proportion of dibasic phosphate precipitated depends on the dilution of the solution, and increases with the concentration until, when the latter passes a certain point, a neutral liquid cannot be obtained because the dibasic phosphate is at once precipitated.

When pure calcium carbonate is dissolved in an excess of phosphoric acid and the liquid evaporated in a vacuum, the monobasic phosphate is obtained in transparent rhomboïdal lamellæ which have the composition $CaH_4P_2O_8 + H_2O$, and do not alter on exposure to air: in contact with water at the ordinary temperature these crystals decompose and yield a crystalline precipitate of the composition $CaHPO_4 + 2H_2O$. When the same weight of water is allowed to act for some time on increasing quantities of the monobasic phosphate, the amount of phosphoric acid liberated continually increases, and the ratio, R, between the total phosphoric acid and that remaining in combination when decomposition has ceased varies from 1 to 1·5. Beyond the latter limit, any further quantity of the monobasic phosphate dissolves in the acid liquid without decomposition, and the ratio diminishes slightly. On the other hand, if one of the more concentrated solutions containing precipitated bibasic phosphate is diluted with water, the precipitate partly redissolves and R diminishes, and in very dilute solutions tends to unity. A solution containing a given percentage of phosphoric acid can dissolve a certain maximum weight of the monobasic phosphate without decomposition, but if this limit is exceeded decomposition takes place and dibasic phosphate is precipitated. If a dilute solution of this kind is concentrated by evaporation in a vacuum, the ratio R increases, dibasic phosphate is precipitated, and by slow evaporation can be obtained in beautiful crystals. When R reaches its maximum value, 1·5, the monobasic phosphate is in turn deposited and the proportion of free acid in the liquid increases.

If a small quantity of any substance capable of combining with phosphoric acid to form a soluble or insoluble compound (*e.g.*, soda, potash, alkaline acetates, ferric oxide, &c.) is added to one of the acid solutions obtained by the decomposition of monocalcium phosphate in presence of water, equilibrium is destroyed and dibasic calcium phosphate is precipitated.

It is evident from these facts that the decomposition of monobasic calcium phosphate by water is not analogous to the decomposition of antimony and bismuth compounds by the same liquid.

C. H. B.

Cerite and the Extraction of Cerium, Lanthanum, and Didymium therefrom. By A. Arche (*Monatsh. Chem.*, 4, 913—925).—Two samples from Trommsdorff were analysed. The analyses add up to 104·26 and 103·29; this is due to the method employed for the decomposition of the mineral, viz., fusion with sodium and potassium carbonate: the silica so obtained when treated with hydrofluoric acid left a residue containing cerium, lanthanum, and didymium. If the mineral be decomposed by sulphuric acid, then the silica obtained is pure.

After allowing for the small quantities of copper, bismuth, molybdenum, and sulphur, as also carbonic anhydride and the corresponding amount of lime, the author expresses the composition by the formula

$(Ce,La,Di)_6Si_5O_{19}.2H_2O$. After discussing the several methods proposed to decompose cerite, the following is mentioned as giving the best results. The substance is obtained as an impalpable powder by grinding and washing. The dried cerite powder is well stirred into half its weight of strong sulphuric acid, the mass thickens, heats, and gives off fumes of sulphuric acid. After cooling it is easily crushed, and is then added with constant stirring to 12 or 20 times its weight of ice-cold water. The solution obtained is worked up according to Bunsen's method; the residue, which may contain undecomposed mineral as well as silica, may be again treated with sulphuric acid.

H. B.

Preparation of Bismuth Free from Arsenic. Atomic Weight of Bismuth. By J. Löwe (*Zeitschr. Anal. Chem.*, 22, 498—505).—The author has already pointed out (Abstr., 1272, 329) that bismuth hydroxide, precipitated from a nitric acid solution by means of caustic potash or soda, dissolves in an excess of these reagents in the presence of glycerol. From this solution the whole of the bismuth is precipitated in a finely divided metallic state on adding a sufficient quantity of grape-sugar and boiling. Iron and nickel if present do not dissolve in the alkaline glycerol, whilst arsenic does. The sugar should be added in the cold, so that any silver or copper may be precipitated as metal or suboxide respectively, and filtered off, whilst the bismuth is not separated until the solution is boiled. In this manner bismuth may be obtained perfectly free from arsenic. The author has determined the atomic weight of bismuth by taking a known weight of the metal so prepared, dissolving it in nitric acid, converting the nitrate into oxide by ignition, and then weighing. Taking the atomic weight of oxygen to be 15·96, the author finds that of bismuth to be 207·330, whilst if oxygen = 16, it is 207·845. The previous determinations of the atomic weight of bismuth have been:—

Dumas	210·27
Schneider	207·995
Lothar Meyer and Seubert........	206·9—208·2

P. F. F.

Pure Chromic Sulphate. By H. Baubigny (*Compt. rend.*, 98, 100—103).—An aqueous solution of carefully purified potassium dichromate is saturated with hydrogen sulphide, and then heated to boiling. The chromium is completely precipitated as hydroxide, and the solution contains potassium sulphate, thiosulphate, and polysulphide, to the latter of which it owes its yellow colour. The precipitate is carefully washed first with cold and afterwards with hot water, and then consists of chromic hydroxide free from alkalis, and containing only traces of oxysulphur compounds, which have no injurious effect. It is dissolved in the least possible quantity of nitric acid, and the solution heated in order to form the violet salt. A slight excess of dilute sulphuric acid is added, and the violet chromium sulphate is precipitated by alcohol, in which the green variety is soluble. The precipitated salt is rapidly filtered off, redissolved in dilute sulphuric acid, again precipitated, and finally purified by repeated solution in water and precipitation by alcohol.

Another method consists in carefully reducing chromic monochlorhydrin with alcohol in such a way as to avoid elevation of temperature, then add the requisite quantity of dilute sulphuric acid, precipitate by alcohol, and purify as above. These are the only methods which yield the perfectly pure sulphate, since this salt obstinately retains traces of free acid even in a vacuum at 440°.

The chromic oxide is tested for alkali by heating it at a high temperature in a muffle, treating the ignited substance with dilute nitric acid, and testing the solution for chromic acid by adding a few drops of silver nitrate solution and evaporating to dryness, when red silver chromate is left.

Dichromates, when heated to redness, lose chromic anhydride, which decomposes into oxygen and chromic oxide, the latter being deposited on the sides of the muffle in crystalline lamellæ.

C. H. B.

Borotungstates. By D. KLEIN (*Bull. Soc. Chim.*, **39**, 581—589). —A continuation of the author's researches (Abstr., 1881, 23, 24, 224, 879, 880; 1882, 17; 1883, 23, 786).—On boiling a saturated solution of sodium paratungstate with three-quarters of its weight of boracic acid, and precipitating the crude product of the reaction with barium chloride, a barium salt of composition $10WO_3,2BaO,B_2O_3 + 20H_2O$, is obtained. It crystallises in orthorhombic prisms. V. H. V.

Reduction of Molybdenum and Tungsten Compounds. By O. v. D. PFORDTEN (*Annalen*, **222**, 137—165).—The experimental part of this paper has already been given (Abstr., 1883, 122 and 785). The author tabulates the colours of the oxides of the chromium group in acid solution as follows:—

	Cr = 52.	Mo 96.	W 184.	U 240.
I.	CrO, blue	—	—	—
II.	Cr_3O_4,* black	—	—	—
III.	—	Mo_5O_7 reddish-brown; *dil.* yellow	—	—
IV.	Cr_2O_3 reddish-violet or green	Mo_2O_3 red or green	—	U_2O_3, dark-red
V.	CrO_2, brownish-red	MoO_2 brownish-red; *dil.* yellow	WO_2 reddish-brown	UO_2, green
VI.	—	Mo_3O_8, blue	W_3O_8, blue	U_3O_8,* greenish-black
VII.	CrO_3, yellowish-red	MoO_3, colourless	WO_3, colourless	UO_3, yellow

The end-products obtained by the reduction with zinc and hydrochloric acid (CrO, Mo_5O_7, WO_2, U_2O_3), and also by the chlorination (Cr_2Cl_6, Mo_2Cl_{10}, WCl_6, U_2Cl_{10}), do not quite follow the order of the atomic weights of this group. With other reducing agents, however, the results are quite regular.

---

* Not known in acid solution.

	H at high temperatures.	HCl.	HI in aqueous solution.	H_2S.
CrO_3 .	Metal, easily	Cr_2O_3	Cr_2O_3	Cr_2O_3
MoO_3.	Metal, easily	Bluish-green oxide, $MoO_3 + MoO_2$	Mo_2O_5 (or MoO_2I)	Blue oxide between MoO_3 and MoO_2
WO_3 .	Metal, but with more difficulty	—	Pale greenish coloration from slight reduction	—

The author believes the irregularity in the former case to be due to the varying conditions under which the reactions are necessarily carried out. L. T. T.

Researches on the Complex Inorganic Acids. By W. Gibbs (*Amer. Chem. J.*, **5**, 361—383).—A continuation of the author's previous investigations on this subject (this Jour., 1877, 847; Abstr., 1882, 469, 702; 1884, 161).

Hypophosphomolybdates.—*Ammonium hypophosphomolybdate*,

$$8MoO_3,2H_3PO_2,2(NH_4)_2O + 2H_2O,$$

is precipitated on adding hydrochloric acid to mixed solutions of 14 : 6 acid ammonium molybdate and sodium hypophosphite. It forms colourless prismatic crystals, readily soluble in hot water, the solution being first pale blue, but soon deepening in colour; it dissolves in cold water to a colourless, strongly acid solution, which gives the following reactions:—With thallious nitrate, a white flocculent precipitate; with mercurous nitrate, a canary-yellow precipitate; with argentic nitrate, a nearly white precipitate, which speedily blackens. The following salts give precipitates only after addition of ammonia: barium, strontium, and calcium chlorides, colourless flocculent precipitates, becoming granulo-crystalline after a time; manganese sulphate, a white flocculent precipitate; cupric sulphate, a green flocculent precipitate. On heating the ammonium salt, it blackens, fumes slightly, and melts to a dark blue mass, which gives off a little molybdenum teroxide when heated to redness.

Hypophosphotungstates.—The *Potassium salt*, $18WO_3,6H_3PO_2,4K_2O + 7H_2O$, is prepared by mixing a strong solution of hypophosphorous acid with 12 : 5 acid sodium molybdate solution, dissolving the resulting gelatinous mass in hot water, and adding potassium bromide, when a white crystalline precipitate forms. On recrystallisation, the salt is obtained in small colourless granular crystals, soluble in hot water to a somewhat turbid acid liquid. The solution gives no precipitate with copper salts, even on boiling; a precipitate of silver on boiling with silver nitrate; a white flocculent precipitate with mercurous salts; and a white precipitate of indistinct feathery crystals with barium salts.

PHOSPHOROSO-MOLYBDATES.—*Ammonium salt*,

$$24MoO_3,4H_3PO_3,4(NH_4)_2O + 17H_2O,$$

is obtained by the action of phosphorus acid on 14 : 6 acid ammonium mobybdate as a pale yellow indistinctly crystalline precipitate, insoluble in cold water, very slightly soluble in hot water, readily soluble in alkalis. It decomposes readily when heated, fusing at a low red heat with evolution of fumes of molybdic teroxide. The following reactions are obtained by boiling the salt with solutions of metallic salts:—Barium chloride forms a fine-grained crystalline salt; silver nitrate, a nearly colourless flocculent substance, which soon darkens, and finally assumes a dull violet colour; mercurous nitrate, a pale yellow flocculent salt; cupric sulphate dissolves the salt to a clear blue liquid.

VANADIO-MOLYBDATES.—Analytical methods. The separation and estimation of vanadium and molybdenum present some difficulties, but may be effected by the two following methods:—1. Any vanadium present as dioxide is to be oxidised to vanadic acid by heating it with nitric acid, the solution nearly neutralised by means of an alkali carbonate, and vanadic and molybdic acids precipitated together by means of mercurous nitrate and mercuric oxide; the precipitate is then carefully ignited, and finally heated to redness with a weighed quantity of normal sodium tungstate, the increase in weight on which gives the sum of the weights of the molybdic and vanadic oxides; the weight of the vanadium oxide alone being determined in another portion of the precipitate by heating it in a current of air when all the molybdic oxide is volatilised. Another method is founded on the precipitation of the vanadium as ammonic metavanadate, the vanadium in the precipitate being determined volumetrically. The author mentions incidentally that very good determinations of the vanadium in alkaline vanadates may be effected by precipitation with mercurous nitrate and mercuric oxide, ignition of the precipitate, solution in hydrochloric acid, and titration of the vanadic pentoxide with standard solution of ferrous ammonium sulphate, the end-point being determined by means of potassium ferricyanide.

6 : 1 *Series.*—The ammonium salt, $6MoO_3,V_2O_5,2(NH_4)_2O + 5H_2O$, prepared by dissolving molybdic teroxide in solution of ammonium metavanadate, crystallises in lemon-yellow octohedrons, and is soluble in a large quantity of cold water. It gives a flocculent yellow precipitate with silver nitrate; a bright yellow precipitate with mercurous nitrate; a pale yellow flocculent precipitate with thallious nitrate; and with barium chloride, on standing, a deposit of well-defined octohedral crystals.

8 : 1 *Series.*—The barium salt, $16MoO_3,2V_2O_5,5BaO + 28H_2O$, is prepared by adding vanadic pentoxide in small quantities at a time to a boiling solution of acid ammonium molybdate, allowing to cool somewhat, and adding barium chloride, when an abundance of beautiful, well-defined, yellow octohedrons separate.

18 : 1 *Series.*—The ammonium salt, $18MoO_3,V_2O_5,8(NH_4)_2O + 15H_2O$, is obtained in pale green tabular crystals by dissolving molybdic teroxide in a boiling solution of ammonium metavanadate, and allow-

ing it to crystallise. The crystals are decomposed if boiled with water.

VANADIO-TUNGSTATES.—The vanadium and tungsten in these compounds can be estimated by methods founded, either on decomposition by boiling with alkalis and precipitation of the vanadium as ammonium metavandate, or on the evolution of chlorine by the action of strong hydrochloric acid on vanadic pentoxide.

5 : 1 *Series*.—The ammonium salt, $5WoO_3,V_2O_5,4(NH_4)_2O + 13H_2O$, crystallises indistinctly in orange-yellow crusts; it is obtained by boiling 12 : 5 ammonium tungstate with solution of ammonium metavanadate.

When the oxides obtained by igniting a mixture of ammonium metavanadate with 12 : 5 sodium tungstate are boiled with water, a greenish-yellow solution is obtained, which takes an orange colour on being boiled with nitric acid, and on standing deposits a sulphur-yellow crystalline substance of the formula $10WO_3,V_2O_5 + 22H_2O$. The mother-liquor, from which the preceding acid had separated, gave on evaporation beautiful crystalline needles of an acid having the formula $18WO_3,V_2O_5,36H_2O$. A. J. G.

Manganese Chloro-silicate. By A. GORGEU (*Compt. rend.*, **98**, 107—110).—When a mixture of 20 grams pure manganous chloride and 1 gram precipitated silica is heated at a cherry-red heat for about 45 minutes in a current of moist hydrogen, a regulus is obtained consisting of rhodonite, tephroite, and a chloro-silicate. The latter is decomposed by water, but is only very slowly acted on by alcohol, and the excess of manganous chloride can be removed by means of this latter liquid. The residue is a mixture of the birefractive silicates with large lamellæ, which have brilliant faces, and do not act on polarised light. By careful treatment with a 1—2 per cent. solution of pure nitric acid mixed with a few drops of sulphurous acid, the chloro-silicate can be dissolved out without sensibly affecting the simple silicates. The chloro-silicate has the composition $SiO_2,2MnO + MnCl_2$, and forms anhydrous crystals, which in all probability belong to the cubic system, but the exact form of which could not be determined. They do not alter when exposed to dry air, but they rapidly absorb moisture from a damp atmosphere and turn brown. When gently heated, the chloro-silicate loses its chlorine in the form of hydrochloric acid, and the manganese is mainly converted into peroxide. Water free from air causes the separation of a neutral hydrated silicate, but in presence of air silica is liberated, and the manganese is converted into peroxide. The chloro-silicate is also decomposed by saturated solutions of carbonic acid and hydrogen sulphide, and by a solution of sodium hydrogen carbonate. The general action of acid and oxidising reagents is similar to that which they exert on the normal silicate, but is more energetic. This chloro-silicate can also be obtained by fusing the normal silicate with an excess of the chloride in a current of dry hydrogen.

When manganous bromide is fused with silica in a similar manner, it yields crystalline lamellæ of similar appearance and properties. Manganous iodide under the same conditions yields the simple silicates, and only forms the iodosilicate in very small quantity. The latter can, however, be obtained by fusing artificial tephroite in a mixture of manganous and potassium iodides. C. H. B.

Mineralogical Chemistry.

Occurrence of Diamonds in a Pegmatite in Hindustan. By CHAPER (*Compt. rend.*, **98**, 113—115).—Not far from Bellary in the Nizam, diamonds occur *in situ*, associated with amorphous corundum, in a pegmatite which also contains epidote. The diamonds are crystallised in octohedra with brilliant faces, but the forms of the crystals are not so distinct as in the case of the South African diamonds. The pegmatite undergoes disintegration and denudation at its outcrop, and the heavy rains wash the *débris* down to lower levels, leaving fresh surfaces of the rock exposed. This explains the fact that from time immemorial the Hindus in this district have found diamonds on the surface of the soil after the rainy season. It seems probable that this rock has furnished the diamonds found in the various alluvial deposits in Hindustan, for it is stated that all these deposits contain "granite," although the particular granitoid rock is not specified. The irregular distribution and not very frequent occurrence of the pegmatite will explain the facts that the diamonds are generally very rare, and that different deposits vary considerably in their richness. Since the diamond has been formed in a rock so old as pegmatite, it may occur in the various deposits such as grits, quartzites, &c., which have been formed by the denudation of pegmatite, and its occurrence in sedimentary rocks associated with crystallised quartz, &c., does not necessarily prove that it has been developed in a sedimentary paste, or has been formed in the same manner as minerals in veins. It would seem that the diamond has been formed by different methods, for it is not probable that the diamonds in pegmatite and those in the aqueous magnesian breccia of South Africa have been formed in the same way. C. H. B.

Amalgam from the Friedrichssegen Mine near Oberlahnstein. By F. SANDBERGER (*Jahrb. f. Min.*, 1884, **1**, Mem., 191—192).—Amalgam having been found to exist at the Friedrichssegen Mine, it occurred to the author to test the specimens of the so-called native silver for mercury. The two specimens examined were purchased from Stürtz in Bonn, and were described as native silver and native copper respectively. Both were situated on white lead ore. In both cases, the mercury reaction was very distinct. B. H. B.

Native Lead and Minium in Idaho. By W. P. BLAKE (*Jahrb. f. Min.*, 1884, **1**, Ref., 198, and *Amer. J. Sci.*, **25**, 161).—At the Jay Gould Mine, Alturas Co., Idaho, metallic lead occurs enclosed in galena. The metal forms rounded masses from $\frac{1}{8}$ to $\frac{1}{4}$ in. in diameter, or in reniform bunches. The metal is surrounded by a crust of minium. B. H. B.

Minerals from Brazil. By A. Kenngott (*Jahrb. f. Min.*, 1884, 1, Mem., 187—191).—This paper contains a crystallographical description of specimens of euclase, topaz, diamond and pyrrhotine, from the province of Minas Geraës, recently presented by C. Heusser and G. Claraz to the mineral collection of the Zürich Polytechnicum. B. H. B.

Sagvandite. By H. Rosenbusch (*Jahrb. f. Min.*, 1884, 1, Mem., 195—198).—The rock named Sagvandite by Pettersen occurs interstratified in the deeper beds of slate of the Balsfjord group between the lakes Sagvand and Tagvand. The rock consists, for the most part, of an irregular granular mixture of a colourless transparent mineral of the pyroxene group and a rhombohedral carbonate. The microscopic and chemical examination of the rhombic pyroxene prove it to be bronzite, and the carbonate is found on analysis to have the composition indicated by the formula $9MgCO_3 + FeCO_3$. Small grains and octohedral crystals of chrome-picotite, sp. gr. 4·843, also take part in the composition. Pyrites is met with occasionally. A colourless mica occurs more frequently, and with a certain amount of regularity. Lastly, around the spinelle-mineral, a colourless substance occurs but sparingly, and never independently. The indices of refraction of this substance are about the same as those of zircon or sphene. B. H. B.

Artificial Reproduction of certain Silicates and Titanates. By L. Bourgeois (*Jahrb. f. Min.*, 1884, 1, Ref., 196—198).—*Wollastonite.*—Equivalent amounts of CaO and SiO_2 were fused together and cooled. The experiment lasted two days. The crystals obtained were long prisms, frequently twins, with positive double refraction. Sp. gr. = 2·7. The product thus differed from the natural wollastonite. The author is of opinion that calcium silicate is dimorphous, and that a product exactly similar to the natural wollastonite has never yet been obtained artificially.

Meionite.—A mixture having the composition $Ca_5Na_2Al_8Si_9O_{36}$, was fused. The microliths observed on cooling were uniaxial with positive double refraction, and, hence, do not exactly correspond with the natural meionite. By fusing a mixture, $Ca_6Al_5Si_9O_{36}$, the author obtained anorthite and glass.

Gehlenite was obtained in tetragonal crystals by fusing a mixture, $Ca_3Al_2Si_2O_{10}$. The author also obtained distinct crystals of gehlenite from mixtures in which the lime was partially replaced by MgO and the Al_2O_3 by Fe_2O_3.

Melilite.—A mixture of 12 parts of lime to 1 of Al_2O_3 and Fe_2O_3, and 9 of SiO_2, after fusing and cooling, gave sections which were recognised as biaxial.

Another experiment, in which 2 parts CaO were replaced by MgO, was more successful, tetragonal sections being obtained which optically corresponded to melilite. The same mineral was obtained by fusing a mixture, $10CaO, 2MgO, \frac{1}{2}Al_2O_3, \frac{1}{2}Fe_2O_3, 9SiO_2$.

Very perfect crystals were obtained from a mixture:

$$Ca_9Mg_2Na_2Al_4Si_9O_{36}.$$

When the soda was replaced by potash, melilite was also obtained.

Garnet.—Various mixtures corresponding with garnet in composition were fused, but only in one case with success; the mixture, $Mn_3Al_2Si_3O_{12}$, giving hausmannite and, probably, spessartine.

Dichroite.—A mixture, $MgO,Al_2O_3,\frac{5}{2}SiO_2$, gave a mass of microliths, the optical properties of which corresponded with those of dichroite.

Rhodonite was obtained by fusing together MnO_2 and SiO_2. By fusing together 3 parts MnO_2 and 2 parts SiO_2, the author obtained a mixture of tephroite, hausmannite, and rhodonite.

Sphene and Perowskite.—A mixture of lime, silica, and TiO_2, corresponding with sphene in composition, was fused, but without any satisfactory results. When the elements of melilite were fused with those of perowskite, crystals of the two minerals were obtained. The two minerals were also obtained when melilite was fused with sphene. When the elements of sphene were fused with those of perowskite, crystals of perowskite were obtained together with calcium silicate and a glassy mass. B. H. B.

Synthetical Mineralogical Studies. By C. Doelter and E. Hussak (*Jahrb. f. Min.*, 1884, 1, Mem., 158—177).—I. *Garnet.*—The authors have already shown (Abstr., 1884, 401) that garnet, when fused in rocks, gives spinelle, glass and augite. The success of this experiment induced them to study the products obtained when the various varieties of garnet are fused alone. The first experiments soon showed that from fused garnet, garnet is not again formed. The varieties fused were: melanite, pyrope, almandine, and grossular. An experiment lasted 12—14 hours. All the garnets, when fused, were decomposed into other minerals: meionite and melilite, anorthite, lime-olivine, lime-nepheline, iron-glance, and spinelle; the latter appearing when glass occurs. 1. Melanite from Frascati was decomposed into a meionite mineral with positive double refraction, and anorthite, together with a biaxial mineral, probably lime-iron-olivine. 2. Grossular from Rezbanya gave a mineral of the meionite group chemically resembling melilite, with positive double refraction, together with lime-olivine, and very rarely anorthite. 3. Grossular from Wilui gave meionite, some anorthite, iron-glance (?), and a melilite-like mineral. 4. Pyrope from Krimlitz gave anorthite, melilite, and pleonast. 5. Almandine from Zillerthal and the garnet from the granite of Aschaffenburg gave lime-nepheline, melilite, pleonast, and some glass. 6. The brown garnet from Franklin gave anorthite, lime-iron-olivine, and some iron glance. 7. The authors repeated Fouqué's experiment of fusing nepheline and augite; but no melanite was obtained.

The decomposition of garnet into meionite and melilite may be expressed as follows:—

$$\underset{\text{Garnet.}}{6(R''_3R'''_2Si_3O_{12})} = \underset{\text{Meionite.}}{Ca_6Al_8Si_9O_{36}} + \underset{\text{Melilite.}}{R''_{12}R'''_4Si_9O_{36}}.$$

The decomposition into anorthite and lime-olivine :—

$$\underset{\text{Garnet.}}{Ca_3Al_2Si_3O_{12}} = \underset{\text{Anorthite.}}{CaAl_2Si_2O_8} + \underset{\text{Lime-olivine.}}{Ca_2SiO_4}.$$

II. *Vesuvian.*—The fusion-products of vesuvian are the same as those of garnet, namely: meionite, melilite, anorthite and, perhaps, lime-olivine. Vesuvian from the Rympfischwäng gave meionite, melilite, some anorthite and hausmannite. The green vesuvian from Ala was reproduced; a meionite-like mineral and melilite were also observed. Anorthite was not visible, but a brown mineral belonging to the spinelle-group occurred. Similar results were obtained on fusing vesuvian from Vesuvius. The manganese-holding vesuvian from Ala gave meionite, anorthite, and a mineral probably belonging to the olivine-group.

In these experiments, the variable character of the double refraction of the minerals of the meionite-group is very remarkable. Bourgeois has recently shown (see preceding Abstract) the positive character of the double refraction of artificial meionite. In the fusion-products of garnet and vesuvian, the melilite and meionite minerals show sometimes positive, sometimes negative double refraction; the former being the more frequent. The double refraction of nepheline, artificial or natural, is always negative. B. H. B.

The Scapolite Group. By G. TSCHERMACK (*Monatsh. Chem.*, 4, 851—888).—The known minerals of this group are crystallographically identical, and are distinguished by their appearance and chemical composition; the numbers and characteristics of the members of this group are not definitely determined. The variations of interfacial angles are very small, the prismatic cleavage is always the same, and the variation of form is also inconsiderable. The crystals have been reported as showing pyramidal and then trapezohedral-hemihedry; owing to the irregularities of the crystals, it is impossible to decide this by mere inspection of the occurring faces. By observing, however, the etching figures produced by hydrofluoric acid, and in a few cases the natural etching figures and raised faces (vicinalflächen) the pyramidal hemihedry is satisfactorily established. The recognised chemical constituents are oxygen, silicon, aluminium, calcium, and sodium; the calcium and sodium appear to replace each other, but no specimens have been found containing only one or other of these two. Potassium often displaces sodium in part; magnesium and iron belong to foreign impurities; water is present in minute quantity only; carbonic anhydride is generally due to admixed calcite, but the author is of opinion that a molecular compound of a silicate and carbonate is occasionally present. Chlorine is also present, and increases with the percentage of sodium and sulphuric acid, but in such small and variable quantity as not to allow of the determination of its mode of occurrence. A table containing five complete analyses is given, as also one of six analyses, showing that as the silica rises from 40 to 62 per cent., the alumina falls from 33 to 22 per cent., the lime from 24 to 5 per cent., whilst the alkalis rise from 2 to 10 per cent.

The chemical resemblance between the scapolite and plagioclase minerals has often been pointed out, and it is here shown that the relation between the silica and the alumina is the same as in the felspars, viz., as 2 : 1 in the calcium, and as 6 : 1 in the sodium compound. Further, it is shown that the ratio of alumina to lime plus soda is as 3 : 4, differing thus from the ratio in the felspars, which is 1 : 1. But as before noticed, chlorine is an essential constituent, and its quantity increases with the amount of sodium; taking those analyses showing the most chlorine with but little sulphuric acid, it is seen that the sodium and chlorine are to each other in the ratio 4 : 1. Coupling together these observations, the author infers that the scapolite minerals are composed of an isomorphous mixture of two substances, $Si_6Al_6Ca_4O_{25}$ and $Si_9Al_3Na_4O_{28}Cl$, which he designates by the names meionite and marialite, the composition of these most nearly corresponding with the above formulæ. Having regard to the composition and isomorphism of anorthite and albite, the author writes the above formulæ:—Meionite, $3(Si_4Al_4Ca_2O_{16}) + 2CaO$; marialite, $3(Si_6Al_2Na_2O_{16}) + 2NaCl$.

The scapolite minerals form an indefinite series of intermediate products; they may, however, be arbitrarily divided into three groups containing (1) 40·31 to about 48 per cent. silica, viz., meionite, and among other opaque varieties wernerite; (2) 48 to 56 per cent. (about) of silica, viz., mizzonite and scapolite, &c., as opaque varieties; (3) 56 to 63·83 per cent. of silica, viz., marialite and riponite, &c., which are opaque.

Tables are given comparing the numbers obtained in thirty analyses with those calculated from the above formulæ; the two series of numbers compare very favourably. The approximate densities are calculated to be, meionite 2·764, and marialite 2·540. The relationships between the composition of these two minerals and plagioclase, epidote, muscovite, and kaolin are pointed out, as also the formation of pseudomorphs after these minerals or after the scapolite minerals.

H. B.

Decay of Rocks Geologically Considered. By T. Sterry Hunt (*Jahrb. f. Min.*, 1884, 1, Ref., 225, and *Amer. J. Sci.*, **26**, 190—213).—Recent geological studies point to the antiquity and universality of the weathering of crystalline rocks. The decay took place, to a great extent, in pre-Cambrian times. The products have frequently remained undisturbed either by being covered by overlying strata, or by being in positions sheltered from erosion. Although the weathering process is continuous, it has been very insignificant since the glacial period, on account of the relatively small time which has since elapsed. This weathering process has furnished the material for the formation of the sedimentary rocks, and of the crystalline limestones, iron-ore beds, &c. The rounded masses left during the process of decay constitute the boulders of the drift, and the similar masses in pre-glacial conglomerates. The outlines of the eroded regions of crystalline rocks were also determined by sub-aërial decay.

B. H. B.

The More Recent Eruptive Rocks of Elba. By W. R. Nessig (*Jahrb. f. Min.*, 1884, **1**, Ref., 232—233).—The eruptive rocks of the central portion of the Island of Elba are quartz-porphyries, and may be classed as granitic porphyries, porphyritic micrograpites, and compact quartz-porphyries. In spite of their apparently eocene age, they have nothing in common with the rhyolites. Tourmaline occurs only in the granitic porphyries and micrograpites. Zircon occurs widely distributed in all the rocks with the exception of the porphyritic micrograpites. Twin crystals of zircon occur but rarely. The author is of opinion that the porphyries are independent rocks, and have nothing to do with the Capanne granite. B. H. B.

Hypersthene Andesite. By C. W. Cross (*Jahrb. f. Min.*, 1884, 1, Ref., 227—229).—The author finds that an apparently typical augite-andesite from the Buffalo Peaks, Colorado, contains hypersthene as its chief pyroxenic constituent. The hypersthene was isolated by Fouqué's method, and gave on analysis the following results:—

SiO_2.	Al_2O_3.	FeO.	MnO.	CaO.	MgO.	Total.	Sp. gr.
51·157	2·154	18·360	0·363	3·812	24·251	100·097	3·307

The interesting results obtained by the author from the investigation of the Buffalo Peaks rocks induced him to examine carefully a series of European augite-andesites. He arrived at the conclusion that the greater part of the pyroxene corresponds optically and structurally with the hypersthene of the Buffalo Peaks rocks. B. H. B.

Chemical Composition of the Phonolites of Hegau. By C. F. Föhr (*Jahrb. f. Min.*, 1884, 1, Ref., 233—235).—Analysis I gives the composition of the phonolite of Hohentwiel; sp. gr. 2·41; 54·8 per cent. soluble in hydrochloric acid. II gives the results of the analysis of the yellow natrolite (sp. gr. 2·171) from the fissures in the rock. III, the natrolite (sp. gr. 2·183) from the phonolite of Hohenkrähen. IV, the hornblende needles (sp. gr. 3·414) of the rock. V, the phonolites of Gennersbohl; 39·19 per cent. was soluble, and gave on analysis the figures under VI, the insoluble portion having the composition VII. VIII is an analysis of the phonolite of Staufen; sp. gr. 2·452; 62·79 per cent. being insoluble. IX is an analysis of the phonolite of Schwintel; sp. gr. 2·471; 51·87 per cent. being insoluble. X is an analysis of the phonolite of Mägdeberg; sp. gr. 2·4999, with 66·22 per cent. of insoluble constituents.

In the phonolite tuffs of Hegau, the author found brown, glassy, rounded nodules resembling volcanic bombs; sp. gr. 2·221. An analysis gave the figures under XI:—

Action of Water containing Carbonic Acid on the Trachyte of Gleichenberg. By C. CLAR (*Jahrb. f. Min.*, 1884, 1, Ref., 229).—100 grams of finely powdered trachyte from the quarry near the Klausner spring at Gleichenberg, together with 2 litres of distilled water saturated with CO_2 at a pressure of 10 atmospheres, were rotated for seven weeks in a tinned copper cylindrical vessel. The analysis of the clear fluid gave for 2000 c.c. the figures under II; I gives the results of the analysis of the rock; III, the composition of the fluid per litre; and IV, that of the Klausner spring also per litre.

Tachylyte of the Western Isles of Scotland. By J. W. Judd and G. A. J. Cole (*Journ. Geol. Soc.*, **39**, 444—464; and *Jahrb. f. Min.*, 1884, **1**, Ref., 236—237).—Basalt-glass or tachylyte has been detected, by the authors, in five places only, viz.: Lamlash, near Arran; the Beal, near Portree, in Skye; Sorne, in Mull; between Gribun and Kilfinichen, in Mull; and Screpidale, in Raasay.

Tachylyte is always found in the Hebrides as a selvage to dykes, and some varieties differ from any tachylyte hitherto described by their high sp. gr. (2 9), and by their low percentage of SiO_2 (45).

From a consideration of the chemical composition of tachylytes, the authors come to the conclusion that the basalts which show a tendency to the vitreous condition are those with a high percentage of silica and alkalis. This is confirmed by the composition of the basalt-glass of the Beal, which was found to be—

SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	CaO.	MgO.	Na_2O_3.	K_2O.	Ignition.	Total.
52·59	17·33	11·14	0·66	6·47	2 62	4·24	2·40	3·27	100·72

The basic glasses of Sorne, Screpidale, and Gribun form much narrower selvages than the more acid ones of the Beal and Lamlash. In its microscopic characters, basalt-glass was found to resemble other vitreous rocks. In the gradual transition into basalt, all stages of devitrification can be observed. B. H. B.

Organic Chemistry.

Haloïd Derivatives of Ethane. By L. HENRY (*Compt. rend.*, **97**, 1491—1494).—Monochlorethylene dibromide, $CH_2Br.CHClBr$, when treated with alcoholic potash in molecular proportions, yields pure potassium bromide, and unsymmetrical chlorobromethylene, $CH_2:CClBr$, boiling at 62—63°. The bromine in the chain CH_2Br is alone eliminated. Potassium cyanide produces the same result.

Monobromethylene dibromide, $CH_2Br.CHBr_2$, when treated with potash, sodium ethylate, potassium acetate, &c., in alcoholic solution, yields unsymmetrical dibromethylene, $CH_2:CBr_2$, boiling at 86—88°. The bromine eliminated is exclusively that in the chain CH_2Br.

When 2 mols. monochlorethylene dibromide are gently heated with 1 mol. antimonic chloride, dichloromonobromethane, $CH_2Br.CHCl_2$, boiling at 137—138°, is obtained, and this, when treated with alcoholic potash, yields unsymmetrical dichlorethylene, $CH_2:CCl_2$, boiling at 35—37°. The bromine in the chain $CHClBr$ is alone attacked by the antimonic chloride.

Ethylidene bromide reacts with antimonic chloride more energetically than does ethylene bromide, and yields exclusively ethylidene chloride boiling at 59°, without any intermediate formation of

$$CH_3.CHClBr,$$

even when the substances are in the proportion of 1 mol. antimonic chloride to 2 mols. ethylidene bromide. In the case of ethylene bromide, the bromine is replaced successively with formation of

$$CH_2Cl\ CH_2Br,$$

and finally $CH_2Cl.CH_2Cl$. This difference in the mode of action of the two isomerides illustrates the difference which exists between a *monatomic multiple compound*, such as $CH_2Br.CH_2Br$, and a *polyatomic monocarbon compound*, such as $MeCHBr_2$.

When monobromethylene bromide is treated with antimonic chloride (not in excess), dichloromonobromethane, $CH_2Br.CHCl_2$, boiling at 137—138°, is exclusively obtained even when the proportions are 1 mol. $SbCl_5$ and 2 mols. $C_2H_3Br_3$; and this when treated with alcoholic potash yields unsymmetrical dichlorethylene, $CH_2:CCl_2$, boiling at 35—37°.

These different reactions of the chains CH_2Br, $CHBr_2$, and $CHClBr$ show that with respect to positive reagents the reaction aptitude of bromine is diminished by a diminution in the number of adjoining hydrogen-atoms, or by the replacement of one of them by a negative radicle such as chlorine or bromine; whilst with respect to the negative reagent, antimonic chloride, it is increased under the same conditions.

Preparation of Higher Olefines, Dodecylene, Tetradecylene, Cetene or Hexadecylene, and Octadecylene. By F. KRAFFT (*Ber.*, **16**, 3018—3024).—By the action of phosphorus pentachloride on palmitic acid on the water-bath, and subsequent separation of the phosphorus oxychloride formed, by distillation under reduced pressure, an oil, palmityl chloride, $C_{16}H_{31}OCl$, is obtained. This latter acts on normal primary dodecyl alcohol (Abstr., 1883, 1075) with evolution of hydrochloric acid. To complete the reaction the mixture is heated at 170°. If molecular quantities are taken, and the product purified by boiling with alcohol, pure dodecyl palmitate, ($C_{28}H_{56}O_2$), is obtained. It is soluble in alcohol, more easily in ether, and crystallises in plates melting at 41°. It distils without decomposition at very reduced pressures, but at ordinary atmospheric pressure, or better at 600 mm., it is almost completely decomposed into the fatty acid and the olefine $C_{12}H_{24}$. The latter distils at 96° by 15 mm. pressure, whilst the palmitic acid distils at 215°. This process is that of Smith (*Ann. Chim. Phys.* [3], 6, 40) for the preparation of cetene from spermaceti, modified chiefly as regards the pressure.

In precisely similar way, tetradecyl alcohol, cetyl or hexadecyl alcohol, and octadecyl alcohol form with palmityl chloride, palmitates and hydrochloric acid, and by distillation at reduced pressures these palmitates yield respectively the olefines, tetradecylene, cetene or hexadecylene and octadecylene. Hexadecylene was also prepared from spermaceti (cetyl palmitate), and found identical in physical properties to that obtained from artificially prepared hexadecyl palmitate. The following table gives the physical properties of these olefines:—

		Melting point.	Sp. gr. at the melting point.	Boiling at 15 mm.
Dodecylene	$C_{12}H_{24}$	−31°	$d_{-31} = 0.7954$	96°
Tetradecylene ..	$C_{14}H_{28}$	−12	$d_{-12} = 0.7936$	127°
Hexadecylene ..	$C_{16}H_{32}$	+ 4	$d_{4} = 0.7917$	155°
Octadecylene....	$C_{18}H_{36}$	+18	$d_{18} = 0.7910$	179°

A. B.

Action of Acetylene Hydrocarbons on Mercuric Salts. By KOTCHEROFF (*Bull Soc. Chim.*, 39, 595—596).—On agitating aqueous solutions of mercuric salts with allylene, white crystalline precipitates are obtained of general formula $m\mathrm{HgX}_2,n\mathrm{HgO}.p(\mathrm{C_3H_4HgO})$, the values of the coefficients *m*, *n*, and *p* varying with the mercuric salt used. These precipitates are insoluble in water, but dissolve in acids with formation of acetone. This property, together with their inaptitude to detonate by percussion or rise of temperature, distinguishes them from the precipitates produced by the action of allylene on ammoniacal solutions of silver or copper. The author considers these compounds to be combinations of basic salts of mercury with acetone in which two atoms of hydrogen are replaced by one of mercury. The hydration of acetylene hydrocarbons by means of mercuric salts can be explained by these facts; the reaction is effected in two phases: 1st, an intermediate substance is formed by the combination of a basic salt of mercury with the group $C_nH_{2n-2}HgO$; 2nd, this substance is decomposed by the acid disengaged in the first change, and the basic is converted into a neutral mercuric salt; while the group $C_nH_{2n-2}HgO$ furnishes an acetone and a neutral salt of mercury resulting from the interchange of one atom of hydrogen for one of mercury. V. H. V.

Ferric Ethylate and Colloïdal Ferric Hydrate. By E. GRIMAUX (*Compt. rend*, 98, 105—107).—When 1 mol. of ferric chloride in alcoholic solution is mixed with 6 mols. of sodium ethylate, sodium chloride is precipitated and a deep red-brown limpid liquid is obtained, which is free from chlorine, but contains all the iron in solution as ferric ethylate. The alcohol can be distilled off, and the ferric ethylate is left as a black pasty mass, soluble in absolute alcohol, benzene, chloroform, ether, petroleum, and methyl alcohol. If, however, this residue is heated in a vacuum so as to expel the last traces of the solvent, the small quantity of water present almost completely decomposes the ethylate, and ferric hydroxide separates out. If the operations of filtration, &c., have been conducted in dry air, the ethylate is not completely decomposed. An alcoholic solution of ferric ethylate is not precipitated by a current of dry ammonia, but with dry carbonic anhydride it yields a brown precipitate. Dry hydrogen sulphide reduces it to a ferrous salt, and potassium ferrocyanide precipitates ferric hydroxide.

The action of water varies with the proportion in which it is present. If the alcoholic solution is exposed to a moist atmosphere, or is mixed with a small quantity of water, ferric hydrate is deposited as a jelly. If, however, the alcoholic solution of ferric ethylate is poured into an excess of water, limpid liquids are obtained which have the properties of the solutions of colloïdal ferric hydroxide described by Graham. They coagulate spontaneously after some time, and are coagulated by addition of various substances, such as carbonic anhydride, sulphuric acid, tartaric acid, potassium chloride, sodium chloride, river water, &c. Acetic, nitric, and hydrochloric acids and ammonia have no effect. Hydrogen sulphide produces a black precipitate. The time which elapses before coagulation takes place increases with the dilution of the solution, and is diminished by an increase of temperature. A higher temperature is required to produce coagulation the greater the amount of water present, and a solution of 1 vol. ferric ethylate solution in 15 vols. of water is not coagulated even after four hours' ebullition.

The coagulated ferric hydroxide forms a thick jelly, which always fills the vessel even if the solution is dilute. At first it is transparent, but it gradually contracts with elimination of water. The coagulation of the ferric hydroxide varies with the conditions in the same way as the coagulation of blood, a fact which indicates that inorganic colloids are analogous to the nitrogenous colloïds of the animal organism. C. H. B.

New Derivatives from Mannitol. By A. FAUCONNIER and others (*Bied. Centr.*, 1883, 789).—By dry distillation of mannitol, a yellowish-brown liquid was obtained, from which voluminous crystals of the second anhydride of mannitol separated. They were found to agree with the formula $C_6H_{10}O_4$; they melt at 87°, and boil in a vacuum at 176°. With acetic anhydride, a diaceto-compound is obtained. Phosphorous chloride gives other derivatives, and an ethyl compound is formed when it is heated with ethyl iodide and potash.

J. K. C.

Influence of the Quantity of the Constituents of Fehling's Solution on the Rate of Separation of Cuprous Oxide by Invert-sugar. By F. URECH (*Ber.*, **16**, 2825—2827).—The author previously described the effect of an excess of invert-sugar (Abstr., 1883, 385), and he now shows that the results obtained are in accordance with theory. With an excess of the constituents of Fehling's solution, the rapidity of separation of cuprous oxide is likewise accelerated provided the amount of water be not increased. With the addition of water the rapidity is diminished; whilst with increased concentration the rate of separation is accelerated to a certain point, beyond which, it gradually becomes diminished. Experiments, in which the quantity of alkali and Rochelle salt was diminished, showed a lower rate of separation. On employing an excess of copper sulphate alone, it is found that the rate of separation is not increased to the same extent as by the employment of an excess of invert-sugar.

A. K. M.

Action of Sodium-amalgam on Glucoses and Saccharin. By C. SCHEIBLER (*Ber.*, **16**, 3010—3011).—The quantity of mannitol obtained by the action of sodium-amalgam on a solution of dextrose or levulose is very small, for from 500 grams Krusemann only obtained 40 grams mannitol in each case. This the author considers to be due to the fact that glucose is very unstable in presence of caustic soda, and that as soon as the latter is formed by the action of the sodium-amalgam, a complicated, and as yet unknown, decomposition of the glucose takes place. He considers also that the formation of mannitol may be due to the addition of hydrogen to one of these products of decomposition. In this preliminary notice he states that he undertakes the study of the decomposition of glucoses by alkalis and alkaline earths, and also of the action of sodium-amalgam on saccharin (which is not accompanied with evolution of hydrogen) and on iso-saccharin.

A. B.

Starch. By F. MUSCULUS (*J. pr. Chem.* [2], **28**, 496—504).—This is a paper written to criticise Salomon's paper (this vol., p. 36) entitled: "The behaviour of starch in the presence of inorganic and organic acids." The author states that Salomon only treats of crystalline soluble starch in his treatise, completely ignoring the amorphous variety. The author himself was the first to prepare crystalline starch. Nägeli obtained amylum four years later in fine needles, and gave to it the name of amylodextrin. Dilute solutions of crystalline soluble starch give a red coloration with iodine, concentrated solutions yielding a blue colour. The crystalline variety dialyses slowly, and reduces Fehling's solution on boiling. The author suggests that Salomon's solution, with which he tried to reduce alkaline copper solution, was probably too dilute. The amorphous modification is soluble in cold water, and always gives a blue coloration with iodine. It cannot be dialysed, nor does it reduce Fehling's solution. Salomon states that only one dextrin exists, and that the different colours which it yields with iodine are due merely to admixed soluble starch, and also that the various rotatory and reducing powers are due to the presence of sugar. The author claims that he has previously shown that crystalline soluble starch owes its power of producing a red colour with iodine to the presence of dextrin. Brucke's erythrodextrin consists of dextrin which gives no colour with iodine. The author states that the evidence of the existence of several dextrins does not rest alone on their behaviour with iodine. Bondonneau prepared in 1875 two dextrins which gave no coloration with iodine, but which differed in their solubilities in alcohol and their rotatory powers. The author (*Bull. Soc. Chim.*, **30**, 4, 1878) has prepared three dextrins, which gave no iodine coloration, and which differed from one another in their behaviour with diatase. They also differ in the time required to dialyse.

Salomon states that maltose has never been prepared by boiling starch with dilute sulphuric acid: the author (*Zeitschr. f. Physiol. Chem.*, 1879), Dubrunfaut, and O'Sullivan have all prepared it in this way. Salomon has fallen into error by assuming that dextrin has a greater rotatory power in an acid solution than in a neutral one; for he has endeavoured to detect the formation of maltose by the variation in the rotatory power of the solution.

J. I. W.

Contribution to the more exact Knowledge of the Chemical Nature of Starch-grains. By B. BRUKNER (*Monatsh. Chem.*, 4, 889—912).—In 1856, Nägeli extracted a substance turned blue by iodine, and termed "granulose," from starch-grains, without, however, destroying their form. In 1859 Jessen found that on rubbing starch-grains with water, that a portion of the soluble starch was dissolved. Nasse, in 1866, gave the name amidulin to a soluble body obtained from starch-paste. Nägeli, in 1874, extracted by dilute hydrochloric acid a body essentially different from starch, which he called amylodextrin. The first object of the author is to determine the relation existing between these four bodies.

Amidulin.—Starch has generally been considered as insoluble in water. Jessen and Dolff, by rubbing starch with water, extracted a portion; this might, however, have been due to the conversion into starch-paste by the heat evolved in the crushing of the granules. W. Nägeli imbedded starch-grains, and then cut sections; the portions of the granules were turned blue by iodine, as also was, to some extent, the small quantity of water employed, and hence a portion must have gone into solution. By rubbing dry starch granules, they may be broken, and if subsequently treated by water and filtered, they give a clear solution turned blue by iodine. But on allowing wheaten starch to digest with water for three weeks, filtering, evaporating to one-fifth, and testing with iodine, no blue coloration was obtained; hence it is impossible to extract the inner and soluble starch with water until the outer membrane is either changed or broken; the character of the solution is that of a micellar solution; it is not capable of diffusion. The substance soluble in cold water and coloured blue by iodine, the amidulin of Nasse and the granulose of Nägeli, are identical.

Starch-paste.—Schimper and Nägeli are not agreed as to the distinction between swollen starch and starch-paste. Between these two states there is no sharp distinction; thus at 46° potato-starch swells distinctly; at 59° it begins to lose its form; and at 62·5° it is converted into a paste, and shows no trace of the original form. After discussing Nägeli's micellar theory, viz., that the smallest particles of starch and similar substances consist not of molecules, but of larger groups, *i.e.*, micellæ, which owing to their comparatively slow movements, due to their greater size and weight, easily unite into micellar clusters, the author concludes that swollen starch and starch-paste differ in nothing but the aggregate condition of their micellæ; they differ therefore physically but not chemically, and accordingly starch-paste, amidulin, and granulose are identical.

Erythrogranulose.—Erythrogranulose and erythrodextrin are the names given to two bodies coloured red by iodine (Brücke). By digesting starch solution with diastase, and testing portions from time to time with iodine and with tannin solution, it was shown that so long as iodine produced a blue coloration, tannin produced a precipitate, but with a red coloration no precipitate was formed, nor under these conditions was a precipitate produced by adding hydrochloric acid: hence the red coloration is due to the presence of dextrin. If very dilute iodine be added to starch-granules (or paste) a red colour is first produced; this is due to the presence of dextrin (erythrodextrin) and its greater solubility in water.

Amylodextrin.—W. Nägeli states that soluble starch is distinguished from amylodextrin by being precipitated from solution by tannin and by lead acetate, and further that freshly precipitated starch is insoluble in water, whilst freshly precipitated amylodextrin is soluble. None of these differences can be confirmed. Further, amylodextrin does not, like starch, swell up with an alkaline solution, but simply dissolves; this, however, is not a distinctive test, since precipitated starch behaves exactly like amylodextrin; amylodextrin is tinted by organic matter just as starch is. It is also stated that Trommer's copper test is not reduced by amidulin, but is by amylodextrin; but it has been shown that the starch-grains themselves contain dextrin, and further, during the progress of the test, the starch becomes converted into dextrin and into sugars, and, still more important, dextrin is formed during the preparation of amylodextrin.

The author has been quite unable to confirm the statement as to the crystalline nature of amylodextrin. Amidulin and amylodextrin are identical. That amydulin—a body not capable of diffusion, can be extracted from starch-grains by dilute acid, is explained by the action of the acid on the micellar aggregates.

The Iodine Reaction.—The so-called iodide of starch is no chemical compound; it has been stated to be decomposed when heated; this depends on the affinity of warm water for iodine being greater than that of cold water; and if this greater absorptive power be satisfied by addition of more iodine, then the blue colour is not destroyed even by boiling. The author considers the blue colour to be simply due to the solution of iodine in potato-starch, just as violet and brown colours are obtained on solution in chloroform and water respectively.

Potato- and arum-starch yield blue colorations, wheat- and rice-starch yield violet, but after boiling they also are turned blue by iodine. Starch-grains have a greater attraction for iodine than unorganised starch; thus a cold clear solution prepared from crushed starch-grains and coloured blue by iodine, is completely decolorised by adding whole starch-grains. Similarly, it is shown that starch grains attract iodine more energetically than dextrin, the red solution being decolorised, and the starch-grains turning blue.

In conclusion, soluble starch, starch-paste, granulose, amidulin, and amylodextrin are identical, *i.e.*, give identical reactions, as also are erythrogranulose, erythrodextrin, and dextrin. H. B.

Action of Cuprammonium Solutions of Cellulose on Polarised Light. By A. Levallois (*Compt. rend.*, **98**, 44).—Solutions of cotton, flax, Berzelius' paper, and German filter-paper in Schweitzer's reagent were examined with polarised light by means of the electric arc. All the solutions are strongly lævogyrate, and the degree of rotation seems to be proportional within certain limits to the concentration of the solution. This fact would indicate that the ammonio-cupric compound of cellulose is not definite. It is observed, however, that the intensity of the blue colour diminishes when the liquid is highly charged with cellulose. C. H. B.

Action of Ammonia Gas on Methyl Nitrate. By E. Duvillier and H. Malbot (*Compt. rend.*, **97**, 1487—1488).—When ammonia gas is passed into methyl nitrate mixed with about one-tenth its volume of wood-spirit, and contained in a flask connected with an inverted condenser, the ammonia is absorbed with development of heat, and when the liquid is saturated it contains different ammonias in approximately the following proportions:—

Ordinary ammonia	5
Tetramethylammonium oxide	3
Monomethylamine	2
Dimethylamine and trimethylamine	Very small quantities

Under those conditions, tetramethylammonium oxide and not monomethylamine is the principal product (compare Duvillier and Buisine, Abstr., 1880, 545). C. H. B.

Trimethylamine Aurochloride. By O. Hesse (*Ber.*, **16**, 3014).—The author states that in 1857 (*J. pr. Chem.*, [2], **27**, 425) he determined the formula and described the properties of this compound lately communicated by Zay (Abstr., 1884, 286). A. B.

Oxallyldiethylamine. By E. Reboul (*Compt. rend.*, **97**, 1556—1558).—Oxallyldiethylamine, $NEt_2C_3H_5O$, is the most volatile of the bases obtained by the action of epichlorhydrin on diethylamine. (See next Abstract.) It is a thick colourless liquid with a powerful poisonous odour resembling that of diethylamine. It boils at about 160°, gradually becomes yellow when exposed to light, and is very soluble in water. When treated with excess of dilute hydrochloric acid and then with platinum tetrachloride, it yields garnet-red rhombic prisms which are not oxallyldiethylamine platinochloride, but are the platinochloride of a base, chlorhydroxyallyldiethylamine,

$$NEt_2.C_3H_5(OH)Cl,$$

formed by the union of HCl with the unsaturated radicle oxallyl, C_3H_5O.

This chlorhydroxyallyldiethylamine is the first product of the action of epichlorhydrin on diethylamine. The epichlorhydrin behaves like chloropropylene oxide, and unites directly with 1 mol. diethylamine after the manner of the glycollic anhydrides, $C_3H_5OCl + NHEt_2 = NEt_2.C_3H_5(OH)Cl$, and this product reacts with a second molecule of diethylamine with formation of hydroxyallyltetrethylamine and liberation of hydrochloric acid, $NEt_2.C_3H_5(OH)Cl + NHEt_2 = HCl + (NEt_2)_2C_3H_5.OH$. C. H. B.

Hydroxyallyldiamines. By E. Reboul (*Compt. rend.*, **97**, 1488—1491).—Epichlorhydrin and diethylamine react at the ordinary temperature, with gradual development of heat; and unless the mixture is cooled, the temperature rises sufficiently high to cause an explosion even in a strong, sealed flask. The product of the reaction is sometimes a very thick syrupy liquid, sometimes is mainly solid, and contains several bases in proportions depending on the temperature and on the proportions of the original substances. It is made alkaline with potash, and the free bases are distilled off, or better, are extracted with ether. The chief products are a monamine, diamine, and triamine, together with polyamines. With 1 vol. epichlorhydrin and 1·5 vol. of diethylamine, the principal product is the diamine formed according to the equation—

$$C_3H_5OCl + 2NHEt_2 = HCl + (NEt_2)_2C_3H_5.OH.$$

This equation simply represents the final products. The diamine is really formed by the action of the diethylamine on a chloro-monamine formed by the union of 1 mol. epichlorhydrin with 1 mol. diethylamine. This diamine, $(NEt_2)_2C_3H_5.OH$, is *hydroxyallyltetrethyldiamine*. It is a very stable liquid lighter than and only slightly soluble in water; it boils at 236—238° without decomposition under atmospheric pressure. It forms a crystalline orange platinochloride,

$$N_2Et_4C_3H_5OH,H_2PtCl_6,$$

and with sulphuric and oxalic acids it forms neutral syrupy salts which do not crystallise.

In a sealed tube at 100° hydroxyallyltetrethyldiamine combines with 2 mols. ethyl iodide, forming a syrupy liquid which solidifies to a translucent mass. This product could not be obtained in crystals, but it is *hydroxyallylhexethyldiammonium iodide*, $N_2Et_6C_3H_5OHI_2$.

The diamine mixes perfectly with allyl bromide in the cold, and after some time the liquid becomes turbid, and a syrupy upper layer consisting of a compound of 2 mols. allyl bromide with 1 mol. hydroxyallyltetrethyldiamine separates out. The diamine also combines directly in the cold with ethylene bromide in the proportion of equal molecules.

Epichlorhydrin reacts violently with ethylamine, forming hydroxyallyldiethyldiamine, $(NHEt)_2C_3H_5.OH$, a colourless syrup which dissolves in water in all proportions, and boils at about 185° without decomposition. C. H. B.

Action of Heat on Aldol and Paraldol. By A. WURTZ (*Compt. rend.*, **97**, 1525—1530).—The principal products of the action of heat on aldol are crotonaldehyde and water, but the exact nature of the decomposition depends on the temperature and on the purity of the original substance. When the aldol contains small quantities of crotonaldehyde and gives a slight turbidity with water, the product of decomposition consists of a small colourless and aqueous lower layer and an abundant dark-brown or black upper layer which consists mainly of crotonaldehyde together with condensation-products of high boiling point. Purer specimens of aldol, on the other hand, when heated in sealed tubes at 160° or 170' for four or six hours, yield a homogeneous almost colourless product which contains a smaller proportion of crotonaldehyde than in the first case, together with products boiling between 250° and 300°. This higher fraction contains a substance which is soluble in water, and the yield of which is never more than 15 per cent. under the most favourable conditions. Very often it is not formed at all, and the conditions under which its formation takes place could not be definitely ascertained. It can, however, be obtained in larger proportion by heating paraldol in sealed tubes at 170° for about four hours. The almost colourless product is distilled, and the fraction boiling between 260° and 300° is washed with water, treated repeatedly with small quantities of ether to remove oily products, the solution concentrated in a vacuum to a syrupy consistency, and then distilled in a vacuum. This new compound has the composition $C_4H_8O_2$, and is a viscous colourless liquid which boils at about 170° under a pressure of 15 mm., and at about 280° at the ordinary pressure; sp. gr. at 0° = 1·095. Its vapour-density by V. Meyer's method in mercury vapour is about 3.

This compound has the appearance and general characters of a glycol. With nascent hydrogen, it yields β-butyl glycol. It reacts energetically with acetic chloride, benzoic chloride, and phosphorus pentachloride with evolution of hydrochloric acid and formation of ethereal derivatives, and when heated with acetic anhydride it yields an acetyl derivative. It does not combine energetically with bromine in the cold, and this would indicate that it does not contain an open chain of 4 carbon-atoms two of which are united by a double bond, a supposition which is also confirmed by its boiling point.

When the substance is heated with an excess of acetic anhydride, first at 100° and finally at 110°, it yields a colourless liquid which boils at 176° under a pressure of 15 mm., and at about 275° under ordinary pressure; sp. gr. at 0° = 1·095. It is insoluble in water, and is saponified when heated with this liquid in sealed tubes for several days. The only formula which agrees with the percentage composition of this compound and with the amount of acid which it yields on saponification, is that of a diacetyl derivative of butyl glycol oxybutyrate,

$$C_8H_{14}\overline{Ac}_2O_4, \text{ or } CHMe(OH).CH_2.CH_2.O.CO.CH_2.CHMe.OH.$$

It would appear to be a compound ether containing two hydroxyls, and therefore possessing some of the properties of glycols. When saponified it yields butyl glycol, acetic acid, and β-oxybutyric acid or its derivative crotonic acid. This supposition does not agree with the vapour-density of the substance or of its acetyl derivative, but the determinations were not satisfactory. C. H. B.

Pentachloracetone. By C. Cloëz (*Bull. Soc. Chim.* [2], 39, 636—641).—Pentachloracetone is generally prepared by the action of hydrochloric acid and potassium chlorate on quinic or citric acid, but the process presents the difficulty of the incomplete removal of chlorine oxides from the final product. In this paper it is proposed to prepare this substance either by passing chlorine through a tubulure, filled with pumice stone, over which trickles a continuous stream of citric acid solution; the whole apparatus being kept at a temperature of 100°: or secondly, by the action of dry chlorine on dry acetone in presence of sunlight. Thus prepared, pentachloracetone is a mobile liquid boiling at 192°, of sp. gr. = 1·576, and transformed by ammonia into dichloracetamide and chloroform.

But by the action of chlorine on symmetrical dichloracetone, there is produced an isomeride of pentachloracetone boiling at 185°, sp. gr. = 1·617, and converted by ammonia into trichloracetamide without a trace of chloroform. According to prevalent views, the molecule of acetone is represented by a formula in which the two methyl-groups are symmetrically associated with the carbonyl-group; if these views be correct, then only one pentachloracetone is possible. On the other hand, if the hypothesis of Chancel and Gerhardt be correct, that one methyl-group is less intimately associated with the carbonyl-group than the other, then one pentachloracetone might be represented by the formula $C_2HCl_2O.CCl_3$, converted into dichloracetamide and chloroform, the other by the formula $C_2Cl_3O.CHCl_2$, converted into trichloracetamide. V. H. V.

Duplothiacetone. By W. Spring (*Bull. Soc. Chim.*, 40, 66—71).—By the action of phosphorus pentasulphide on acetone, Wislicenus obtained a thiacetone, $2C_3H_6S$, boiling between 183° and 185°, which, according to Claus and Kühlze, can be obtained from isopropyl mercaptan, and is transformable into isopropylsulphonic acid. On distilling the crude product of the above reaction, the author obtained besides methyl- and isopropyl mercaptans, a liquid of no fixed boiling point, which decomposed continuously into duplothiacetone and acetone; this substance, probably of formula C_3H_6S,C_3H_6O, may be called oxythiacetone.

By sodium-amalgam, duplothiacetone is transformed into isopropyl mercaptan, and a substance, $C_6H_{20}S'$, the sulphur analogue of mesityl oxide. With nitric acid, duplothiacetone yields besides other oxidation products, isopropyl- and methyl-sulphonic acids, and a nitroso-acid, $C_9H_{10}(SO_3H)(NO)_2$, probably derivable from the hitherto unknown thiophorone, $C_9H_{14}S$.

Chlorine converts duplothiacetone into isopropylsulphonic acid and sulphonyl chloride and chlorine derivatives of formulæ, C_6H_6SClO, and $C_6H_6SCl_2O$, probably also referable to mesityl sulphide.

V. H. V.

Isonitroso-compounds. By B. WESTENBERGER (*Ber.*, 16, 2991—2998).—*Isonitrosoisopropylacetone*, $Me.CO.C(NOH).CHMe_2$. This member of the series of isonitrosoketones, of which nitrosoacetone is the first, is obtained by dissolving isopropyl acetoacetate in dilute potash, treating the solution with sodium nitrite in excess, and afterwards acidifying it. On evaporating the ethereal extract, it yields white crystals melting at 75°, and soluble in alcohol, ether, alkalis, and hot water, but only sparingly soluble in cold water.

Œnanthaldoxime, $C_7H_{15}NO$.—This aldoxime is obtained by the action of hydroxylamine on an alcoholic solution of œnanthaldehyde. It crystallises from alcohol in white plates melting at 50° and boiling at 125°, and is soluble in ether and hot water. Unlike the known aldoximes, it does not combine with dry hydrochloric acid or with sodium ethylate to form a sodium compound, but with silver nitrate it yields a compound, $(C_7H_6NO)_2.AgNO_3$; this is soluble in hot water, and was proved to be a nitrite by its reaction with diphenylamine. *Ethyl œnanthaldoxime*, $C_9H_{19}NO$, formed by the action of sodium ethylate and ethyl iodide, is an oil boiling at 185—187°.

Anisaldoxime, $C_8H_9O_2N$, melting at 45°, and *Cuminaldoxime*, $C_{10}H_{13}NO$, melting at 52°, obtained by the action of hydroxylamine on anisylaldehyde and cuminaldehyde respectively, are also crystalline substances soluble in alcohol and ether.

Terephthalaldoxime, $C_6H_4(CH:NOH)_2$, obtained by the action of hydroxylamine on terephthaldehyde, is also a crystalline substance melting at 114°, soluble in alcohol and ether. This compound was prepared in order to ascertain if one or both aldehyde-groups would be acted on by hydroxylamine. The *ethyl derivative*,

$$C_6H_4(CH:NOEt)_2,$$

melts at 55°; an *acetyl derivative*, $N\overline{Ac}:CH.C_6H_4.CH:N.O\overline{Ac}$, melting at 155°, was obtained by the action of acetic chloride.

Action of Hydroxylamine on Ethylic Acetoacetate.—By this reaction ethylic β-isonitrosobutyrate, $CMe(:NOH).CH_2.COOEt$, is formed as an oil which neither crystallises, nor distils without decomposition. By saponifying it with alkali in the cold, β-isonitrosobutyric acid is obtained melting at 140° with decomposition, and but sparingly soluble in water, alcohol, or ether. The following have also been prepared: *Ethylic isonitrosomethylethylacetate*,

$$CMe(:NOH).CHMe.COOEt,$$

from ethylic methylacetoacetate; *ethylic isonitrosodiethylacetate*,

$$CMe(:NOH).CHEt.COOEt,$$

from ethylic ethylacetoacetate; and *ethylic isonitrosotriethylacetate*, $CMe(:NOH).CEt_2.COOEt$, from ethylic diethylacetoacetate.

A. B.

Action of Acids on Methyl Acetate. By W. OSTWALD (*J. pr. Chem.* [2], 28, 449—495).—When aqueous solutions of ethyl acetate, methyl acetate, or similar compounds are allowed to stand at the ordinary temperature, they undergo a slow decomposition into alcohol and acid. When dilute acids are added, the process of decomposition is accelerated. It is found that the velocity of the action is dependent on the quantity and the nature of the acid which is present. The acid does not take any chemical part in the reaction. According to Guldberg and Waage, if a be the amount of the acid, and b the amount of the salt, then the amount dx decomposed in an interval of time dt, will be proportional to the product of the masses taking part in the reaction, when a remains unaltered and b and x decrease. Therefore if a be a constant, we have $\frac{dx}{dt} = c \, . \, a \, (b - x)$ or $- \log (b - x) = cat - \log b$ (the log being natural). This equation $\log b - \log (b - x) = cat$ represents very correctly the progress of this reaction. b represents not the whole of the salt which is present; but only that part which is decomposable. The author finds that if acetone be added to the solution, the progress of the decomposition is retarded in exact proportion to the amount of acetone which is present. Methyl alcohol exerts a greater, but not quite so regular, influence. Ethyl alcohol occasions great irregularity in the decomposition, and the general formula does not appear to be trustworthy in this case.

Experiments made with hydrochloric, hydrobromic, and nitric acids, show conclusively that the rate of decomposition varies with the amount of acid present.

The nature of the acid employed affects the rate of decomposition. The following numbers, given in columns I and II, compiled from an extensive series of experiments, represent the velocities for various acids referred to HCl = 100. Column III contains results obtained by the volume method (*J. pr. Chem.* [2], 18, 362, 1878). Columns IV and V consist of figures obtained in an investigation of the solubility of calcium oxalate in acids, made for the purpose of estimating their affinities :—

J. I. W.

New Method of Preparing Glycocine. By M. NENCKI (*Ber.*, **16**, 2827—2828).—This consists in heating chloracetic acid with three times its weight of dry powdered ammonium carbonate, the operation being conducted in an open flask in a bath of sulphuric acid. The action begins at 60—70°, and on gradually raising the temperature to 130°, the mass, after previously melting, again solidifies. The melt is dissolved in water, boiled with lead oxide to expel the ammonia, the lead separated by means of hydrogen sulphide, and the filtrate concentrated on a water-bath. The yield by this method is 20 per cent. of theory. A. K. M.

Action of Carbamide on Ethylic Acetoacetate. By R. BEHREND (*Ber.*, **16**, 3027—3028).—Carbamide and ethylic acetoacetate combine at 100—110° with separation of water. The product, $C_7H_{12}N_2O_3$, is insoluble in water, soluble in ether and alcohol, and forms crystalline needles melting at 147°. The quantity is, however, small, being only 10 to 20 per cent. of the acetoacetate employed. On heating the new compound with dilute acids, it is reconverted into carbamide and ethylic acetoacetate. With sodium acetate, it readily forms a compound of the formula $C_5H_7N_2O_3Na$. The author is investigating the constitution and properties of these compounds, and the action of substituted carbamides and ketones on ethylic acetoacetate. A. B.

Preparation of Glycollic Acid. By A. HÖLZER (*Ber.*, **16**, 2954—2957).—On boiling monochloroacetic acid with water, the glycollic acid formed is prevented by the resulting hydrochloric acid from crystallising. In the use of caustic potash a difficulty is found in the separation of the potassium glycollate from potassium chloride; and in the use of caustic lime a diglycollate is obtained along with calcium glycollate, the separation of the two being difficult. The author's method is to add 560 grams powdered marble to 500 grams monochloroacetic acid, dissolved in 4 litres water, and to heat these in a flask with upright condenser on the water-bath for two or three days. On cooling, a crystalline mass is obtained, which consists of two or three layers; the top one is a hydrated calcium glycollate, $Ca(C_2H_3O_3)_2 + 4H_2O$; the second, which does not always exist, is anhydrous calcium glycollate; and the lowest is a double salt of calcium chloride and glycollate, $CaClC_2H_3O_3 + 3H_2O$. The second layer can be converted into the first by dissolving it in boiling water and recrystallising; and the third also by dissolving it in boiling water, recrystallising, and forcing out the more soluble calcium chloride in a filter-press. About 66 per cent. of the theoretical quantity can thus be obtained. The acid is obtained by precipitating the calcium salt with oxalic acid. The author finds that calcium glycollate crystallises with 4 mols. of water of crystallisation, and gradually loses part of them over sulphuric acid. A. B.

Water of Crystallisation of Normal and Acid Potassium Succinate. By T. Salzer (*Ber.*, 16, 3025—3027).—Owing to the improbability of these salts having the same number of molecules of water of crystallisation and also to the disagreement in Fehling's and Döppling's determinations, fresh specimens were prepared and analysed. The author finds that normal potassium succinate crystallises over sulphuric acid in large thin plates as $C_4H_4O_4K_2 + 3H_2O$, which at 100° lose 2 mols. H_2O; the third at 130°. The acid salt was found to have the formula $KHC_4H_4O_4 + 2H_2O$. A. B.

Action of Hydroxylamine on Carboxytartronic Acid. Ethers of Isonitrosophenylacetic Acid. By A. Müller (*Ber.*, 16, 2985—2987).—By acting on sodium carboxytartronate with hydroxylamine nitrate and subsequent addition of silver nitrate, a precipitate is obtained. On removing the silver from this precipitate by hydrochloric acid, filtering, and evaporating the solution over sulphuric acid in a vacuum, an acid crystallised out in prisms; on analysis this was found to be di-isonitrososuccinic acid. Its formation is represented by the equation $COOH.CO.CO.COOH + 2H_2N.OH = 2H_2O + COOH.C(N.OH).C(N.OH).COOH$. This acid melts at 128°, but explodes at a somewhat higher temperature. It gives insoluble salts with the heavy metals. Some of its properties are similar to those of isonitrosomalonic acid. This formation is in accordance with the constitutional formula COOH.CO.CO.COOH for carboxytartronic acid, as advocated by Kekulé (Abstr., 1884, 41), but not with the supposed formula $C(COOH)_3.OH$.

The author has prepared methyl isonitrosophenylacetate,

$$CPh(NOH).COOMe,$$

melting at 138°, from isonitrosophenylacetic acid, and by the action of sodium ethylate and methyl iodide on this, dimethyl isonitrosophenylacetate, CPh(NOMe).COOMe, melting at 55—56°, is formed. Both compounds are crystalline; the former is soluble in boiling water, whilst the latter is insoluble, and both decompose on attempting to distil them. A. B.

Furfuraldehyde Derivatives. By E. ODERNHEIMER (*Ber.*, **16**, 2988—2991).—This investigation of the action of hydroxylamine on compounds of the furfuraldehyde group was undertaken in the hope of throwing some further light on the constitution of the radical C_4H_3O.

Furfuraldoxime, $C_4H_3O.CH:NOH$, is obtained by the action of 2 mols. hydroxylamine hydrochloride and soda on furfuraldehyde, and is deposited in thin, white, odorous refractive crystals from its solution in light petroleum, but in spite of frequent recrystallisations, it had an inconstant melting point. Analysis leads to the above formula. An attempt to replace the second oxygen-atom by the action of hydroxylamine hydrochloride in excess failed, and the author has also failed to obtain an isomeride of the compound, which, owing to the variable melting point, was suspected to be present. Furfuraldoxime melts at 89°, and is soluble in ether, alcohol, carbon bisulphide, benzene, and glacial acetic acid, and sparingly in water. It distils at 201—208° with slight decomposition. By oxidising reagents, it is decomposed with evolution of hydrocyanic acid, but reducing reagents give negative results. It evolves hydroxylamine when boiled with acids.

Furfuraldoxime hydrochloride, $C_4H_3O.CH:NOH,HCl$, is obtained by the action of dry hydrochloric acid gas on the ethereal solution of furfuraldoxime; it is a white crystalline mass, soluble in alcohol and water, and readily decomposed on exposure to air with evolution of hydrochloric acid. The sodium salt, $C_4H_3O.CH:NONa + 3H_2O$, obtained by the action of sodium ethylate on an ethereal solution of furfuraldoxime, is soluble in alcohol, and gives characteristic coloured precipitates with the salts of the heavy metals.

Ethylfurfuraldoxime, $C_4H_3O.CH:NOEt$, is obtained by the action of sodium ethylate and ethyl iodide on the aldoxime, and extraction with ether. Furfuraldoxime yields dye-stuffs with aniline, toluidine, &c.

Hydroxylamine does not act on pyromucic acid or on furfuryl alcohol; it is also without action on phthalanil and phthalimide. A. B.

Synthesis of Pyrocoll. By G. L. CIAMICIAN and P. SILBER (*Gazzetta*, 563—567).—This substance, obtained by the dry distillation of gelatin (Abstr., 1881, 295), and represented by the empirical formula C_5H_3NO, has been regarded as probably consisting of the anhydride of carbopyrrolic acid, $C_5H_5NO_2 - H_2O = C_5H_3NO$; but it has not hitherto been prepared by dehydration of this acid. Moreover, its vapour-density indicates that its true formula is $C_{10}H_6N_2O_2$, and this conclusion is confirmed by the existence of a monobromo-derivative, $C_{10}H_5BrN_2O_2$. The dehydration of carbopyrrolic acid cannot be effected by means of the ordinary dehydrants, P_2O_5, SO_4H_2 or HCl, but the authors have effected it through the medium of the acetyl-derivative, which, when heated to 300°, gives off a molecule of acetic acid and leaves pyrocoll, $2C_5H_4\overline{Ac}NO_2 = 2\overline{Ac}OH + C_{10}H_6N_2O_2$.

The preparation is effected by distilling a solution of carbopyrrolic acid in acetic anhydride, and heating the oily residue to the temperature above mentioned; the pyrocoll then sublimes in yellow scales, which melt at 267°, and exhibits all the properties of pyrocoll obtained from gelatin. H. W.

The Thiophene and Pyrroline Groups. By V. MEYER (*Ber.*, 16, 2968—2975).—In this preliminary notice the field which the author with his collaborators intends to take up in the study of the derivatives and homologues of thiophene is defined. For purposes o nomenclature, it is proposed to call the radical C_4H_3S *thienyl*, by contraction of thiophenyl, to distinguish it from other phenyl derivatives containing sulphur.

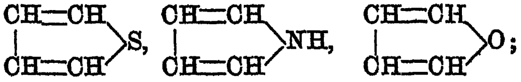
Simple Condensation-products of Thiophene.—Like aromatic hydrocarbons, thiophene gives condensation-products. With chloral in presence of glacial acetic acid and sulphuric acid, a crystalline substance, $CCl_3CH : (C_4H_3S)_2$, is formed; a similar compound with bromal; and with methylal, a compound dithienylmethane, so closely resembling diphenylmethane as to have even the same strong characteristic smell of oranges, are formed. Almost all the thiophene derivatives give the blue colour due to the formation of indophenine when heated with isatin and sulphuric acid. Thiophene reacts with benzyl chloride, benzoic chloride, and phthalic chloride in presence of aluminium chloride, due regard being paid to the prevention of formation of sulphuretted hydrogen; with benzoic chloride it forms for example phenylthienyl ketone, $Ph.CO.C_4H_3S$, analogous to diphenyl ketone. This derivative yields with hydroxylamine the isonitroso-compound $CPh(NOH).C_4H_3S$, which latter, when heated with soda-lime, breaks up directly into benzoic acid and thiophene. The investigation of similar consequential reactions is in process.

Homologues of Thiophene.—Owing to the difficulty of obtaining the monobromo-derivative of thiophene, Fittig's synthesis, which doubtless otherwise would be found applicable, has not been available for the formation of methylthiophene. As, however, the purest toluene obtained from tar contains some sulphur, the presence of methylthiophene was suspected (Abstr., 1884, 45), and on treatment of 2000 kilos. in a manner similar to that by which thiophene was obtained from benzene (Abstr., 1883, 1091), it was extracted. The pure substance has not yet been isolated, but dibromomethylthiophene, C_4HBr_2Me, has been obtained chemically pure, and is an oil similar in character to aromatic dibromo-derivatives, boiling at 227—229°. The corresponding thiophenes may be expected to be obtained from coal-tar xylene, and cumene. Thiophene also yields a large number of dye-stuffs. The violet dye-stuff obtained by the action of phenylglyoxylic acid on benzene is due to the presence of thiophene. As a general rule, ketones which consist only of carbon, hydrogen, and oxygen, give dye-stuffs with thiophene if they contain the group CO.CO; simple ketones, or double ketones which do not contain the two carbonyl groups as above, do not. Phenanthraquinone yields a violet dye-stuff, $C_{19}H_{12}SO$, with methylthiophene, and with thiophene a green dye-stuff, insoluble in ether, benzene, light petroleum, and concentrated sulphuric acid, but soluble in chloroform. Dibenzoyl and thiophene give a blue, and alloxan and thiophene a deep-blue dye-stuff; on the other hand, phenyl methyl ketone (acetophenone), diphenyl ketone (benzophenone), anthraquinone, &c., give none. Phenanthraquinone, as an ortho-diketone, yields a dye-stuff, whilst anthraquinone does not. Thiophene also yields dye-stuffs with isatin, benzoyl cyanide, &c., and various aldehydes (with benzaldehyde a deep blue); but the formation of these is due to a more complicated condensation than the above. The intensity of the dye-stuff formed depends on the chromogenic nature of the substance containing the group CO.CO. Thus with compounds of the aromatic series or of the uric acid group, the colours are beautiful and deep, whilst this is less the case with compounds of the paraffin series.

Thiophenesulphonic Acid.—In conjunction with Weitz the author has prepared numerous derivatives of this acid, some of which have been already described (Abstr., 1884, 45), and at present they are investigating the sulphinic acid derivative, $C_4H_3S.SO_2H$, and the mercaptan, $C_4H_3S.SH$; the latter is of special interest, as the corresponding compound, $C_4H_3S.OH$, has not yet been obtained.

Coal-tar Dyes containing Nitrogen.—From a coal-tar oil distilling between 90° and 109°, the author has also obtained with isatin and dilute sulphuric acid a deep blue dye-stuff, which has been found to be due to the presence of pyrroline. The same dye-stuff has been obtained with ease from pure pyrroline. It is an indigo-blue powder, soluble in acetic acid, but only sparingly in alcohol, ether, and concentrated sulphuric acid.

From these and other properties the author considers that thiophene, pyrroline, and furfurane (*Ber.*, 16, 1476) must be considered analogous, as shown by the graphic formulæ:—



also that they are related to benzene by the replacement of one of the three acetylene-groups which form the benzene molecule by S, NH, or O, and that this takes place without obliterating the peculiar characteristics of benzene and its derivatives. A. B.

Oxidation of Diethylbenzene. By ALLEN and UNDERWOOD (*Bull. Soc. Chim.*, **40**, 100—101).—The diethylbenzene boiling at 176—179°, obtained as one of the products of the action of ethyl chloride on benzene in presence of aluminium chloride, if submitted to partial oxidation with chromic acid mixture yields an acid,

$$COOH.C_6H_4.CH_2.COOH,$$

crystallising in white needles, which sublime without melting at 200—210°. By more prolonged oxidation of this acid, or by oxidation of the original hydrocarbon with potassium permanganate, the [1 : 3] phthalic acid is formed. Further experiments on the relation between the diethylbenzene and of these acids derived from it are promised.

V. H. V.

Preparation of Mesitylene. By E. VARENNE (*Bull. Soc. Chim.*, **40**, 266—267).—Attempts to convert acetone into mesitylene by the action of zinc chloride under different conditions led to negative results. A good yield was obtained by treating 180 grams of acetone with 300 grams of strong sulphuric acid for an hour. The liquid is then heated in a flask until it begins to froth up, when it is distilled in a current of steam; 40 grams of mesitylene were obtained from the distillate. W. C. W.

Bromine Derivatives. By V. MERZ and W. WEITH (*Ber.*, **16**, 2890—2896).—Chloranil is comparatively readily converted into perchlorobenzene by the action of phosphorus pentachloride (*Annalen*, **146**, 12), whilst the analogous conversion of bromanil into perbromobenzene is found to require a much higher temperature (260—280°), and to be even then very incomplete. Perbromobenzene is more readily obtained by heating pentabromophenol with phosphorus pentabromide. Berthelot and Jungfleisch showed that acetylene tetrachloride is decomposed at 360° into perchlorobenzene and hydrochloric acid. On heating acetylene tetrabromide in a sealed tube at 300°, it becomes carbonised, a trace of a substance being, however, obtained which does not melt at 300°, and is probably perbromobenzene. On heating benzonitrile with bromine containing iodine at about 350°, it is converted into perbromobenzonitrile; this is very sparingly soluble in boiling alcohol or ether, and is not readily dissolved by hot benzene or carbon bisulphide. It melts above 300°, and sublimes with slight carbonisation in the form of long slender needles; it is no less stable than the corresponding chlorine derivative, hydrochloric acid at 200° having scarcely any action on it, although alcoholic alkali at 180—200° slowly decomposes it with formation of ammonia and metallic chloride. By the action of an excess of bromine on potassium ferro- and ferri-cyanides, an abundant yield of cyanuric bromide is produced, from which pure cyanuric acid can be readily obtained. When ferrocyanide is employed, it should be heated with 10 times its weight of bromine for 8—10 hours at 200—220°, whilst in the case of potassium ferricyanide 6 parts of bromine are recommended, the mixture being heated for 5—6 hours at about 220°. A. K. M.

Exhaustive Chlorination of Aromatic Substances. I. By V. MERZ and W. WEITH (*Ber.*, **16**, 2869—2889).—Ruoff showed that the energetic chlorination of diphenyl yields perchlorodiphenyl and not perchlorobenzene (*Ber.*, **9**, 1491). Phenanthrene on the other hand, although a diphenyl-derivative, is converted into perchlorobenzene. In the case of certain diphenyl-derivatives, different results were, however, obtained, being affected apparently either by the way in which the chlorination is carried out, or by the presence of impurities. The chlorination is effected by treating the substance with a large excess of antimony pentachloride, and after the reaction (if any) has ceased, heating the mixture gradually up to 360°, and maintaining it at this temperature until no more hydrochloric acid is liberated. If antimony pentachloride acts too violently, the substance is first treated with chlorine, and subsequently with the pentachloride. At the end of the reaction, the decomposed pentachloride is renewed, and the mixture again heated to insure complete chlorination. Treated in this way, phenanthraquinone (unlike phenanthrene) is converted almost entirely into perchlorodiphenyl with formation of very little perchlorobenzene. Diphenic acid yields similar results, although a somewhat larger proportion of perchlorobenzene, whilst in the case of diphenyleneglycollic acid, a large proportion of perchlorodiphenyl was obtained in some experiments, and in others a considerable amount of perchlorobenzene. Similar differences were observed with carbazol, but as a rule the perchlorobenzene is largely in excess of the perchlorodiphenyl, although under certain conditions the latter alone is produced. Benzidine yields principally perchlorobenzene with very little perchlorodiphenyl. Ditolyl yields perchlorodiphenyl and perchloromethane, whilst dibenzyl, trimethylmethane, and diphenylenephenylmethane yield perchlorobenzene. Diphenyleneacetic acid and fluorene could not be completely decomposed, perchlorofluorene being apparently the chief product. The chlorination of rosaniline and violaniline is also very incomplete, very little perchlorobenzene being formed whilst the product still contained nitrogen. Chrysene is comparatively readily acted on and yields perchloromethane, perchlorethane, and perchlorobenzene; pyrene on the other hand offers a greater resistance to the action of chlorine, and yields perchloromethane and the two compounds $C_{16}Cl_{10}$ and $C_{14}Cl_{10}$. Diphenylbenzene and triphenylbenzene are converted into the corresponding chlorine-derivatives, $C_{18}Cl_{14}$ and $C_{24}Cl_{18}$, the former separating from hot nitrobenzene in crystalline grains, the latter in needles. Benzonitrile yields perchlorobenzonitrile, $C_6Cl_5.CN$, on chlorination, whilst β-naphthonitrile yields perchlorobenzene. Perchlorobenzonitrile is sparingly soluble in cold alcohol or ether, readily in boiling alcohol, from which it crystallises in clusters of colourless needles, also in carbon bisulphide and chloroform. It melts at 210°, is not acted on by hydrochloric acid even at 200°, but is decomposed when heated with alcoholic soda with formation of ammonia and metallic chloride; perchlorobenzene and perchlorodiphenyl are also decomposed when treated with alcoholic soda. From the above results, it is seen that certain diphenyl-derivatives yield perchlorobenzene, and practically no perchlorodiphenyl. From the chlorination of the immediate derivatives of benzene, no perchlorodiphenyl is produced. The formation of perchlorodiphenyl by perchlorination would seem to indicate the pre-existence of a diphenyl-substance, and the reaction will at any rate in some cases throw light on the constitution of aromatic compounds.

A. K. M.

Methyl Ethers of Phenol. By C. Vincent (*Bull. Soc. Chim.*, **40**, 106—107).—In order to convert the phenols into their corresponding methyl ethers, the sodium or potassium phenate is heated in a rapid current of commercial methyl chloride. For example, phenol is thus converted into anisoïl, together with smaller quantities of methylparacresol derived from impurities of the phenol. Similarly, α- or β-naphthol is converted into the corresponding α- or β-methyl naphthol ether.

This process is to be recommended for its simplicity of execution, and the purity of the products thereby formed. V. H. V.

Condensation of Aromatic Aldehydes with Phenols. By W. Trzcinski (*Ber.*, 16, 2835—2841).—According to Baeyer and his pupils, aldehydes of the paraffin series unite with phenols in the proportion of 1 mol. to 2, whilst with aromatic aldehydes they unite in equal molecular proportions (*Ber.*, 5, 25, 280, 1094; 6, 220; 7, 1181). By the action of salicylaldehyde on phenol, Liebermann (*Ber.*, 9, 800; 11, 1436) obtained a substance the composition of which differed entirely from that indicated in either of the equations: $2C_7H_6O_2 + 2C_6H_6O - H_2O = C_{26}H_{22}O_5$ or $C_7H_6O_2 + 2C_6H_6O - H_2O = C_{19}H_{16}O_3$, and from parahydroxybenzaldehyde and phenol he obtained a compound, $C_{26}H_{22}O_6$, which he imagined to be formed thus: $2C_7H_6O_2 + 2C_6H_6O + O = C_{26}H_{22}O_6 + H_2O$, and to have the constitution—

$$(C_6H_4.OH)_2C(OH).C(OH).(C_6H_4.OH)_2.$$

By heating parahydroxybenzaldehyde (5 parts) with β-naphthol (12 parts) and concentrated sulphuric acid (50 parts) on a water-bath, the author has prepared an orange-yellow crystalline and very stable compound, which is the trisulphonic acid of a condensation-product of the formula $C_{34}H_{20}O_3$. On treating the product with water, *melinointrisulphonic acid* is obtained in yellow flakes. It yields a calcium salt readily soluble in hot water, and on decomposing this with hydrochloric acid, a yellow precipitate is produced which is a compound of the new substance with hydrochloric acid. Melinointrisulphonic acid is insoluble in absolute alcohol, moderately soluble in water. In thin layers it is pink with a green fluorescence, and in thicker layers pure yellow. Concentrated sulphuric and nitric acids dissolve it readily with green fluorescence; but it is precipitated from its aqueous solution by mineral acids. In alkaline solution it can be reduced by zinc-dust, and on treating the filtrate with hydrochloric acid, the reduction-product separates in brownish-red, concentrically grouped prisms, which readily oxidise to the original substance.

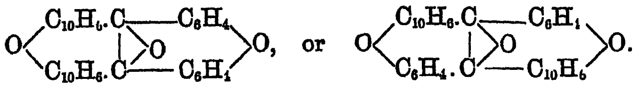
Melinointrisulphonic acid does not melt at 300°; it is a powerful acid, forms colourless solutions with the alkalis, and is not precipitated from its salts by dilute acetic acid. The potassium salt,

$$C_{34}H_{17}O_3(SO_3K)_3,$$

forms slender colourless needles readily soluble in water, sparingly in alcohol; it contains water of crystallisation, which it loses in the desiccator. The calcium salt $(C_{34}H_{17}O_3)_2(S_2O_6Ca)_3$, also forms colourless needles containing water of crystallisation, whilst the barium salt, $(C_{34}H_{17}O_3)_2(S_2O_6Ba)_3$, is obtained as an amorphous precipitate, or from very dilute solutions in microscopic needles. The ammonium salt crystallises in slender silky colourless needles, readily soluble in water.

Melinointrisulphonic acid is also formed when β-naphtholsulphonic acid is employed in the place of naphthol, but cannot be produced from salicylaldehyde and β-naphthol, nor from parahydroxybenzaldehyde and α-naphthol, nor from β-dinaphthol and parahydroxybenzaldehyde.

It is, however, produced on heating bitter almond oil with β-naphthol and sulphuric acid at 200—220°, this being the most economical method of preparing it in quantity. Disregarding the sulphonic groups, the author regards the constitution as represented by one of the following formulæ :—



The composition of the substance obtained from salicylaldehyde and phenol shows that oxidation occurs in these condensations besides the separation of water. The author has prepared this compound by the method employed by Liebermann (*Ber.*, **11**, 1437), and obtained a dye-stuff which does not form a crystalline product with hydrochloric acid, its alkaline solution having a more violet shade than aurin. From its formula, $C_{19}H_{14}O_4$, the author names it oxyaurin, and explains its formation by the following equation :—

$$C_7H_6O_2 + 2C_6H_6O + O_2 = C_{19}H_{14}O_4 + 2H_2O.$$

A. K. M.

Action of Aniline on Resorcinol and Quinol. By A. Calm (*Ber.*, **16**, 2786—2814).—When resorcinol (1 mol.) is heated with aniline (4 mols.) and anhydrous calcium chloride (2 mols.) for 8 hours at 270—280°, *metahydroxydiphenylamine*, $C_6H_4(OH).NHPh$, is formed and can be separated either by solution in hydrochloric acid and subsequent precipitation of the base, or by distillation with superheated steam. It crystallises in white nacreous scales, melts at 81·5—82°, and distils at about 340° ; it dissolves in large quantities of water and also in acids and in alkalis with formation of salts, the hydrochloric acid solution yielding a yellowish crystalline precipitate with platinic chloride. It is also readily soluble in wood spirit, alcohol, ether, acetone, and benzene, sparingly in light petroleum; it dissolves in pure concentrated sulphuric acid without coloration, but a little nitric acid colours the solution deep red-brown; sodium nitrite produces a yellowish-green, and manganese dioxide a bluish-violet coloration. Metahydroxydiphenylamine is reduced by distillation with zinc-dust to diphenylamine. *Metahydroxydiphenylamine sulphate*, $(C_{12}H_{11}NO)_2,H_2SO_4$, crystallises in lustrous needles, and is rapidly decomposed by water or alcohol. The *hydrochloride*, $C_{12}H_{11}NO,HCl$, forms readily decomposable small white needles. The potassium and sodium derivatives crystallise from warm concentrated alkali in colourless needles; their solutions yield precipitates with the alkaline earths and heavy metals. The *barium derivative*, $(C_{12}H_{10}NO)_2Ba,5H_2O$, forms crystalline scales soluble in water and in alcohol.

Metahydroxydiphenylamine is also produced when resorcinol and aniline are heated together at a high temperature. To prepare *diphenylmetaphenylenediamine*, $C_6H_4(NHPh)_2$, the resorcinol (1 mol.) is best heated with aniline (4 mols.), calcium chloride (3—4 mols.), and zinc chloride (½ mol.) for 30—40 hours at about 210°, and the product treated with glacial acetic or hydrochloric acid, the hydroxy-diphenylamine being separated by washing with water and treatment with alkali. It forms colourless needles melting at 95°, is insoluble in water, dilute acids, and alkalis, slightly soluble in concentrated hydrochloric acid, readily in concentrated sulphuric acid; it is readily soluble in ether and hot benzene, less so in cold benzene and hot alcohol, sparingly in cold alcohol, and warm light petroleum. Its colourless solution in sulphuric acid becomes yellowish-green, and then bluish-violet on addition of potassium nitrate or nitric acid, whilst sodium nitrite produces a reddish violet-blue coloration. Potassium dichromate produces a greenish and then a bluish-violet coloration, the latter colour being also produced on warming the sulphuric acid solution with manganese dioxide.

Diphenylmetaphenylenediamine hydrochloride, $C_6H_4(NHPh,HCl)_2$, is obtained by passing dry hydrochloric acid into a solution of the diamine in benzene. The *acetyl-derivative*, $C_6H_4(NPh\overline{Ac})_2$, is sparingly soluble in cold alcohol and ether, more readily in benzene and in chloroform, very sparingly in water and light petroleum; it melts at 163°. The *benzoyl-derivative*, $C_6H_4(NPh\overline{Bz})_2$, melts at 184°, is readily soluble in hot benzene and in chloroform, less so in hot alcohol and in ether, sparingly in cold alcohol and in light petroleum. *Dinitroso-diphenylmetaphenylenediamine*, $C_6H_4(NPh.NO)_2$, is obtained on adding hydrochloric acid to an alcoholic solution of diphenylmetaphenylenediamine and then gradually sodium nitrite. It crystallises in needles melting at 102°, and is readily soluble in alcohol, ether, benzene, and glacial acetic acid, almost insoluble in light petroleum. It dissolves in concentrated sulphuric acid with a very characteristic violet-blue coloration, whilst with phenol and sulphuric acid it yields a bluish-violet coloration gradually changing to green.

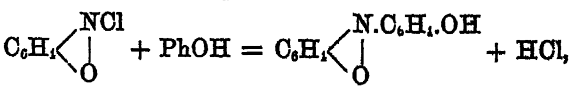
To prepare *parahydroxydiphenylamine*, $C_6H_4(OH).NHPh$, quinol (1 mol.) is heated with aniline (4 mols.) and calcium chloride (2 mols.) for 8—10 hours at 250—260°. It crystallises in scales melting at 70°, and boils at 330°. Pure concentrated sulphuric acid dissolves it almost without coloration, but the addition of nitric acid colours the solution brownish-yellow to brownish-red. It is readily soluble in methyl and ethyl alcohols, ether, chloroform, and warm benzene and toluene, sparingly in hot water, very slightly in cold water and in light petroleum; it also dissolves in acid and alkaline solutions. When distilled with zinc-dust it is converted into diphenylamine. *Parahydroxydiphenylamine hydrochloride*, $C_{12}H_{11}NO,HCl$, crystallises in white needles which become greenish by exposure to light. The derivatives of the alkali and alkaline earth-metals are more readily soluble and less crystalline than the corresponding derivatives of the meta-compound. Parahydroxydiphenylamine can likewise be obtained by heating quinol with aniline for 16 hours at 290—300°, in which case it is accompanied by a second substance which is insoluble in hydrochloric acid. *Diphenylparaphenylenediamine*, $C_6H_4(NHPh)_2$, can be most conveniently prepared by heating quinol and aniline with a mixture of zinc and calcium chlorides by themselves (see above) for 18 hours at 200—210°. Diphenylparaphenylenediamine forms colourless lustrous scales melting at 152°, and distilling unchanged at a high temperature. It is readily soluble in warm benzene, toluene, glacial acetic acid, ether, and chloroform, less readily in even warm alcohol, very sparingly in light petroleum, and is practically insoluble in dilute acids. It forms a colourless solution with pure concentrated sulphuric acid, the addition of nitric acid, potassium nitrate, or sodium nitrite producing a splendid red coloration; chlorine-water produces the same colour, whilst bromine-water colours the solution reddish-violet, then bluish-violet; manganese dioxide colours the solution violet to violet-blue. Fuming nitric acid in small quantity gives a blood-red coloration with the diamine. *Diphenylparaphenylenediamine hydrochloride*, $C_{18}H_{16}N_2,2HCl$, is obtained partly in the form of slender white needles and partly as a granular crystalline greyish-white mass, and is readily decomposed by water. The *acetyl-derivative*,

$$C_6H_4(NPh\overline{Ac})_2,$$

crystallises in small plates or prisms melting at 191·7°; it dissolves readily in warm benzene and in chloroform, less so in hot alcohol, sparingly in cold benzene, alcohol, and light petroleum, and is insoluble in water. The *benzoyl-derivative*, $C_6H_4(NPh\overline{Bz})_2$, melts at 218·5°, is moderately soluble in hot benzene, toluene, amyl alcohol, and chloroform, sparingly in cold benzene, and very sparingly in light petroleum, cold alcohol, and ether. The *dinitroso-derivative*, $C_6H_4(NPhNO)_2$, forms golden-yellow scales sparingly soluble in alcohol, ether, glacial acetic acid, benzene, and light petroleum; the alcoholic solution becomes deep red when heated, probably from decomposition. Powerful reducing agents convert it into diphenylparaphenylenediamine. The nitroso-compound is coloured red by pure sulphuric acid, the colour becoming more violet in the presence of phenol.

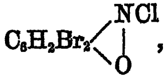
On heating parahydroxydiphenylamine with paratoluidine, and calcium and zinc chlorides, with the view to produce paratolylphenylparaphenylenediamine, $C_6H_4Me.NH\,C_6H_4.NHPh$, a different result was obtained, a substance being formed agreeing in composition and properties with *diparatolylparaphenylenediamine*, $C_6H_4(NH.C_6H_4Me)_2$, prepared from quinol and paratoluidine. Diphenylparaphenylenediamine is also produced. A. K. M.

Indophenol-like Dyes and Indophenols. By R. Möhlau (*Ber.*, 16, 2843—2857).—From differences in composition and properties, the author divides these substances into two classes: he suggests that the former (indophenol-like dyes) should be termed indophenols from their pronounced phenol character, and the latter *indoanils*, indicating their derivation from aniline. The first group contains the colouring substances first mentioned by Hirsch (*Ber.*, 13, 1909), and which may be obtained thus: By the action of quinonechlorimides on phenols, and by the oxidation of a paramidophenol and a phenol in molecular proportions. The view that the action of quinonechlorimide on phenol took place as in the equation



$$C_6H_4\Big\langle\begin{matrix}NCl\\ |\\ O\end{matrix} + PhOH = C_6H_4\Big\langle\begin{matrix}N.C_6H_4.OH\\ |\\ O\end{matrix} + HCl,$$

was not confirmed by Hirsch, as he was unable to isolate the quinonephenolimide, and the author has therefore examined the reaction, employing dibromoquinonechlorimide in the hopes of obtaining crystallisable products. To prepare *dibromoquinonechlorimide*,



$$C_6H_2Br_2\left\langle\begin{matrix}NCl\\ |\\ O\end{matrix}\right. ,$$

dibromoparamidophenol, from the corresponding paranitrophenol, is treated with chloride of lime in the usual way. The product crystallises from alcohol or glacial acetic acid in long dark yellow prisms melting at 80°, and decomposing at 121°. On introducing dibromoquinonechlorimide, mixed with dilute alcohol, into solution of phenol in caustic soda, the *sodium derivative of dibromoquinonephenolimide*,  $C_6H_2Br_2\left\langle\begin{matrix}N.C_6H_4.ONa\\ |\\ O\end{matrix}\right.$, separates. It crystallises in long prisms of a splendid golden-green lustre, but is blue by transmitted light, and yields blue solutions with water and alcohol. On warming it with dilute soda solution, the colour changes to pale red, probably from the formation of the compound $C_6H_2Br_2(ONa).N(OH)C_6H_4.ONa$. *Dibromoquinonephenolimide* is obtained on gradually adding acetic acid to a warm aqueous solution (60°) of the sodium derivative. It crystallises in dark red, almost black, prisms of metallic lustre, yields red solutions with alcohol, ether, and glacial acetic acid, but is insoluble in water. By the action of strong mineral acids it yields *dibromoparamidophenol* and *quinone*. When an alkaline solution of the sodium derivative of dibromoquinonephenolimide is warmed with glucose, the colour disappears, owing to the formation of the sodium salt of a leuco-derivative, which, from its solubility and from the readiness with which it becomes oxidised, is very difficult to isolate. *Leuco-dibromoquinonephenolimide*, $C_6H_2Br_2(OH).NH.C_6H_4.OH$, is, however, readily obtained in colourless prisms on passing sulphurous anhydride into a warm aqueous solution of the sodium salt; it dissolves readily in the usual solvents, water excepted, and melts at 170° with darkening. If the reaction between dibromoquinonechlorimide and phenol be a typical process, it proves the correctness of Hirsch's view. The colour-reactions produced by the union of dibromoquinonechlorimide with other phenols in alkaline solution, and the behaviour of dibromoquinonephenolimide towards mineral acids, show that it is the hydrogen-atom in the para-position to the hydroxyl of the phenol which is eliminated by the chlorine-atom of the chlorimides. Dibromoquinonephenolimide can also be obtained by dissolving dibromamidophenol, and phenol in caustic soda solution, and oxidation with potassium dichromate. Dibromamidophenol crystallises from alcohol in lustrous prisms, melts at 180°, is soluble in dilute acids, and much more readily soluble in alkalis.

The indophenols (indoanils) are distinguished from the above by not yielding soluble salts with the alkalis, whilst they show a more or less distinctly basic character, due to the presence of a tertiary amido-group. Phenol-blue and α-naphthol-blue can be prepared by the action of nitrosodimethylaniline on phenol, and on α-naphthol in alkaline solution at the ordinary temperature, especially in the presence of reducing agents; also by the oxidation of dimethylparaphenylenediamine and phenol (or α-naphthol) under like conditions. Trichloroquinonedimethylanilenimide, which, according to the author, also belongs to this class of substances, is formed by the action of trichloroquinonechlorimide on dimethylaniline, and from the resemblance in its properties to those of phenol-blue and α-naphthol-blue, the author assumes that these have an analogous constitution to that of trichloroquinonedimethylanilenimide, namely, that they are respectively *benzoquinonedimethylanilenimide*,  $C_6H_4<\begin{matrix}N.C_6H_4.NMe_2\\ |\\ O\end{matrix}$, and *α-naphthaquinonedimethylanenilimide*,  $C_{10}H_6<\begin{matrix}N.C_6H_4.NMe_2\\ |\\ O\end{matrix}$. On treating indophenol paste (α-naphthol-blue) with hydrochloric acid a dark yellow solution is obtained, which soon solidifies to a grey jolly, and on agitating this with ether, α-naphthaquinone is extracted, whilst dimethylparaphenylenediamine hydrochloride remains in the acid solution. Phenol-blue treated in the same way yields benzoquinone and dimethylparaphenylenediamine. A. K. M.

Crystalline Bases of Methyl-violet. By H. WICHELHAUS (*Ber.*, 16, 3044—3045).—A question of priority.

Constitution of Methylene-blue. (Preliminary notice.) By E. ERLENMEYER (*Ber.*, 16, 2857—2858).—According to the author's views Bindschedler's green has the constitution

$$NMe_2.C_6H_4.N<\begin{matrix}CH_2\\C_6H_4\end{matrix}>NMe,HCl.$$

By the action of hydrogen sulphide on this, he thinks that the compound $NMe_2.C_6H_4.NH.CH_2.NMe.C_6H_4.SH'$ may possibly be formed, which, by the action of ferric chloride, is converted into methylene-blue,  $NMe_2.C_6H_4.N<\begin{matrix}-CH_2-\\S.C_6H_4\end{matrix}>NMe$. Methylene-white is assumed to have the constitution $NMe_2.C_6H_4.NH.S.C_6H_4.NMe_2$. The author thinks it improbable that the sulphur-atom in methylene-blue occupies a position between two nitrogen-atoms, as assumed by Möhlau.

A. K. M.

Methylene-blue and Allied Dye-stuffs. By A. BERNTHSEN (*Ber.*, 16, 2896—2904).—The close relation between methylene-blue and Laut's violet obtained from paraphenylenediamine is indicated by analytical results, and if the formula $C_{24}H_{20}N_6S_2$ be halved and modified to $C_{12}H_9N_3S$, in accordance with the law of even numbers, it would seem probable that methylene-blue is homologous with Laut's violet, and that its formula is $C_{16}H_{17}N_3S$, and not $C_{16}H_{19}N_3S$, as previously supposed by the author. By heating a mixture of diphenylamine and sulphur (10 : 4) at 250—300°, hydrogen sulphide is evolved and *thiodiphenylamine*, $C_{12}H_9NS$, obtained. This appears to be the parent substance to the above dye-stuffs, the leuco-violet being probably a *diamidothiodiphenylamine*, and the leuco-blue a *tetramethyldiamidothiodiphenylamine*. Thiodiphenylamine crystallises from alcohol in pale yellow lustrous plates; it is moderately soluble in cold ether, sparingly in cold alcohol, glacial acetic acid, and benzene, although more readily when heated. It has no basic properties, melts at 180°, and can be distilled almost unchanged, its boiling point being about 371°; its vapour-density (determined in nitrogen) agrees with the formula given. It is oxidised by exposure to air, its alcoholic solution assuming a red coloration, whilst ferric chloride and bromine vapour produce a green coloration. Solid thiodiphenylamine is coloured brownish-red by nitrous acid. It forms a greenish-brown solution with cold concentrated sulphuric acid, from which water throws down a crystalline precipitate. The following is a characteristic and delicate reaction: the substance is treated with a few drops of fuming nitric acid, water added, and the product boiled with acid stannous chloride solution. The tin is then thrown down by means of zinc, and an excess of ammonia added, when the solution soon assumes an intense violet coloration from the absorption of oxygen. If ferric chloride is added after removing the tin, a reddish-violet precipitate is produced if the solution is concentrated, and a violet coloration if dilute. *Acetylthiodiphenylamine*, $C_{12}H_8NS\overline{Ac}$, prepared by boiling thiodiphenylamine with excess of acetic anhydride, is sparingly soluble in hot glacial acetic acid, alcohol, and benzene, and crystallises from alcohol in thin glistening prisms. It resembles thiodiphenylamine in its behaviour to sulphuric acid, and in giving the above colour reaction. *Methylthiodiphenylamine*, $C_{12}H_8NSMe$, obtained on heating thiodiphenylamine with methyl iodide and methyl alcohol at 100—110°, forms magnificent long prisms, is moderately soluble in cold alcohol and ether, readily in hot alcohol, melts at 99·3°, and volatilises at higher temperatures almost unchanged. It yields a greenish-brown solution with sulphuric acid, and with nitric acid a bright yellow nitro-derivative; when this is treated with stannous chloride and hydrochloric acid, a product is obtained crystallising in white needles. *Ethylthiodiphenylamine*, $C_{12}H_8NSEt$, melts at 102°, and crystallises from hot alcohol in long thin white prisms. The formula of thiodiphenylamine is probably

$C_6H_4<\begin{smallmatrix}NH\\S\end{smallmatrix}>C_6H_4$. By the oxidation of its methyl-derivative by potassium permanganate, a substance, $C_{13}H_{11}NSO_2$, is obtained, which is probably *methyldiphenylaminesulphone*. It is sparingly soluble in alcohol, ether, and glacial acetic acid, insoluble in water; it melts at about 222°, has neither basic nor acid properties, and is not altered by boiling concentrated potash, nor by hydrochloric acid. On heating it with concentrated sulphuric acid, a blue solution is obtained, and on pouring this into water, the colour changes to brownish-violet.

The close relationship of thiodiphenylamine to Laut's violet and to methylene-blue is indicated by the following considerations: Thiodiphenylamine is very readily acted on by nitric acid with formation of a dinitro-derivative, soluble in alkalis and in strong ammonia. On treating the nitro-derivative with acid stannous chloride solution, a colourless liquid is obtained containing the tin double salt of a leuco-base, and by the oxidation of this a violet dye-stuff is produced which bears a very close resemblance to Laut's violet. Instead of treating diphenylamine with sulphur, and subsequently introducing amido-groups, experiments are being made with the view to obtain violet and blue dye-stuffs by the introduction of sulphur into amidodiphenylamines. On reducing a slightly acid solution of dimethylphenylene-green, $C_{16}H_{19}N_3$, by hydrogen sulphide to *tetramethyldiamidodiphenylamine*, and then oxidising by means of ferric chloride, a green coloration is at first produced, but soon changes to blue-green with separation of sulphur, and finally to blue, the product containing methylene-blue. A. K. M.

Preparation of Phenylhydrazine. By V. Meyer and M. T. Lecco (*Ber.*, **16**, 2976).—Phenylhydrazine hydrochloride is easily obtained by the action of stannous chloride and hydrochloric acid on diazobenzene chloride, $PhN\colon N.Cl + 3HCl + 2SnCl_2 = 2SnCl_4 + NHPh.NH_2$. It may be obtained direct from aniline by dissolving 10 grams aniline in 200 grams concentrated hydrochloric acid, and slowly adding to the cooled solution 7·5 grams sodium nitrite dissolved in 50 c.c. water, and afterwards 45 grams stannous chloride dissolved in 415 grams concentrated hydrochloric acid. The reaction takes place at once, and a white crystalline mass of the salt is obtained. By decomposing this with alkali and exhausting with ether the pure base may be obtained in the crystalline state. A. B.

Action of Aldehydes on Phenols. (I.) By A. Michael (*Amer. Chem. J.*, **5**, 339—349).—Benzaldehyde and resorcinol may be heated together in closed vessels for days without any reaction occurring; heated in sealed tubes at 200° a resinous substance is formed. In the presence of acids, on the contrary, the substances react with great readiness. The addition of one drop of hydrochloric acid to a solution of 1 gram resorcinol and 1 gram benzaldehyde in 3 grams absolute alcohol causes the temperature to rise to 55—60°, and a crystalline deposit is formed. The filtered alcoholic liquid is poured into water, when a white resin is precipitated; this cannot be crystallised, and assumes a reddish tinge if dried in a current of carbonic anhydride; analysis gave numbers agreeing with the formula $C_{26}H_{20}O_4$. It is readily soluble in alcohol, benzene, ether, and glacial acetic acid, and also in alkalis. It melts at about 330° with decomposition. The acetyl-derivative, $C_{26}H_{16}O_4\overline{Ac}_4$, which is white and amorphous, is somewhat less soluble than the resin. The crystalline deposit mentioned above is formed by the action of acids on the resin; it is best prepared by heating 5 parts of benzaldehyde and 10 parts of resorcinol in 20 parts of water on the water-bath, and then adding a few cubic centimeters of very dilute hydrochloric acid. It consists of two substances, one crystallising in square plates, the other in needles. The former, which is separated by extracting the deposit with alcohol, has the formula $C_{26}H_{20}O_4 + 4H_2O$, melts with decomposition at above 330°, is moderately soluble in hot, sparingly soluble in cold alcohol, insoluble in water and ether. It dissolves in alkalis, and is reprecipitated by acids in the amorphous form. On fusion with potash it yields resorcinol and benzoic acid. The acetyl-derivative,

$$C_{26}H_{16}O_4\overline{Ac}_4,$$

crystallises in obliquely truncated, translucent prisms, insoluble in cold, sparingly soluble in hot alcohol. The second substance obtained by the action of acids on the resin is only obtained in small quantity; it crystallises in needles, and is only very slightly soluble in hot alcohol. The conversion of resorcinol and benzaldehyde into a resin is effected also by small quantities of other acids, such as sulphuric, phosphoric, acetic, oxalic acids, &c., also by the fixed alkalis and potassium carbonate. A. J. G.

Action of Aldehydes on Phenols. (II.) By A. MICHAEL and A. M. COMEY (*Amer. Chem. J.*, **5**, 349—353).—The addition of a drop of hydrochloric acid to a mixture of acetaldehyde and orcinol at 100° causes an abundant precipitate of small round plates of a substance of the formula $C_{18}H_{20}O_4$. It is insoluble in the ordinary organic solvents, but is soluble in alkalis, the solution rapidly oxidising on exposure to air. Resorcinol gives a similar substance, which could not, however, be obtained in a state fit for analysis.

Five parts of chloral hydrate, 10 parts resorcinol, and 40 parts of water were heated for 12—24 hours in a flask provided with a reflux condenser; a crystalline product separates which, after purification, forms fine yellowish needles of the formula $C_8H_6O_3$, somewhat soluble in hot water, readily soluble in hot alcohol and acetic acid. Its solution in concentrated sulphuric acid assumes a fine blue colour on exposure to air. Potassium permanganate completely oxidises it to carbonic anhydride. The acetyl-derivative, $C_8H_4O_3\overline{Ac}_2$, forms white prismatic crystals melting at 120°. The benzoyl-derivative, $C_8H_4O_3\overline{Bz}_2$, is obtained in small crystals of a slight pinkish tint melting at 165°. Chloral hydrate and orcinol yield a similar compound melting at 250°, whose acetyl-derivative melts at 150°. A. J. G.

Action of Bromacetophenone on Ethyl Sodacetoacetate. By C. PAAL (*Ber.*, **16**, 2865—2869).—By the action of bromacetophenone on ethyl sodacetoacetate in alcoholic solution, sodium bromide separates, and in a few minutes the reaction is complete:—

$$CH\overline{Ac}Na.COOEt + CH_2Br.COPh = CH_2\overline{Bz}.CH\overline{Ac}.COOEt + NaBr.$$

The product is diluted with water, the oil which separates taken up with ether, the solution dried with calcium chloride and evaporated. The heavy, slightly reddish-brown coloured oil obtained (*ethyl acetophenoneacetoacetate*) is almost insoluble in water; it is decomposed by distillation, even under diminished pressure. In order to prepare acetophenoneacetoacetic acid, $CH_2\overline{Bz}.CH\overline{Ac}\,COOH$, its ethyl-derivative is treated with rather more than the calculated quantity of a 2 per cent. aqueous potash solution for some hours with repeated agitation; it is then filtered into dilute sulphuric acid, when the liquid at first becomes milky, the liberated acid however soon becoming crystalline. This is extracted with ether, the solution evaporated, and the crystalline mass washed with ether to remove adhering oil. It is of a pure white, but rapidly becomes yellow, dissolves in alkalis with a yellow colour, and on warming the solution an oil separates; but from a cold solution the acid can be reprecipitated unchanged by mineral acids. It melts at about 130—140°, heat decomposing it into carbonic anhydride and an oil. Owing to the readiness with which it is decomposed, this acid has not been obtained pure enough for analysis; after two crystallisations from ether the oil already mentioned alone remains. This oil is *acetophenoneacetone*,

$$CH_3.CO.CH_2.CH_2.COPh,$$

and can be obtained in larger quantities by heating acetophenoneacetic acid with absolute alcohol, when carbonic anhydride is abundantly evolved. Acetophenoneacetone is a yellowish oil, heavier than water, in which it is sparingly soluble in the cold, somewhat more readily when heated; it is insoluble in alkalis. By distillation under diminished pressure, water is given off, an oil of penetrating odour passing over, whilst a portion of the diketone is entirely decomposed. The author has not succeeded in obtaining a di-isonitroso-derivative by means of Meyer's hydroxylamine reaction. The mon-isonitroso-derivative,

$$CMe(NOH).CH_2.CH_2.COPh \text{ or } CH_3.CO.CH_2.CH_2.CPh : NOH,$$

is obtained on mixing the calculated quantities of hydroxylamine, diketone, and sodium carbonate in dilute alcoholic solution, when it soon separates in small crystals. It forms long white lustrous needles melting at 122—123°, and soluble in acids and in alkali. When ethyl acetophenoneacetoacetate is added to boiling alcoholic potash, the mixture boiled for a short time, poured into water and dilute sulphuric acid added, an acid, $C_{12}H_{10}O_3$, is precipitated in yellowish flakes; this crystallises from dilute alcohol in clusters of long needles melting at 114—115°. Its formation is explained thus:—$C_{14}H_{16}O_4 + KOH = C_{12}H_9O_3K + C_2H_5OH + H_2O$. A. K. M.

Substituted Benzoic Acids. By H. HÜBNER (*Annalen*, **222**, 166—203). Part II.—This paper is a continuation, in conjunction with other investigators, of Part I, already abstracted (this vol., 314).

V. Metabromometanitrobenzoic Acid and its Derivatives. By F. HESEMANN and L. KÖCHLER.—Metamidometanitrobenzoic acid is dissolved in glacial acetic acid, aqueous hydrobromic acid (sp. gr. 1·49) added, the cold mixture saturated with nitrous anhydride, and the whole then heated until nitrogen ceases to be evolved. The crude acid is purified by means of its crystalline barium salt. Metabromometanitrobenzoic acid crystallises in needles or plates melting at 161°. It is easily soluble in alcohol, ether, and glacial acetic acid, more sparingly in benzene, carbon bisulphide, and chloroform, very sparingly in water. The *potassium salt*, $C_7H_3BrNO_4K + \frac{1}{2}H_2O$, crystallises in long, yellowish, glistening needles: the *barium salt*, $(C_7H_3BrNO_4)_2Ba + 5\frac{1}{2}H_2O$, in colourless needles easily soluble in boiling, sparingly so in cold water: the *calcium salt*, $(C_7H_3BrNO_4)_2Ca$

+ H_2O, in colourless prisms: the *magnesium salt* in colourless needles with 1 mol. H_2O: the *zinc salt* in small colourless needles with $4\frac{1}{2}H_2O$: the *cadmium salt* in colourless needles with $4\frac{1}{2}H_2O$: the *strontium salt* in colourless anhydrous needles: the anhydrous *silver salt* forms a white precipitate very sparingly soluble in boiling water, from which it crystallises in long colourless needles: the *lead salt* forms a white precipitate.

Metabromometamidobenzoic acid was obtained by the reduction of the nitro-acid with tin and hydrochloric acid. It is thus obtained in the form of its hydrochloride, from which the free acid is liberated by sodium acetate. It crystallises in needles melting at 215°, easily soluble in alcohol, sparingly in benzene, almost insoluble in water. The metallic salts crystallise with difficulty; those formed with acids easily. The hydrochloride, $C_7H_6BrNO_2,HCl$, crystallises in prisms easily soluble in boiling water: the sulphate, $(C_7H_6BrNO_2)_2,H_2SO_4$, in prisms which are decomposed by water. The *barium salt* crystallises with $4H_2O$; the *calcium salt* with $5\frac{1}{2}H_2O$; the *silver salt* forms an almost insoluble crystalline precipitate. *Dimetabromobenzoic acid* was obtained from the bromamido-acid by means of the diazo-reaction. It is easily soluble in alcohol and glacial acetic acid, sparingly in benzene and boiling water; crystallises in flakes and melts at 213—214°. The *barium salt* crystallises in colourless needles with $4H_2O$; the *calcium salt* with $5H_2O$; the *cadmium salt* with $4H_2O$; and the *lead salt* forms an insoluble white precipitate.

Dimetabromorthonitrobenzoic acid,

$$C_6H_2Br_2(NO_2).COOH\ [COOH : Br : Br : NO_2 = 1 : 3 : 5 : 2],$$

was obtained by gradually adding the dibromo-acid to about 10 times its weight of warm fuming nitric acid (sp. gr. 1·53). It crystallises in long colourless needles, sparingly soluble in boiling water, benzene, and glacial acetic acid; easily in ether and boiling alcohol. It melts at 233—234°, and sublimes unchanged. The *barium salt* crystallises with $4H_2O$; the *potassium* and *calcium salts* yield anhydrous crystals; the *lead* and *silver salts* almost insoluble white precipitates.

Dimetabromorthamidobenzoic acid, obtained by the reduction of the nitro-acid with tin and hydrochloric acid, crystallises in colourless needles soluble in glacial acetic acid, hot concentrated hydrochloric acid, and boiling alcohol; almost insoluble in water; it melts at 225°. The *barium* and *calcium salts* crystallise with $4H_2O$; the *copper salt* forms a light green crystalline precipitate: the *alkaline salts* crystallise from water with difficulty, more easily from alcohol. The ortho-position of the amido- and nitro-groups in these two acids was proved by the reduction of the amido-acid with sodium-amalgam. The orthamidobenzoic acid, melting at 143—144°, obtained, was converted into salicylic acid by the diazo-reaction.

VI. Parabromobenzoic and Parachlorobenzoic Acids and their Derivatives.

Parabromometanitrobenzoic Acid. By J. W. Raveill.—This acid, obtained by adding pure parabromobenzoic acid, melting at 248°, to slightly warmed fuming nitric acid, crystallises in long colourless needles easily soluble in alcohol and boiling water, sparingly so in cold water: it melts at 199°. *Parabromometamidobenzoic acid* was prepared by the reduction of the nitro-acid with tin and hydrochloric acid. It forms small colourless needles which become reddish when exposed to the light. It fuses at 225° and sublimes unchanged. Burghard has examined the following compounds of this acid. *Parabromometamidobenzoic acid hydrochloride* forms colourless needles which become discoloured by exposure to light; the sulphate, $(C_7H_6BrNO_2)_2,H_2SO_4$, crystallises in needles; the nitrate in flat prisms: all three compounds are decomposed by water. The *copper salt* forms a green, the *lead salt* a white insoluble powder. Metamidobenzoic acid, melting at 174°, was obtained by the action of sodium-amalgam on the bromo-amido-acid, thus proving the meta-position of the nitro- and amido-groups. *Parachlorometanitrobenzoic acid*, melting at 179—180° (Hubner and Biedermann, *Annalen*, **147**, 257), has been re-examined. Its *calcium salt*, $(C_7H_3ClNO_4)_2Ca + 5\frac{1}{2}H_2O$, forms yellowish needles which effloresce in the air: the *sodium salt*, $C_7H_3ClNO_4Na + (?)H_2O$, crystallises in long yellowish needles easily soluble in water, sparingly in alcohol. The *ethyl salt* was obtained by acting on parachlorometanitrobenzoyl chloride (prepared by treating the acid with phosphoric chloride at 120°) with alcohol. It forms long yellow needles easily soluble in alcohol, benzene, and glacial acetic acid, very sparingly so in water, and melting at 59°. *Parachlorometanitrobenzanilide* is produced by acting on the benzoyl chloride with aniline. It crystallises in shining prisms, easily soluble in alcohol, benzene, and glacial acetic acid, almost insoluble in water. It melts at 131°. By reducing the nitro-acid with tin and hydrochloric acid, it yields the amido-acid, which is further reduced to metamidobenzoic acid by the action of sodium-amalgam.

Parabromometabromobenzoic Acid. By BURGHARD and BEUTNAGEL.—This acid was obtained by diazotising parabromometamidobenzoic acid and decomposing the resulting compound with hydrobromic acid. It forms colourless needles or plates, easily soluble in alcohol, sparingly in water, and melts at 229—230°. The *barium* and *strontium salts* both crystallise in needles with $4H_2O$: the *copper salt* is precipitated from solution as an insoluble light-green powder: the *silver salt* first separates in a gelatinous form, becoming afterwards flocculent: the lead salt is pale yellow, the *zinc salt* a white powder: the *potassium salt* forms a very soluble crystalline mass. The *ethylic salt* crystallises from chloroform in long needles melting at 38—38·5°. Dibromobenzamide was prepared from the acid chloride by treatment with aniline. It crystallises in small needles melting at 151·5°.

Parametadibromorthonitrobenzoic Acid. By E. F. SMITH.—Prepared by dissolving the dibromo-acid in fuming nitric acid heated to 100°. It is easily soluble in boiling water and in alcohol, crystallises in colourless needles, melts at 162°, and sublimes under partial decomposition. The *barium salt* crystallises with 1 mol. H_2O: the *calcium salt* with $3\frac{1}{2}H_2O$: the *sodium* and *potassium salts* give easily soluble, the *magnesium salt* sparingly soluble anhydrous crystals: the *ammonium salt* forms colourless needles: *lead*, *copper*, *iron*, and *silver salts* yield respectively white, green, yellow, and white precipitates. *Parametadibromorthamidobenzoic acid*, obtained by the reduction of the nitro-acid, is very sparingly soluble in water, more easily in alcohol, from which it crystallises in colourless needles melting at 225°. The *barium salt* crystallises with $4H_2O$; the *strontium salt* with $2H_2O$; the *calcium salt* with $4\frac{1}{2}H_2O$: *copper salts* yield a yellow precipitate; *lead salts* a white precipitate; and *silver salts* a white precipitate which is decomposed by boiling water: the sodium salt yields very soluble scales. The ortho-position of the nitro- and amido-groups in these acids was proved by M. Ulrich by converting them successively into orthamidobenzoic acid and salicylic acid. Their constitution is therefore—

$$\mathrm{COOH : Br : Br :} \left\{\begin{matrix} \mathrm{NO_2} \\ \mathrm{NH_2} \end{matrix}\right. = 1 : 3 : 4 : 6, \text{ or less probably } = 1 : 3 : 4 : 2.$$

VII. Orthochlorobenzoic Acid and its Derivatives. By F. Wilkens and G. Rack.—*Orthochlorobenzanilide* (Kekulé, *Annalen*, **117**, 157) melts at 114°. Dissolved in cold fuming nitric acid it yields *orthochlorobenzoparanitranilide*, $C_6H_4Cl.CO.NH.C_6H_4.NO_2$. The latter crystallises in yellow needles soluble in alcohol, benzene, and glacial acetic acid, but insoluble in water, and melts at 180°. Heated with alcoholic potash, it yields paranitraniline and orthochlorobenzoic acid. In the process of nitration, a small quantity of the orthonitranilide appears always to accompany the para-body. Orthochlorometanitrobenzoic acid was obtained by Hubner (*Ber.*, **6**, 175) by adding orthochlorobenzoic acid to about five times its weight of fuming nitric acid and heating gently until the former was dissolved. Rack has carefully investigated this reaction, but could find no trace of an isomeric acid: small quantities of a *chlorodinitrobenzoic acid* crystallising in colourless needles easily soluble in water, alcohol, and ether and petroleum, melting at 238°, were however obtained. The *ammonium salt* of orthochlorometanitrobenzoic acid crystallises in easily soluble anhydrous plates; the sodium salt in soluble needles; the *barium salt* in yellow needles with $3H_2O$; the *strontium salt* with $4\frac{1}{2}H_2O$; the *zinc salt* in long easily soluble needles with $5\frac{1}{2}H_2O$; the *cadmium salt* with $5H_2O$; the *lead salt* yields anhydrous yellow needles; the copper salt sparingly soluble blue needles. The following new salts of the orthochlorometamidobenzoic acid, obtained by the reduction of the nitro-acid, have been examined:—A dark-green *basic copper salt*, $(C_7H_5ClNO_2Cu)_2O$; the *lead salt* crystallises in brownish needles with $1\frac{1}{2}H_2O$; the *barium salt* could not be obtained in a crystalline form. The *hydrochloride* forms small needles easily soluble in water: the *acid sulphate* forms large colourless needles, and suffers slight decomposition on solution: the nitrate crystallises in reddish easily soluble needles. With sodium-amalgam, this acid yields metamidobenzoic acid. The nitro-group must therefore be in the *meta*-position to the carboxylic-group, and the constitution be $COOH : Cl : NO_2 = 1 : 2 : 5$ or, less probably $= 1 : 2 : 3$.

Orthochlorometachlorobenzoic acid was obtained from the chloramido-acid by means of the diazo-reaction. It crystallises in colourless needles melting at 150°, and is soluble in 1176 parts of water at 14°, more soluble in boiling water. The *barium salt* yields efflorescent and easily soluble needles with $3H_2O$; the *calcium salt* colourless

needles with $2H_2O$: the *lead salt* forms a white precipitate. Orthometachlorobenzanilide crystallises from benzene in large prisms melting at 240°.
L. T. T.

β-Phenyltribromopropionic Acid. By L. P. KINNICUTT and G. M. PALMER (*Amer. Chem. J.*, **5**, 583—587).—β-phenyltribromopropionic acid is prepared by the action of dry bromine on β-monobromocinnamic acid; it is crystalline, melts at 151°, and is soluble in alcohol, ether, carbon bisulphide, chloroform, and benzene. (According to Glaser, *Annalen*, **143**, 339, β-bromocinnamic acid melts whilst absorbing bromine, and the liquid acid thus formed solidifies after some days, and then melts at 45—48°. The authors cannot confirm this statement.) When boiled with water, β-phenyltribromopropionic acid yields dibromostyrene, α-monobromocinnamic acid, and a crystalline acid of the formula $C_9H_8Br_2O_3$, melting at 184°, readily soluble in water, alcohol, and ether, soluble in chloroform, sparingly soluble in carbon bisulphide and benzene; it is probably phenyldibromolactic acid.

Dibromostyrene, on exposure to bromine-vapour, is converted into a thick viscous oil of the formula $C_6H_6Br_4$. This is soluble in alcohol, ether, and carbon bisulphide, and is readily decomposed by heat.
A. J. G.

Substituted Aromatic β-Lactones and Derivatives of Cinnamic Acid. By A. BASLER (*Ber.*, **16**, 3001—3007).—This is an account of the para-derivatives of nitrocinnamic acid, the orthoderivatives of which have been prepared by A. Einhorn (Abstr., 1884, 65). *Paranitrophenyl-β-bromopropionic acid*,

$$C_6H_4(NO_2).CHBr.CH_2.COOH,$$

is not obtained direct from paranitrocinnamic acid, as is the orthoacid, but by the action of 5 parts hydrobromic acid dissolved in glacial acetic acid at 0°, on the dry ether, subsequently heating it for two or three hours in a sealed tube at 100°. The acid crystallises out and is purified by recrystallisation from alcohol or acetone. It forms white cubical crystals, melting with decomposition at 170—172°, dissolves in the above-mentioned solvents, but is nearly insoluble in other ordinary solvents, and is decomposed by water. Concentrated sulphuric acid dissolves it in the cold, and decomposes it on heating. Boiled with dilute sulphuric acid (1 to 4), it yields paranitrocinnamic acid by separation of water from intermediately formed paranitrophenyllactic acid. When boiled with water, it yields 27·5 per cent. paranitrosostyrene and 72 per cent. paranitrophenyllactic acid. With sodium carbonate in the cold, the reaction is precisely similar to that of the ortho-acid (Abstr., 1884, 65), but with boiling sodium carbonate it yielded 29 per cent. nitrosostyrene and 65 per cent. paranitrophenyl-β lactic acid. The *ethyl derivative* is very stable, but on prolonged boiling with soda or water yields paranitrocinnamic acid, without any nitrosostyrene or the expected nitrophenyllactic acid.

β-Lactone of paranitrophenyllactic acid, $C_6H_4(NO_2).CH\!<\!\overset{CH_2}{\underset{-O-}{}}\!>\!CO$, is obtained by the action of sodium carbonate in the cold as described by Einhorn for the ortho-compound. It crystallises from absolute alcohol in needles, melting at 91·9°, and is soluble in hot benzene, alcohol, and ether. The following reactions are proof of its being a β-lactone:—1st. On heating it slightly above the melting point, it forms paranitrostyrene with evolution of carbonic anhydride. 2nd. With hydrobromic acid in glacial acetic acid, the original acid is regenerated. 3rd. With water or alkali the corresponding or hydroxy-acid is formed, which may be converted into the original acid by treatment with hydrobromic acid at 150°. 4th. The hydroxy-acid,

$$C_6H_4(NO_2).CH(OH).CH_2.COOH,$$

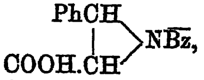
is identical with the oxidation-product of the substance formed by the condensation of paranitrobenzaldehyde and aldehyde, melting at 129—131°.

Paranitrostyrene, $C_6H_4(NO_2).CH : CH_2$, obtained by heating the lactone, crystallises from hot light petroleum in yellow prisms, melting at 29°, which smell of cinnamic alcohol, and by further application of heat or in time, are converted into a polymeric insoluble form. It is decomposed by distillation.

Paranitrostyrene dibromide, $C_6H_4(NO_2).CHBr.CH_2Br$, is formed from the above by the action of bromine. It is crystalline, melting at 72—73°, and is soluble in hot benzene, alcohol, and ether. *Paranitrophenyl-β-lactic acid*, $C_6H_4(NO_2).CH(OH).CH_2.COOH$, is obtained as mentioned above by heating the lactone with 20 times its volume of water. On evaporation, the acid crystallises out without water of crystallisation, melting at 130—132°, and is barely soluble in cold water, ether, or benzene, but soluble in hot water, alcohol, ether, and light petroleum. Unlike the lactones, it is very stable. With dilute sulphuric acid, it behaves as does the ortho-acid; with calcium and silver, it forms crystalline soluble salts. The *ethyl* and *methyl derivatives* melt at 45° and 72—74° respectively. The action of ammonia, &c., on the β-lactones is under investigation. A. B.

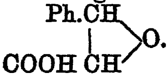
Phenylglycidic Acid. By J. Plöchl (*Ber.*, 16, 2815—2825).—When benzaldehyde and hippuric acid are heated with excess of acetic anhydride, a condensation-product is produced, and may be purified by recrystallisation from hot alcohol. It melts at 164—165°, has a feebly alkaline reaction, is insoluble in water, sparingly soluble in ether, more readily in hot alcohol, from which it crystallises in yellow needles. Its formation may be represented thus:

$$Ph.CHO + COOH.CH_2.NH\overline{Bz} + \overline{Ac}_2O = C_{16}H_{13}O_3N + 2\overline{Ac}OH,$$
and $2C_{16}H_{13}O_3N + \overline{Ac}_2O = C_{32}H_{24}O_5N_2 + 2\overline{Ac}OH.$

It is the anhydride of benzoylimidocinnamic acid,


$\begin{matrix}PhCH \\ | \\ COOH.CH\end{matrix}\!>\!N\overline{Bz}$,
into which it may be converted by heating with mineral acids until the yellow colour has disappeared. By saponification with alkalis, a

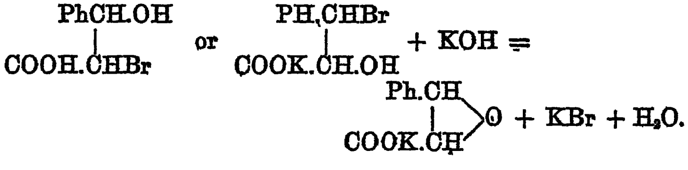
portion of the acid is decomposed and the yield considerably diminished. Benzoylimidocinnamic acid crystallises in monoclinic needles resembling those of hippuric acid; it melts at 225° with decomposition, is almost insoluble in water, readily soluble in ether and alcohol. That this substance has the above constitution and not that of benzoylamidocinnamic acid, CHPh : C(NH$\overline{Bz}$).COOH, is indicated by its properties. It yields no addition-compound with hydrobromic acid, and is not converted into a nitroso-derivative by nitrous acid. Heated with dilute hydrochloric acid at 120° in a sealed tube, ammonium chloride, benzoic acid, a new acid of the formula $C_9H_8O_3$, and a substance (probably a polymeric phenylethylene oxide) insoluble in sodium carbonate solution are formed, the latter crystallising in glistening flat needles melting at 171°. The benzoic acid is separated from the oxy-acid by fractional precipitation from the alkaline solution, the acid $C_9H_8O_3$ being precipitated last as an oil. The same acid is also obtained if benzoylimidocinnamic acid is boiled with alkalis as long as ammonia is evolved. It is a strong acid, very sparingly soluble even in hot water, readily in ether and alcohol, and crystallises from chloroform in lustrous scales melting at 154—155°, with evolution of carbonic anhydride; its alcoholic solution gives an intense green coloration with ferric chloride. Its constitution is



$$\begin{array}{l}\text{Ph.CH}\diagdown \\ \quad\;\; | \quad\; \rangle\text{O} \\ \text{COOH CH}\diagup\end{array}$$

. This, however, is the same as that assigned by Erlenmeyer to Glaser's phenyloxyacrylic acid (*Annalen*, **147**, 100; *Ber.*, **13**, 300), a body of very different properties to the above. Since epichlorhydrin can be obtained from both dichlorhydrins, and glycidic acid from both α- and β-chlorolactic acids, the two phenylbromolactic acids might be expected to yield the same phenylglycidic acid, unless in the splitting off of the hydrobromic acid the bromine should combine with the hydrogen-atom directly united to the carbon, in which case hydroxycinnamic acids would be formed.

I.



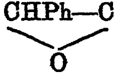
$$\begin{array}{c}\text{PhCH.OH} \\ | \\ \text{COOH.CHBr}\end{array} \text{ or } \begin{array}{c}\text{PH.CHBr} \\ | \\ \text{COOK.CH.OH}\end{array} + \text{KOH} = \begin{array}{l}\text{Ph.CH}\diagdown \\ \quad\quad | \quad \rangle\text{O} \\ \text{COOK.CH}\diagup\end{array} + \text{KBr} + H_2O.$$

II. CHPh(OH).CHBr.COOK + KOH = CPh(OH) : CH.COOK + KBr + H_2O.

III. CHPhBr.CH(OH).COOK + KOH = CHPh : C(OH).COOK + KBr + H_2O.

On treating phenyl-β-bromolactic acid with alcoholic potash, the chief product is resinous, but the potassium salts of two acids are also produced, neither of which is identical with Glaser's phenyloxyacrylic acid. The one salt is decomposed by mineral acids, yielding phenylethaldehyde and stycerinic acid, whilst the other yields a stable acid melting at 154—155°, and identical with the author's phenylglycidic acid. This acid cannot be obtained from phenyl-α-bromolactic acid, either by means of alcoholic or of aqueous alkalis. The experiments show that whilst phenyl-β-bromolactic acid is decomposed according to equations I and III (see above), the corresponding α-acid suffers only the one decomposition shown in equation II. Phenylglycidic acid resembles glycidic acid in yielding an amido-derivative when heated with ammonia at 100°, whilst Glaser's phenoxyacrylic acid yields no amido-acid under like conditions. Phenylamidolactic acid is sparingly soluble in water, insoluble in ether, soluble in hot alcohol, from which it crystallises in prisms melting at 189—190°. Phenylglycidic acid, unlike glycidic acid, does not combine with hydrobromic acid, but this is readily explained by the resistance offered by the very negative character of the compound, the conversion of the stable saturated phenylglycidic acid into the less stable phenyl-β-bromolactic acid being improbable. On the assumption of Erlenmeyer's formula for Glaser's phenyloxyacrylic acid, this would be expected to yield α-phenyllactic acid by reduction; the β-acid, melting at 94°, is however produced, whilst the α-acid is readily obtained by the reduction of the author's phenylglycidic acid.

From these results, it is inferred that Glaser's phenoxyacrylic acid, obtained from phenyl-α-bromolactic acid, is β-hydroxycinnamic acid, $CPh(OH){:}CH.COOH$, and that the two acids obtained from phenyl-β-bromolactic acid are distinct from Glaser's acid, the one being α-hydroxycinnamic acid, $CHPh{:}C(OH).COOH$, and the other phenylglycidic acid, $\underset{\diagdown\, O\, \diagup}{CHPh{-}CH.COOH}$, with which the author's oxy-acid (see above) is identical.



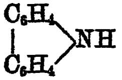
With regard to the influence of the phenyl-group, the author points out the stability of the salts of the halogen-lactic acids of the fatty series, those of the two phenyl-halogen-lactic acids being very unstable, although the acids themselves are stable; whilst the former yield the same glycidic acids on treatment with alcoholic potash, those of the aromatic series yield unsaturated hydroxy-acids, and in the case of phenyl-β-bromolactic acid also a small quantity of phenylglycidic acid. Both glycidic and phenylglycidic acids are stable, and both yield stable salts.

The above condensation of benzaldehyde and hippuric acid differs from Perkin's reaction, the carbon-atom of the aldehyde radicle uniting with both nitrogen- and carbon-atoms in the hippuric acid.

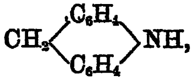
A. K. M.

Violet Derivatives of Triphenylmethane. By O. Fischer and G. Körner (*Ber.*, 16, 2904—2911).—In continuation of work published by Fisher and German (Abstr., 1883, 1097) the authors of this paper confirm the presence of other substances (containing free amido-hydrogen) in commercial methyl-violet besides the dye which yields the reduction-product melting at 173° (hexamethylparaleucaniline). When methyl-violet prepared from pure dimethylaniline is reduced and the product crystallised from alcohol, the substance melting at 173° separates out, whilst the mother-liquor contains other substances yielding acetyl-derivatives, which show the same behaviour on oxidation as tetramethylacetylparaleucaniline previously described. The methyl-violet is heated with an excess of acetic anhydride and fused sodium acetate for several hours on a water-bath, the melt dissolved in water and the dye-stuff precipitated by salt and zinc chloride. The substance obtained is dissolved in water and fractionally precipitated by salt, when the unattacked violet separates first, the green acetyl-derivative remaining in solution. On adding alkali to the solution, a grey flocculent precipitate is obtained, which, after recrystallisation from alcohol, melts at 223—225°. The figures obtained on analysis agree with the formula $C_{28}H_{33}N_3O_3$ (diacetylpentamethylpararosaniline). Investigation shows that one acetyl-group is attached to nitrogen, whilst the other is united to the oxygen of the carbinol-group. It is insoluble in water, sparingly soluble in alcohol, the solution assuming a violet coloration on exposure to air; on adding acetic acid, the formation of the green dye takes place gradually in the cold, instantly on heating. The salts are soluble in water with splendid emerald-green coloration, but the dye is too unstable to be of technical value. On reducing the acetic acid solution with zinc-dust and adding alkali, a precipitate is obtained, crystallising from alcohol in aggregates of colourless concentrically-grouped needles melting at 142—143°, and from the numbers obtained on analysis is very probably *acetylpentamethylparaleucaniline*, $C_{26}H_{31}N_3O$. By careful oxidation, it is reconverted into the green dye-stuff. On boiling it with hydrochloric acid, the acetyl-group is split off, and *pentamethylparaleucaniline*, $C_{24}H_{29}N_3$, obtained, crystallising from dilute alcohol in groups of colourless needles, melting at 115—116°; on oxidation, it yields a violet intermediate in shade between tetra- and hexa-methyl-violet. The position of the amido-groups is the same as in the tetra- and hexa- methylparaleucaniline and in paraleucaniline, since it yields the same methiodide as the latter when heated at 100° with methyl iodide and methyl alcohol. It is thus shown to be a true methyl-derivative of paraleucaniline. A. K. M.

Acridine. By C. GRAEBE (*Ber.*, 16, 2828—2832).—The researches of Riedel (Abstr., 1883, 1152) and of Bernthsen and Bender (Abstr., 1883, 1133) show that the formula of acridine is most probably $C_{13}H_9N$, and not $C_{12}H_9N$, as previously assumed by Graebe and Caro. The author has prepared the pure base from repeatedly crystallised hydrochloride and sulphite, and on analysing it his figures also agree with the formula $C_{13}H_9N$. The low percentage of carbon obtained in previous analyses is probably due to the absorption of oxygen by the acridine, which is especially observable when the latter is melted. Analyses of the platinochloride, $(C_{13}H_9N)_2,H_2PtCl_6$, and aurochloride, $C_{13}H_9N,HAuCl_4$, also confirm the above formula, whilst the author's previous vapour-density determination (6·02) agrees well with both formulæ. Acridine sulphite, $(C_{13}H_9N)_2,H_2SO_3$, is obtained as a very characteristic salt by the action of sulphurous acid on a solution of the hydrochloride; it separates in the form of reddish-brown needles. It can also be prepared by mixing solutions of acridine hydrochloride and sodium sulphite, and then acidulating with hydrochloric acid, when it is obtained in larger yellowish-red needles. If, instead of acidulating, the solution be concentrated, the salt $C_{13}H_9N,SO_3NaH$ crystallises out in colourless prisms, very soluble in water. On heating its solutions, acridine and acridine sulphite are produced. The addition of hydrochloric acid precipitates acridine sulphite. *Octohydroacridine*, $C_{13}H_{17}N$, is prepared by heating acridine (5 grams) or its hydrochloride (6 grams) with amorphous phosphorus (2 grams), and hydriodic acid (6—7 c.c.) for 6—7 hours at 220—230°. The product is crystallised from water and the base separated by means of ammonia. It crystallises from alcohol in colourless scales or long plates, melts at 84°, and distils at 320°. Its solutions do not fluoresce, and it has not the powerful action on the skin and mucous membrane so characteristic of acridine. The hydrochloride, $C_{13}H_{17}N,HCl$, forms colourless plates, readily soluble in hot, sparingly in cold water. With acetic anhydride and with benzoic chloride, it yields acetic and benzoic derivatives, and with methyl iodide, it forms methylacetohydroacridine. In the conversion of hydroacridine into octohydroacridine, a well characterised base is produced from a non-basic imido-compound, a change analogous to the conversion of carbazol into carbazoline:



Carbazol.



Hydroacridine.

the reduction of the C_6H_4-groups affecting the chemical character of the nitrogen in the same way in both cases. A. K. M.

Hydrides of Naphthalene. By C. GRAEBE and P. A. GUYE (*Ber.*, 16, 3028—3032).—Agrestini (Abstr., 1883, 345) having, in his attempt to prepare Graebe's naphthalene tetrahydride, only obtained naphthalene hexhydride along with naphthalene, the authors repeated the former experiments (this Journal, 1873, 1008). Their results confirm the work previously published. They heated 10 grams of naphthalene, 3 of red phosphorus, and 9 of hydriodic acid boiling at 127° in a sealed tube at 210—225° for 7½ hours, and obtained without any separation of iodine 7—8 grams naphthalene tetrahydride boiling at 205°. The difference in Agrestini's results seem to be due to the higher temperature (235°) which he employed. Analysis and a vapour-density estimation confirmed the formula $C_{10}H_{12}$, but in a short time the hydride is partially oxidised.

Tetrahydronaphthalenesulphonic acid was also again prepared. The monosulphonic acid is obtained by heating the tetrahydride with 3½ parts of concentrated sulphuric acid at 40° for three hours. At 100° the disulphonic acid is formed. The sodium salt, $C_{10}H_{11}SO_3Na$, is soluble in alcohol and water, and crystallises in plates. The barium salt, $(C_{10}H_{11}SO_3)_2Ba\frac{1}{2}H_2O$, is soluble in hot water and alcohol, and crystallises in plates.

Naphthalene hexhydride is obtained by heating 6·7 grams naphthalene with 3 of red phosphorus, and 9½ of hydriodic acid (127° b. p.) in a sealed tube for nine hours at 245°. No iodine separates out, but some phosphonium iodide is formed. About 80 per cent. of a hydride is obtained, which analysis proves to be the hexhydride. Its boiling point is 199·5°; Agrestini gives 205°, and the authors suppose that his specimen may have been slightly oxidised, as they have found that by oxidation in air the boiling point of these hydrides is raised. The observation that *naphthalene dihydride* can be obtained by treating naphthalene trahydride with bromine was also confirmed.

A. B

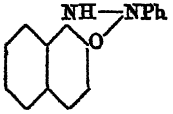
Two Isomeric Benzylnaphthalenes. By C. VINCENT and L. ROUX (*Bull. Soc. Chim.* [2], **40**, 163—166).—A good yield of α-benzylnaphthalene is obtained by heating a mixture of benzyl chloride and naphthalene at 150° for 1½ hours, zinc chloride being added from time to time in small quantities. The product is decanted before it solidifies in order to remove the zinc chloride; it is then purified by distillation and by recrystallisation from alcohol. After drying over sulphuric acid, it is crumbled to powder between the fingers and sifted. The α-derivative passes through the meshes, and is purified by two or three crystallisations from alcohol. The β-derivative is retained by the sieve.

Pure α-benzylnaphthalene is deposited from alcohol in brilliant rhombic plates, which act powerfully on polarised light. The crystals (sp. gr. 1·165) dissolve freely in benzene, chloroform, ether, and boiling alcohol. They melt at 59°, and boil at 345°.

The β-compound is best prepared by heating a mixture of benzyl chloride and naphthalene at 160° for an hour, aluminium chloride being added in small quantities. The product is poured into water, and then distilled and purified by recrystallisation from boiling alcohol. The crystals melt at 55°, and boil at 315°. Their sp. gr. at 0° is 1·176. The compound is freely soluble in benzene, chloroform, and boiling alcohol.

By the prolonged action of nitric acid, α-benzylnaphthalene is converted into α-naphthyl phenyl ketone melting at 75°, and the β-compound into the β-ketone, which melts at 81·5°. W. C. W.

Constitution of Azonaphthol-dyes. By C. LIEBERMANN (*Ber.*, **16**, 2858—2864).—From an observation made by Pfaff, the author is led to an opinion opposed to that generally accepted that the two series of azo-derivatives obtained from α- and β-naphthol respectively are alike constituted, except in the difference of positions of the α- and β-hydroxyl groups. When the calculated quantity of aniline hydrochloride and sodium nitrite is added to α-naphthol in a thin paste, the formation of the dye-stuff begins at once; whilst, if the same mode of proceeding be adopted with β-naphthol, the mixture remains practically colourless, the dye being, however, produced on the addition of alkali. Similar results are obtained when other aromatic bases are substituted for aniline. A more striking difference between the α- and β-derivatives is the ready solubility of the α-compound, $Ph.N_2C_{10}H_6.OH$, even in cold dilute alkali; whilst the corresponding β-compound is quite insoluble in cold alkali, dissolves slightly on heating, and separates unchanged when the solution cools. The β-dye-stuffs are also distinguished from the corresponding α-compounds by their capacity for crystallising, their more sparing solubility, and their lower melting points. *Benzene-azo-α-naphthol*, $Ph.N_2.C_{10}H_6.OH$, prepared as above, and recrystallised from alcohol, forms steel-blue needles melting at 193°, with evolution of gas. According to Typke (*Ber.*, **10**, 1580), who employed a different method of preparation, two isomerides exist melting at 166° and 175° respectively. The author has not yet succeeded in establishing the existence of an isomeride. Benzene-azo-β-naphthol, $C_{16}H_{12}N_2O$, separates from boiling alcohol in lustrous golden-red coloured scales when the solution is rapidly cooled, and when slowly cooled, in long needles of a cantharides-like lustre. It forms a rosaniline-red solution with concentrated sulphuric acid, and is also soluble in ether, benzene, light petroleum, and carbon bisulphide. It melts at 134°, is insoluble in aqueous alkali, but is readily dissolved even by cold sodium ethylate, from which solution water reprecipitates it unchanged. It has feebly basic properties, uniting with hydrochloric and hydrobromic acids to form unstable compounds. Benzene-azo-α-naphthol also dissolves in these acids, but to a very small extent. On reduction, benzene-azo-β-naphthol yields α-amido-β-naphthol and aniline, showing that the diazo-group occupies the ortho-position to the hydroxyl in the naphthalene nucleus. This ortho-grouping is one however which, as shown by Jacobsen and Liebermann, also by Worms and by Böttcher (Abstr., 1883, 1113), readily yields anhydro-compounds. The application of this view to benzene-azo-β-naphthol leads to the constitution



which at once explains the insolubility of this compound in alkali, and also the lower melting points of the β-derivatives. The same explanation will also probably hold for the very numerous sulphonated azonaphthol-dyes employed in the arts. Anthrol, which, from the position of the hydroxyl-group, may be compared with β-naphthol, also yields azo-derivatives, insoluble in alkali. The less ready formation of the β-naphtholazo-dyes is explained by the fact of there being no para-position for the azo-group to assume, which is therefore forced to take up the ortho-position. A. K. M.

Reactions of Hydroxylamine. By E. NÄGELI (*Ber.*, **16**, 2981—2984).—*Derivatives of Camphoroxime* (Abstr., 1883, 728).—Camphoroxime with dry hydrochloric acid yields camphoroxime hydrochloride, $C_{10}H_{16} : N.OH,HCl$. It is a white powder, insoluble in ether, sparingly soluble in water, but readily in alcohol and acids. With sodium ethylate, it gives the sodium salt, $C_{10}H_{16} : N.ONa$, and with sodium ethylate and ethyl iodide ethylcamphoroxime, $C_{10}H_{16} : N.OEt$. No acetyl-compound is formed with acetic chloride, but a liquid anhydride boiling at 216—218° of the formula $C_9H_{15} : C : N$.

$$\underbrace{C_9H_{15} : C : N}$$

As hydroxylamine reacts with *amylene oxide* obtained by boiling amylene bromide with water, the author was led to doubt that the group  could exist in the oxide as Niederist (*Annalen*, **196**, 360) had supposed, more especially as Meyer had observed that hydroxylamine does not react with ethylene oxide, or generally with substances containing that group; and as Eltekoff (*Jour. Russ. Chem. Soc.*, **10**, 215) had obtained methyl isopropyl ketone by boiling amylene bromide with water and oxide of lead. The author found that on preparing methyl isopropyl ketone, and treating it with hydroxylamine, he obtained a compound identical with that obtained from amylene oxide. Both boiled at 157—158°, had the same odour and all the reactions of acetoximes. Analysis gives the formula of methylisopropylacetoxime, $CHMe_2.CMe : NOH$. There seems little doubt, therefore, that Niederist's supposed amylene oxide is methyl isopropyl ketone, as shown by the equation $CHMe_2.CHBr.CH_2Br + H_2O = 2HBr + CHMe_4.COMe$. A. B.

Matico-camphor. By K. KÜGLER (*Ber.*, **16**, 2841—2843).—A specimen of matico-camphor (from *Piper angustifolium*), examined by the author had the odour and taste of matico-leaves, and melted between 89° and 103°. After repeated crystallisations, it melted at 94°, the mother-liquors containing a yellow amorphous resin. Matico-camphor exhibits a rotatory motion on the surface of water; it is not attacked by aqueous alkalis, is readily soluble in alcohol, ether, chloroform, benzene, and light petroleum. The pure substance lacks both taste and odour. In contact with hydrochloric acid, it assumes an intense violet colour, which changes to blue and then to green, the compound yielding brown crystals from ether, showing green fluorescence, and having an ethereal odour. With sulphuric acid, it becomes yellow, then red, and finally violet. With sulphur and nitric acids, it assumes first a yellow, then a violet, and finally a blue colour. Matico-camphor has the formula $C_{12}H_{20}O$; it is, perhaps, the ethyl-derivative of ordinary camphor. A. K. M.

Pyridine Bases from Coal-tar. By H. GOLDSCHMIDT and E. J. CONSTAM (*Ber.*, **16**, 2976—2981).—The authors are investigating these bases in order to observe which of the theoretically possible picolines, lutidines, &c., are present in coal-tar. The bases were obtained in the usual way from the tarry acid liquor produced by washing crude benzene with sulphuric acid, by neutralising and subsequently distilling off the volatile bases by steam. From 10 litres of the acid liquor 1 kilo. of volatile bases boiling between 92—200° was obtained. By repeated fractional distillation little was obtained under 100°; about half was pyridine (114—117°), but above 160° very little was obtained. The small fraction under 100° consisted chiefly of a liquid boiling at 92—93°, which had a strong odour of pyridine, and yielded that base after treatment with solid potash and distillation. By mixing pyridine with one-half its volume of water, and distilling, two fractions are obtained, the heavier at 92—93°, the lighter at 115°. The former appears on analysis to be a molecular compound of water and pyridine ($C_5H_5N + 3H_2O$), judging from the constant boiling point and from its sp. gr. being higher than that of a mixture of water and pyridine.

The fraction between 130° and 140° was found to consist of picoline, which on oxidation and treatment with cupric acetate yielded (1) a precipitate of cupric picolate, from which picolinic acid melting at 137° was obtained, thus showing that the picoline in coal-tar is α-picoline; and (2) a solution of a small quantity of a copper salt, which yielded an acid melting at 310°, giving on analysis the formula of a pyridinemonocarboxylic acid. This is isonicotinic acid or γ-pyridinecarboxylic acid, and is derived possibly from γ-picoline present in the coal-tar, but more likely from the oxidation of some lutidine present as an impurity, which Weidel and Herzig (*Vienna Acad. Ber.*, 1880, 848) have shown does yield isonicotinic acid. The presence of α-picoline was also verified by a careful preparation, an analysis, and a crystallographical examination of the platinochloride.

A. B.

Anderson's Reaction. By O. de Coninck (*Bull. Soc. Chim.* [2], **40**, 271—276 and 466).—When the platinochloride of a pyridine base is treated with boiling water, 2 mols. HCl are eliminated, and the new salt combines with the unaltered platinochloride to form a double salt, *e.g.*,

$$(C_nH_{2n-5}.N.)_2,H_2PtCl_6 - 2 \text{ mols. } HCl = (C_nH_{2n-5}N)_2,PtCl_4.$$

The double salt has the composition

$$(C_nH_{2n-5}.N)_2,H_2PtCl_6 + (C_nH_{2n-5}N)_2PtCl_4.$$

The author points out that this reaction, which he terms "Anderson's Reaction," is characteristic of pyridine bases. It distinguishes between pyridine and quinoline platinochlorides, as the latter are not affected by boiling water. The hydroquinoline platinochlorides are, however, easily decomposed. The platinochloride of quinoline, derived from cinchonine, and that of quinoline prepared synthetically, both resist the action of boiling water to precisely the same extent. The author therefore regards these bases as identical. The exact conditions for the formation of the double salt are difficult to attain. If the action of the boiling water on the platinochloride is not continued for a sufficient length of time, the double salt is mixed with unaltered platinochloride. If it is carried on too far, then it is partly decomposed.

W. C. W.

Action of Pyridine Bases on Alcoholic Iodides. By O. de Coninck (*Bull. Soc. Chim.* [2], **40**, 276—279).—Methyl iodide unites rapidly with pyridine bases. Ethyl iodide enters into combination less rapidly, and by means of this reagent, it is possible to distinguish between three classes of pyridine bases:—1. Cinchonine and brucine combine energetically with ethyl iodide. 2. Coal-tar pyridine bases unite less readily. 3. Dippel-oil bases combine slowly with ethyl iodide. Pyridine combines more rapidly than picoline, and β-collidine more rapidly than β-lutidine. Skraup's quinoline prepared by synthesis, and quinoline from cinchonine, require the same time for their union with ethyl iodide. W. C. W.

Creatines and Creatinines. By E. DUVILLIER (*Compt. rend.*, **97**, 1486—1487. See also Abstr., 1883, 220 and 1153).—If a saturated aqueous solution of cyanamide is mixed with an equivalent quantity of ethylamido-α-butyric acid and a few drops of ammonia, the liquid after about a month begins to deposit bulky tabular crystals of dicyandiamide, and dicyandiamide and ethylamido-α-butyrocyamidine remain in solution. Ethylamido-α-butyrocyamidine, $C_7H_{13}N_3O$, forms somewhat large transparent anhydrous tabular crystals which are very soluble in water and alcohol.

The action of cyanamide on ethylamido-isovaleric acid did not yield satisfactory results. C. H. B.

Morphine. By O. HESSE (*Annalen*, **222**, 203—234).—The author has studied the action of acetic and propionic anhydrides on morphine and its derivatives. With regard to the nomenclature introduced by Grimaux, the author contends that the term codeine is unjustifiable. When the hydroxylic hydrogen in morphine is replaced by the acetyl group, the resulting product is mono- (or di-) *acetylmorphine;* and when it is similarly replaced by methyl, &c., the resulting compounds should be called *methylmorphine*, &c., and not codeïne, codethyline, &c. For derivatives where one of the hydrogen-atoms of the nucleus is replaced by methyl, &c., the author proposes the name of *morphimethine*, &c.

Morphine dissolves easily in excess of acetic anhydride at 85°, to form *diacetylmorphine.* This substance crystallises in anhydrous prisms, which are easily soluble in alcohol, sparingly so in ether, melt at 169°, and with hydrochloric acid yield a hydrochloride which gives no coloration with ferric chloride. No more highly acetylised body could be obtained. *Dipropionylmorphine* was prepared in a similar manner. It is amorphous, easily soluble in alcohol, ether, and chloroform, sparingly so in water. The *hydrochloride* is an amorphous powder easily soluble in water and yielding a pale yellow amorphous *platinochloride*, $[C_{17}H_{17}(C_3H_5O)_2NO_3]_2,H_2PtCl_6$. Morphine methiodide treated with freshly precipitated silver chloride yields *morphine methochloride* crystallising in long colourless needles, containing $2H_2O$, which it loses at 120°. It dissolves in concentrated sulphuric acid without discoloration, but the solution turns violet when heated. It gives a dark blue coloration with ferric chloride in aqueous solution. The *platinochloride* forms orange needles containing 1 mol. H_2O. Morphine methiodide dissolves with difficulty in acetic anhydride at 100—120°, and forms the diacetyl-compound. The yield is, however, very bad, a much more satisfactory result being obtained with morphine methochloride. *Diacetylmorphine methochloride* crystallises in concentrically grouped needles, which are easily soluble in water, and give no coloration with ferric chloride. From its solutions potassium iodide precipitates *diacetylmorphine methiodide.* The chloride yields a pale yellow *platinochloride* crystallising in small needles containing 1 mol. H_2O, which they partly lose on exposure to the air, completely at 110°. The action of methyl iodide on morphine in the presence of bases has already been studied by Grimaux (Abstr., 1881, 829). With acetic anhydride codeine (methylmorphine) gives *acetylcodeine* crystallising from ether in prisms which melt at 133°. When propionic is substituted for acetic anhydride, *propionylcodeine* (*propionylmethylmorphine*) is formed; on evaporating its ethereal solution, this is left as a colourless film easily soluble in ether, benzene, and alcohol. It dissolves in sulphuric acid with a bluish tint, which turns dark blue on the addition of a trace of ferric chloride. When heated, both solutions turn dark green. It yields crystallisable salts with acids. The *hydrochloride* crystallises in large colourless needles containing $2H_2O$, and soluble in water and alcohol: it gives a yellow crystalline *platinochloride*. The *acetate* crystallises in colourless needles soluble in water. It loses a part of its acetic acid at 100°. The *hydriodide* crystallising with 1 mol. H_2O, the *oxalate* with $3H_2O$, and the sulphate are all soluble in water. *Codeïne methochloride* (*methylmorphine methochloride*) is obtained from codeïne methiodide by treatment with silver chloride; and crystallises in large rhombic prisms with 1 mol. H_2O. It yields a yellow flocculent *platinochloride* with $3H_2O$. The *sulphate* gives colourless needles containing $4H_2O$. A solution of the last-named salt yields, with barium hydroxide, a colourless solution of *codeïne methylhydroxide*, which on evaporation over sulphuric acid, deposits crystals of *methocodeïne* (*methylmorphimethine*). The unchanged hydroxide solution precipitates hydrates from solutions of metallic salts, and rapidly absorbs carbonic anhydride from the air. Codeïne methiodide dissolves in acetic anhydride at 85°, and deposits oblong rectangular tables of *acetylcodeine methiodide* on cooling. Thus obtained, the crystals are anhydrous; but on recrystallisation from alcohol, colourless needles containing $4H_2O$ are obtained. The *platinochloride* forms a yellow crystalline precipitate. If a solution of sodium, potassium, ammonium, barium, or calcium hydroxide be added to an aqueous solution of codeine methiodide, a colourless strongly alkaline solution is obtained which gradually becomes coloured, and deposits *methocodeine*. The reaction is quickened by using an excess of the alkali and heating to boiling. The action of the alkalis is therefore to liberate the hydroxide from which the elements of water are subsequently eliminated,

$$C_{18}H_{21}NO_3,CH_3(OH) = C_{19}H_{23}NO_3 + H_2O.$$

For the preparation on a large scale, it is best to boil the methiodide with rather more than the molecular weight of potassium hydroxide, extract the hot solution with benzene, and shake out the latter with acetic acid. The acetic solution is then saturated with sodium chloride, and the precipitated chloride recrystallised from a small quantity of water. A concentrated aqueous solution of the chloride is then decomposed with sodium hydroxide, and the base at once extracted with ether. In a few minutes the ethereal solution deposits long colourless prisms of methocodeïne. Freshly precipitated, this substance dissolves freely in ether, but when crystallised only sparingly. It crystallises from boiling alcohol in prisms, from boiling water in needles, in the latter case with 1 mol. H_2O. It melts at 118·5°, and dissolved in 97 per cent. alcohol gives $[\alpha]_D = -208\cdot6°$ when $p = 4$ and $t = 15°$. In moderately concentrated sulphuric acid, the base and its salts dissolve to a colourless solution, which gradually becomes of a purplish-violet tint, and turns olive-green when heated. The base gives a blue colour when heated with concentrated sulphuric acid. The *hydrochloride* crystallises with $2H_2O$ in needles soluble in 10·8 parts of water at 18°. The platinochloride is of a dark green colour.

Methocodeïne dissolves in acetic anhydride at 85°, and yields *acetylmethocodeïne.* It melts at 66°, and gives a blue coloration with concentrated sulphuric acid. It is soluble in alcohol, sparingly so in water. The salts crystallise easily: the *hydrochloride* with $\frac{1}{2}H_2O$, the *platinochloride* with $4H_2O$, the nitrate with $3H_2O$, and the sulphate with $8H_2O$.

With methyl iodide, methocodeïne forms *α-methocodeïne methiodide,* crystallising in prisms with $\frac{1}{2}H_2O$ and soluble in water. The *α-methochloride* is obtained from the methiodide by the action of silver chloride, but could not be obtained in a crystalline form. It gives a blue colour with concentrated sulphuric acid. The *α-platinochloride* is a yellow flocculent precipitate. α-Codeïne methochloride dissolves in acetic anhydride forming *α-acetylcodeïne methochloride,* which crystallises with $2\frac{1}{2}H_2O$ in long colourless silky needles, easily soluble in alcohol and boiling water, sparingly so in cold water. It gives up 2 mols. H_2O at 100°, but the remainder cannot be expelled without decomposition setting in. With concentrated sulphuric acid it gives a brownish-red coloration. The *platinochloride* forms a sparingly soluble yellow crystalline precipitate. An aqueous solution of the α-iodide becomes milky on addition of potassium or sodium hydroxide, and gradually deposits an oil which appears to be unchanged iodide. If, however, the solution be boiled with alkali, an oil is deposited on cooling, which solidifies after a time. This substance is not the original iodide, but is isomeric with it, and the author therefore names it *β-codeïne methiodide.* It differs from the α-iodide in crystalline form, in containing no water of crystallisation, and in being less soluble in water. The *β-chloride* was not obtained in the crystalline form, and gave a purplish-violet colour with concentrated sulphuric acid. The *β-platinochloride* yields small orange needles: the sulphate is amorphous. Decomposed with barium hydroxide, the sulphate yields the alkaline *β-methocodeïne methylhydroxide,* which crystallises in small colourless plates and flat prisms, soluble in water and alcohol. If the solution be evaporated at 30—40°, an amorphous deliquescent and highly caustic mass is left. This, however, is not a pure body. The *β-chloride* yields *β-acetyl-methocodeïne methochloride,* from which the β-iodide can be obtained by double decomposition. The *platinochloride* forms a yellow powder containing $3H_2O$.

These results confirm the presence of only two hydroxyl-groups in morphine; and the author points out that these two groups are different in character, the hydrogen of one being replaceable by either positive or negative radicals, that of the other only by the radicals of the fatty acids. Morphine methiodide is not decomposed by boiling with bases, whereas directly the hydroxylic hydrogen-atom is replaced by an alcohol radical, the stability of the methiodide is at once reduced, and in the presence of bases, its decomposition and the introduction of the methyl radical into the nucleus takes place even at ordinary temperatures. The author believes the hydrogen-atom thus replaced to be one in close proximity to the hydroxyl-group which is only displaceable by acid radicals, and not, as Gerichten and Schrötter contend, one of those combined with the nitrogen-atom. He declines to accept as proved, the formation of methylethylpropylamine by the decomposition of ethocodeïne methyl-hydroxide, on which Gerichten and Schrötter base their argument. On the latter supposition, the author should have obtained dimethylpropylamine by the decomposition of methocodeïne methyl-hydroxide, whereas he only obtained trimethylamine. He believes the decomposition to take place according to the equation—

$$C_{18}H_{20}NO_3(CH_3),CH_3OH = N(CH_3)_3 + C_{15}H_{10}O_2 + CH_3.OH + CH_2 + 2H_2O.$$

The ethyl compound would then give ethylene in the place of methylene, and this was observed by Gerichten and Schrötter, but ascribed by them to a secondary reaction.

The author is inclined to look upon *laudanine* as a morphine derivative containing propionyl, but in which the relative character and stability of the two hydroxyl-groups is different to what is the case in morphine. He is now continuing his researches in that direction.

L. T. T.

Pseudomorphine. By O. HESSE (*Annalen*, **222**, 234—248).—In his first communication on this alkaloïd, which he obtained from opium, the author stated his belief that it was identical with the oxymorphine of Schützenberger, and that its formula was $C_{17}H_{19}NO_4$. Brockmann and Polstorff (Abstr., 1880, 408) contended that this oxymorphine had the constitution $(C_{17}H_{18}NO_3)_2$, and based their assumption principally on the fact that nitric oxide was evolved in its production from a solution of morphine hydrochloride and silver nitrite, whereas the formula $C_{17}H_{19}NO_4$ would require an evolution of nitrous oxide. The author now shows that if an aqueous solution of morphine hydrochloride is mixed in molecular proportions with a solution of potassium nitrite, and the whole heated for some time at 60°, crystals of oxymorphine are formed, and a gas evolved which does not turn red in contact with the air, and is consequently not nitric oxide. The formation is evidently due to the decomposition of morphine nitrite, $2C_{17}H_{19}NO_3,HNO_2 = 2C_{17}H_{19}NO_4 + N_2O + H_2O$, and the author points out that an evolution of nitric oxide, when silver nitrite is used, might also be explained by the equation $4C_{17}H_{19}NO_3,HNO_2 = 4C_{17}H_{19}NO_4 + N_2 + N_2O_2 + 2H_2O$.

The author now finds that the body $C_{17}H_{19}NO_4$ is a hydrate of the real base, and that the formula for oxymorphine is therefore

$$C_{17}H_{17}NO_3.$$

The hydrate loses its water at 130°, but the base is so very hygroscopic that it is only by taking special precautions that rehydration can be prevented. The less crystalline the specimen in question, the more marked is its hygroscopic character. The alkaloïd is best purified by solution in ammonia, from which it crystallises in colourless crusts containing $1\frac{1}{2}H_2O$, which it loses at 130°. The *hydrochloride*, $C_{17}H_{17}NO_3,HCl$, crystallises in scales containing, under varying conditions, respectively 1, 2, 3, and 4 mols. H_2O. A *basic hydrochloride*, $(C_{17}H_{17}NO_3)_2,HCl + 6H_2O$, is obtained in microscopic crystals from a hot neutral acetic solution on the addition of sodium chloride: from a cold solution, the basic salt crystallises with $8H_2O$. With platinum chloride both the neutral and basic salts yield a yellow flocculent platinochloride, $(C_{17}H_{17}NO_3)_2,H_2PtCl_6$

The *hydriodide*, $C_{17}H_{17}NO_3,HI + H_2O$, loses its water when exposed to the air: the *chromate*, $(C_{17}H_{17}NO_3)_2,H_2Cr_2O_7 + 6H_2O$, loses $4H_2O$ at 80°: the sulphate crystallises with $6H_2O$, and effloresces slightly in dry air, but when crystallised from boiling water it is stable: the *oxalate* yields shining scales, with $8H_2O$: the *acid tartrate*,

$$C_{17}H_{17}NO_3,C_4H_6O_6 + 6H_2O,$$

crystallises in needles or prisms. Heated for two hours at 120° with acetic anhydride, pseudomorphine yields *diacetylpseudomorphine*, $C_{17}H_{15}(C_2H_3O_2)_2NO_3$. It crystallises from ether in concentrically grouped flat prisms, containing $4H_2O$, which it loses in the desiccator. It is moderately soluble in ether and chloroform, very soluble in alcohol, in which it yields a strongly alkaline solution. It contracts at 250°, but does not melt until 276°. It gives no coloration with ferric chloride. With hydrochloric acid, it forms a salt crystallising in quadratic tables, easily soluble in water. With platinum chloride, this salt yields a pale yellow flocculent *platinochloride*,

$$[C_{17}H_{15}(C_2H_3O)_2NO_3]_2,H_2PtCl_6 + 6H_2O.$$

The di-acetyl compound is easily reconverted into the original base by heating it with alcoholic potash. It is clear, therefore, that the hydroxyl-groups of morphine are still present in pseudomorphine. The author was unable to obtain a methyl compound by the action of potassium hydroxide and methyl iodide. He, however, obtained pseudomorphine methyl-hydroxide, $C_{17}H_{17}NO_3,MeOH$. The author also believes pseudomorphine to be identical with the substance which E. L. Meyer (*Ber.*, **4**, 121) obtained by the action of moderately concentrated sulphuric acid on a nitro-compound which he had obtained by passing a strong current of nitrous anhydride into water in which morphine was suspended. L. T. T.

Ptomaïnes and Analogous Compounds. By A. G. POUCHET (*Compt. rend.*, **97**, 1560—1562).—The alkaloïdal compounds which exist normally in urine, fæces, and the excrements generally, are identical with or very closely related to those formed by the putrefaction of proteïds out of contact with air. The alkaloïdal products from both sources are certainly mixtures, probably of homologous compounds. They are separated by converting them into tannates, which are then decomposed by lead hydroxide in presence of strong alcohol, the lead being finally removed by hydrogen sulphide, and the liquid submitted to dialysis. After some time, the mixture is separated into

(1) a liquid portion difficult to dialyse, and (2) crystalline substances which dialyse easily.

The liquid portion obtained from urine, which the author terms the *extractive matter of urine*, is a neutral syrupy liquid which does not crystallise even after prolonged exposure in a vacuum. It has the composition $C_3H_5NO_2$, yields precipitates with the general reagents for alkaloïds, is altered on exposure to air, is converted into a resin by hydrochloric acid, and is rapidly oxidised when mixed with platinum chloride solution. It does not yield a platinochloride.

The dialysate from urine contains a base $C_7H_{12}N_4O_2$ or $C_7H_{14}N_4O_2$, which crystallises in bundles or irregular spheres, and is soluble in dilute alcohol, almost insoluble in strong alcohol, insoluble in ether. It has a feebly alkaline reaction, and yields crystallisable salts. The platinochloride forms deliquescent golden-yellow rhombic prisms.

The liquid portion from the products of putrefaction is a mixture of volatile bases (probably the hydropyridic bases described by Gautier and Etard) and variable substances.

The dialysate when mixed with platinum chloride yields two platinochlorides, the one, $(C_7H_{18}N_2O_6)_2,H_2PtCl_6$, crystallising in prismatic needles, and insoluble in strong alcohol, the other,

$$(C_5H_{12}N_2O_4)_2,H_2PtCl_6,$$

forming a dull yellow powder somewhat soluble in strong alcohol, but insoluble in ether. Both these bases are allied to the oxybetaïnes. Their hydrochlorides form silky needles, which are altered by excess of hydrochloric acid and by exposure to air. The base, $C_7H_{16}N_2O_6$, forms short, thick prisms, which become brown when exposed to light, the other, $C_5H_{12}N_2O_4$, crystallises in needles which seem to be more stable. Their solutions give the general reactions for alkaloids. The precipitates with sodium phosphomolybdate are reduced somewhat rapidly, and are soluble in ammonia with formation of a blue solution, like the precipitate formed by aconitine under the same conditions.

All these compounds are violently poisonous to frogs, producing torpor and paralysis, with destruction of reflex action, and rapid death.

C. H. B.

"Ptomaïne." By J. GUARESCHI and A. MOSSO (*J. pr. Chem.* [2], **28**, 504—512).—*Influence of Ptomaïne Hydrochloride on Nerves and Muscles.*—The experiments made on frogs after destroying the spinal cord yielded the following results:—When a frog has been poisoned with ptomaïne hydrochloride, the gastrocnemius muscle no longer contracts regularly when the ischiadic nerve is slightly irritated. Its irritability is soon lost. It appears as if some time were required for the energy to accumulate in the nerve centre before the same amount of irritation will produce the contraction of the muscle. The authors state that the destruction of the irritability of the motor nerves is by no means an action characteristic of curare, for they find that when a nerve dies from any cause whatever the motive fibres are first affected, and the direct irritability of the muscle is the last to disappear. There is no poison known which kills the muscle and leaves the nerves their functions. By slightly compressing the ischiadic nerve of a frog with a pair of nippers, the leg becomes paralysed, and exactly the same appearances are manifested during its loss of irritability as are shown in a case of poisoning by curare.

The authors have made a chemical examination of fresh brain substance according to the Stas-Otto method, and find it to contain ammonia, trimethylamine, and ptomaïnes. The experiment was made in winter, and 24 hours after the death of the animal. An examination was also made of the constituents of fresh beef. Ten minutes after the death of a calf 50 kilos. of its flesh was cut up and heated for several hours on a water-bath with dilute sulphuric acid. The mass then filtered, and the filtrate, after separation of the fat, evaporated to a syrup. This was twice treated with three times its volume of 97 per cent. alcohol. The alcoholic liquor was partially distilled, the volatile products being passed into hydrochloric acid. The remainder was evaporated and the residue treated with ether. On evaporating the ether a yellow residue A was obtained. The acid solution was rendered alkaline by adding ammonia and then shaken with ether. The ether on evaporation left a residue B. Finally the pulpy residue was extracted with benzene. Residue A contained succinic acid, lactic acid, and small quantities of alkaloïds. B consisted of a yellow alkaline liquid, which, on standing, deposited microscopic crystals. The quantity obtained was not sufficiently large to allow a thorough analysis to be made. The authors give a list of the reactions of the substance. The residue from benzene consisted of minute traces of alkaloïds.

Considering the possibility that in the method just described the alkaloïds may be produced by the action of sulphuric acid on the albuminoid substances, the authors repeated the process, substituting tartaric for sulphuric acid. They found that residue A was very much less; succinic acid could not be detected. Residue B was reddish-brown and contained traces of alkaloïds.

By extracting the flesh with water only at 50—60°, crystals of methylhydantoïn melting at 159—160·5° were obtained, but no trace of alkaloïds. It appears that in the absence of foreign acids, fresh acid animal substance yields only traces of alkaloïds, or none, and that their formation is due to the decomposition of albuminoïd substances.

Gelatin. By H. Weiske (*Bied. Centr.*, 1883, 673).—The author has prepared gelatin in various ways, and has found that the products differ in properties. Pieces of bone were treated repeatedly and for a long time with dilute hydrochloric acid to remove the inorganic matter as completely as possible; they were then washed. Gelatin made from this is not precipitated from its solutions by tannic acid unless a few drops of a solution of a salt (sodium chloride, &c.) are added simultaneously; in other respects it does not differ from ordinary gelatin. By boiling bones free from mineral matter with repeated quantities of water, and then dissolving the residue by heating with water under pressure, two solutions are obtained which when evaporated to dryness at 100° yield two kinds of gelatin differing from one another and also from the above variety in various properties. Physiological Chemistry.

Influence of the Salts of Sea-water on Fresh-water Animals and the Causes of the Death of Freshwater Animals in Sea-water and Marine Animals in Fresh Water. By H. DE VARIGNY and P. BERT (*Bied. Centr.*, 1883, 652—655).—Varigny has studied the influence of some of the salts contained in sea-water on the development of frog-spawn and tadpoles. Their development was not arrested either by solutions containing per litre 2·2 grams magnesium sulphate, or by solutions containing as much as 3 grams of potassium chloride per litre, or even 4 grams of magnesium chloride. Sea-water contains 2 2 grams $MgSO_4$, 0·7 gram KCl, 3·5 grams $MgCl_2$, and 20—25 grams NaCl per litre. Moreover tadpoles hatched in the 2·2 grams per litre magnesium sulphate solution can thrive in a solution in which the magnesium sulphate is gradually increased to 4 grams per litre. But sodium chloride, even in quantities below the proportion in sea-water, destroys the vitality of frog-spawn and tadpoles. In solutions of equal parts of fresh and sea-water, tadpoles 10—20 days old die, whilst those 5 or 6 weeks old make scarcely any perceptible progress in their development. These results confirm those obtained by Bert (*Compt. rend.*, 97, 133), who, moreover, points out that the amount of chlorides in sea-water is sufficient to kill fresh-water animals in from 30—40 minutes. The cause of death in animals protected by slime is exosmotic action on the gills; whilst in animals not so protected, such as frogs, &c., the body becomes dry through exosmose, and the animal loses from $\frac{1}{4}$ to $\frac{1}{3}$ of its weight; thus a frog will die if one of its feet is immersed in sea-water. A fully grown and uninjured eel can live a long time in sea-water; if, however, any of the protecting slime is removed the animal dies in a few hours. Larger animals can resist this action better than smaller ones. The activity of the water increases as the temperature rises. Experiments were now made on adaptability, and it was observed that when sea-water is gradually added to fresh water containing living tadpoles, crustaceans, &c. (also conferva), the animals (and plants) continue to live in a salted fresh water in which they would soon succumb if removed direct from fresh water into such a mixture. Perfect adaptation was obtained with the crustacean water-fleas, for after some time they became so accustomed to the mixed waters that they died when they were returned to their original element—fresh water. In another experiment with these animals 1 part of sea-water was added to 2 parts of fresh water; within a few days all the animals died, but in another few days fresh animals appeared, having been hatched from the eggs of their deceased progenitors, from which they differed only in size.

Fresh water infusoria and conferva can withstand a water containing enough salt to kill fish and crustaceans, which is about the quantity equivalent to a mixture of 1 part sea with 2 parts fresh water. They may be made to live in a water equivalent to equal parts of sea and fresh water, provided the amount of salt is only increased at the rate of 0·1 gram per litre per diem.

By converse experiments with marine animals the authors find that they die in fresh water from want of sodium chloride; and the want cannot be supplied by either potassium or magnesium salts, or by raising the sp. gr. of the fresh water by means of glycerol or sugar, &c.

The immediate cause of death is endosmosis; the gills of fish, mollusca and annelida swell, whilst the muscles of annelida and amphioxus and the arms of cephalopoda lose their power of contraction.

Adaptation experiments with marine animals under reverse conditions to those described above, give perfectly analogous results. The authors are now studying the effect on marine animals of raising the quantity of salt in sea-water. D. A. L.

Influence of Fresh Water on Marine Animals and Vice Versâ. By F. PLATEAU (*Bied. Centr.*, 1883, 786).—The author was working in this direction in 1870, and arrived at the same results as Varigny and P. Bert (preceding Abstract), in spite of the fact that his method was a totally different one. J. K. C.

Action of Cold and Warm Baths on the Temperature of the Animal Body. By A. PLETZER (*Bied. Centr.*, 1883, 712).—It is a known fact that cold baths lower the temperature of the body, but that in consequence of the external cooling the influence of the regulating power of the skin is soon at work, and causes an increase in temperature. If, however, an animal cooled by cold water is immersed in a warm bath a further reduction of temperature takes place with astonishing rapidity. This fact has been verified by many experiments with healthy and feverish rabbits; the following are examples of the investigations:—

Temperature of Animal at Starting, 38·6—38·7° C.

Temperature of bath, °C.....	30	40	9
„ „ animal, °C...	38·5—38·2	38·1—38·0	38·05

Temperature of bath, °C.....	40	9	40
„ „ animal, °C...	37·7—37·5	37·5	37·0—36·8

Feverish Animal, 40·2—40·3°C.

Temperature of bath, °C.....	30	40	29	12 (air)	40
Temperature of animal, °C...	40·0	39·8—39·7	39·7—39·4	39·0	38·6—38·5

Temperature of bath, °C.	9	40	9	40
„ „ animal, °C. ..	38·3	37·8—37·2	37·5	36·6

In one case the temperature of the body was reduced 5° by alternate treatment with warm and cold water. It was also observed that simultaneously with the lowering of the temperature there is a decrease in the amount of oxygen required, and consequently a reduction in the oxidation-process of the body. D. A. L.

Comparative Value of Fresh and Artificial Butter. By A. Mayer and P. Uldall (*Bied. Centr.*, 1883, 776—778).—This paper gives the results of Mayer's work (which has already been abstracted in this Journal, Abstr., 1884, 92), together with some critical remarks by Uldall. The latter adverts to a feature in Mayer's experiments, that the persons under treatment were not fed for some days previously with the butter on trial. This, however, he thinks would only slightly alter the results in favour of artificial butter, making the digestibility of the two about equal. J. K. C.

Value of Bran for Human Food. By M. Rubner (*Bied. Centr.*, 1882, 677—679).—Bran, as is well known, contains nearly the same proportion of the most important group of food constituents as flour, the quantity of albuminoids and fat being even greater; therefore the question as to the expediency of employing flour prepared from the entire grain, or flour without bran, for bread-making is a very important one, and of course amounts to this:—Is it better to separate the bran and use it as fodder for cattle, or to leave it in the flour employed for human food? In order to decide this point, the author has conducted some experiments which, along with his conclusions, are briefly described below. A man was fed on bread made from different qualities of flour; he received about 900 grams of bread and 1·5 litre of beer daily, water being given if more drink was required. The experiments were continued for periods of three days. The qualities of flour employed were:—1. The *finest* constituting 30 per cent. of the yield from wheat-corn, which was a mixture of Odessa, Californian, and English wheat. 2. A *medium quality*, being 70 per cent. of the flour obtained from a mixture of Girka and Minnesota wheat. 3. The *whole-meal flour* of the Bread Reform League. The loss per cent. of the food-constituents passing away unused with the excrement in each case is as follows:—

Kind of flour.	Dry matter.	Nitrogen.	Fat (ether extract).	Carbohydrates.	Ash.
Finest	4·03	20·07	44·69	1·10	19·28
Medium	6·66	24·56	62·83	2·57	30·35
Whole meal..	12·23	30·47	51·14	7·37	44·98

These numbers speak for themselves. The cellulose walls of the husk-cells form doubtless the chief obstacle to the complete utilisation of the nutritious matter in coarse bread. The author points out that although the quantity of coarse bread digested in the human body is less than that of fine bread, nevertheless there is a quantity of nutritious matter utilised in the intestines from it and from the bran contained in it; and from this stand-point alone no objection can be raised against its use as an article of human diet. When however it is used it should be ground very much finer than it is at present customary to do. But from an economical point of view, the use ot bran in bread is not recommended, for to obtain it, it is taken from animals which can digest it more completely than human beings, and do therefore obtain more value from it. It is further shown that taking into consideration the husks which must be removed, and other losses which occur during grinding, a greater yield than 85 per cent. cannot in any case be expected from the mill. D. A. L.

Influence of Feeding with Cotton-cake Meal on Milk Excretion. (*Bied. Centr.*, 1883, 683—684.)—On the whole, results from three series of experiments determine in favour of the use of cotton-cake meal for increasing the yield of milk. D. A. L.

Guanine in Fish. By E. EWALD and C. F. W. KRUCKENBERG (*Chem. Centr.*, 1883, 705).—Guanine is pretty generally distributed in the skin of fishes; it is, however, not a characteristic excretion, but is simply produced in certain tissues. D. A. L.

Researches on the Diseases of Animals. By PASTEUR and others (*Bied. Centr.*, 1883, 674—677).—Pasteur's results may be summarised as follows:—It is proved by inoculation experiments that both quiet and raving madness originate from the same poison. The symptoms of madness are extremely variable, and depend apparently on the part of the nervous system attacked by the poison. The infectious matter is in the form of microbes in the saliva of mad animals; inoculation with it causes death in three ways—either by microbating the saliva, or by the excessive production of pus, or by the development of madness. The marrow, brain, and spinal cord are always virulent in all animals dying of madness, the virulence increasing until putrefaction sets in. In one case a brain was sustained at a temperature of 12° for three weeks by this action. To produce madness quickly and surely, after trepanning, inoculate in the skin on the surface of the brain; the disease will make its appearance in 6, 8, or 10 days. The malady produced by injection into the blood system exhibits symptoms which differ greatly from those of raving madness caused by a bite or by inoculation after trepanning, and hence many cases of the quiet form may escape observation. In those which may be termed moderate, pronounced paralysis ensues, whilst raving and howling are not observed. When the poison is injected into the blood, the spinal cord seems to be the first point attacked. Injection of saliva or blood from a mad subject into the veins does not protect a dog from a subsequent outbreak of madness or from death after a second inoculation of mad matter, either by trepanning or injection in a vein. Cases of spontaneous recovery have been observed when early symptoms only were developed, but never after the symptoms became violent. In some cases after they had disappeared they returned after two months, whereupon death followed.

As a great many sheep are lost after protective inoculation for sheep-pock, Peuch has investigated the subject, and from the results of his experiments draws the conclusion that this danger may be greatly reduced by using small quantities of lymph diluted 60—120 times.

Thiernesse and Degive have made experiments on protective inoculation for lung epidemics. Their results show that 2 grams of lung-epidemic poison may be injected into the veins without danger, provided it does not touch the cell-tissue. Immunity to the same extent results from this injection as from the tail inoculation recommended by Willems. Immunity in this case is sometimes perfect, and does not cause changes which occur when the disease is taken in the natural way. D. A. L.

Chemistry of Vegetable Physiology and Agriculture.

Effect of Artificial Influences on the Internal Causes of Growth. By E. Wollny (*Bied. Centr.*, 1883, 690—698).—It has been stated that the development of plants can be usefully modified by artificial means (C. Kraus, *ibid.*, 1882, 324). The author has now experimentally proved such to be the case.

Effect of Drying the Seed Tubers on the Yield of Potatoes.—The drying was conducted in two ways, either at a moderate room temperature, 8—10°, when the tubers were laid out and exposed to light for some time before sowing, or at 30—35° a short time before planting. In the first case shoots were developed, whereas in the second case no germination ensued. In field experiments, plots planted with seed tubers dried by either method yielded greater weight, larger number, and more large tubers than plots planted with fresh seed tubers at the same time and treated in the same manner as the foregoing. This increase was more marked in the case of plants from small seeds; this result is, however, exceptional. These facts only apply to wet soils and damp climates.

Influences of Climate, of Condition, and Extent of Soil on the Stem Production of Cultivated Plants.—Light favours development of side shoots; want of light, on the other hand, favours growth of the stalk; therefore plants grown in diffused light or under the shade of trees do not excel in side shoots. The soil must contain sufficient water, and must be sufficiently warm to supply the necessary nourishment for the development and growth of the side shoots. Thick planting is not recommended, because the plants shade one another, and in this way affect the light, and the growth above ground is excessively long, which is not favourable to side growth. Moreover evaporation is increased, and the temperature and humidity of the soil are therefore lowered, which is detrimental. In fact the stem production is weaker the closer the plants are placed together, other conditions being similar.
